Histopathologically, the ovaries from POI patients may show a complete or partial loss of ovarian follicles (Hoek et al., 1997). Oophoritis is represented by infiltration of monocytes, lymphocytes (mainly effector CD4+ T cells), macrophages, and plasma cells in the theca layer of large, antral follicles; in contrast, the earlier stage follicles are consistently free of lymphocytic infiltration (Bakalov et al., 2005; La Marca et al., 2010). There is upregulation of class II MHC antigen expression in granulosa cells and an increase in the number of CD8+ T cells and NK cells (Hill et al., 1990; Giglio et al., 1994; Wu et al., 2004). Because the primordial follicles are unaffected in POI, fertility may be partially conserved in autoimmune oophoritis but may progress to severe POI and infertility (Gloor and Hurlmann, 1984; Bannatyne et al., 1990).

## CONCLUDING REMARKS

Recent basic research on EAO and AOD has unraveled exciting new approaches to investigate human gonadal autoimmunity and chronic inflammation of the gonads associated with subfertility and infertility. In this chapter, we have described in detail autoimmune diseases that occur in several animal models associated with global perturbation of immune regulation, including: d3tx, the Dereg mice with Treg depletion, vasectomy with Treg depletion, *AIRE*-deficient mice, hypothalamic–pituitary deficiency, and transgenic HLA B27/ $\beta$ 2m expression. It is surprising that in all instances of global immune perturbation, the testis and the ovary are the frequent and major targets. Moreover, Treg and *AIRE* are the major perturbed regulatory elements. We propose that the gonads, and their unique functions, demand exceptional protection from autoimmune destruction, and this requires the thymic Treg. We also hypothesize that Treg protection may extend to the other events in normal reproduction to assure successful procreation. They include gamete production, gamete transfer, embryo implantation, and maintenance of the pregnancy itself (Trowsdale and Betz, 2006; Mold et al., 2008; Guerin et al., 2009; Kahn and Baltimore, 2010; Samstein et al., 2012; Jiang et al., 2014).

## Acknowledgments

We wish to thank the following graduate students and postdoctoral fellows for their contribution to the chapter: Sallie Agersborg, Harini Bagavant, Kristina Garza, Vanesa A. Guazzzone, Jessica Harakal, Patricia Jacobo, Sabrina Jarazo-Dietrich, Yahuan Lou, An Ming Luo, Cecilia Pérez, Claudia Rival, Eileen Samy, Yulius Setiady, Hedy Smith, Cristian M. Sobarzo, María S. Theas, Karen Wheeler, and Terecita Yule. The work is supported by NIH grant RO1 AI 41236 to KSKT and by Universidad de Buenos Aires and Consejo Nacional de Investigaciones Científicas y Técnicas to LL and VAG.

## CLINICAL, PATHOLOGICAL, AND EPIDEMIOLOGIC FEATURES

The clinical profile of rheumatic fever (RF) was first described by Cheadle in 1889, and the manifestation of the disease follows defined criteria established by Jones in 1944, which were updated in 1992 and remain useful today (Dajani et al., 1992). Briefly, the disease follows an untreated *Streptococcus pyogenes* infection in children and teenagers that present some genetic factors that predispose to the diverse clinical manifestations. The diagnosis is made in a clinical basis. The major manifestations include polyarthritis, carditis, chorea, subcutaneous nodules, and *erythema marginatum*. The minor manifestations are fever, arthralgia (clinical), and prolonged PR interval, increased erythrocyte sedimentation rate, and presence of C-reactive protein.

Polyarthritis and carditis are the most frequent manifestations of the disease and occur in around 70% of the children. Arthritis is one of the earliest and most common features of the disease, present in 60%–80% of the patients. It usually affects the peripheral large joints; small joints and the axial skeleton are rarely involved. Knees, ankles, elbows, and wrists are most frequently affected. The arthritis is usually migratory and very painful. Carditis is the most serious manifestation of the disease, occurring a few weeks after the infection, and usually present as a pancarditis. Endocarditis is the most severe sequel and frequently leads to chronic rheumatic heart disease (RHD). Mitral and aortic regurgitation (AR) are the most common events caused by valvulitis. Sydenham's chorea is less common (30%–40%) characterized by involuntary movements, especially of the face

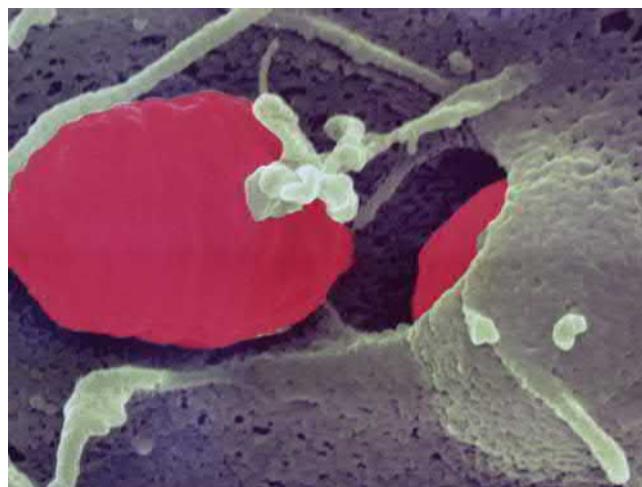

and limbs, muscular weakness, and disturbances of speech, gait, and voluntary movements. It is usually a delayed manifestation, and often the sole manifestation of acute RF. Other manifestations such as subcutaneous nodules and erythema marginatum can also occur during RF episodes and are characterized by nodules on the surface of joints and skin lesions, respectively (Mota et al., 2009).

*S. pyogenes*, or group A streptococci, was identified in 1941 by Rebecca Lancefield through serology based on its cell wall polysaccharide that is composed by carbohydrates such as N-acetyl- $\beta$ -D-glucosamine linked to a polymeric rhamnose backbone. Group A streptococci contain M, T, and R surface proteins and lipoteichoic acid, involved in bacterial adherence and invasion to throat epithelial cells (Fig. 63.1). The M protein, which extends from the cell wall, is composed by two polypeptide chains with approximately 450 amino acid residues, in an alpha-helical coiled-coil configuration. The amino-terminal (N-terminal) portion is composed by two regions, A and B, which present variable numbers of amino acid residues. The A region shows high polymorphism and defines the different M types, currently more than 225 according to CDC (Centers for Disease Control and Prevention; <http://www.cdc.gov/ncidod/biotech/strep/streblast.htm>). These M types were more recently grouped in 48 emm-clusters based on their structural and binding properties. The C-terminal portion (regions C and D) is highly conserved (Smeesters et al., 2010).

Epidemiological studies indicate the *emm1*, *emm* 12, and *emm* 28 as the most common *emm* types found in both high- and low-income countries (Steer et al., 2009b).

It is interesting to note that some strains are predominant in different regions of the world (Table 63.1) and could be related with population migrations and genetic background (Arya et al., 2014; Arêas et al., 2014; Baroux et al., 2014; Boyd et al., 2016; Dundar et al., 2010; Engel et al., 2014; Espinosa et al., 2003; Freschi de Barros et al., 2015; Friães et al., 2012; Hraoui et al., 2011; Imöhl et al., 2010; Koutouzi et al., 2015; Lindsay et al., 2016; Lopardo et al., 2005; Luca-Harari et al., 2008; Ma et al., 2009; Meisal et al., 2010; O'Brien et al., 2002; O'Grady et al., 2007; Rogers et al., 2007; Seale et al., 2016; Shea et al., 2011; Shulman et al., 2009; Smeesters et al., 2006; Steer et al., 2009a; Tamayo et al., 2014; Tanaka et al., 2016; Tapia et al., 2015; Tartof et al., 2010; Turner et al., 2016; Williamson et al., 2014).

The incidence of ARF in some developing countries exceeds 50 per 100,000 children. The worldwide incidence of RHD is of at least 15.6 million cases and the major cause of around 233,000 deaths/year. However, since these estimates are based on conservative assumptions, the actual disease burden is probably substantially higher. The incidence of ARF can vary from 0.7 to 508 per 100,000 children per year in different populations from several countries (Carapetis et al., 2005). More recently, it was showed that the prevalence of RHD varied from less than 50,000 cases to more than 8,000,000 depending on the region of the world (Carapetis et al., 2016). In Brazil, according to the WHO epidemiological model and data from IBGE (Brazilian Institute of Geography and Statistics), the number of *Streptococcal pharyngitis* infections is around 10 million cases, which could lead to 30,000 new cases of RF, of which around 15,000 could develop to cardiac lesions (Barbosa and Müller, 2009).

## AUTOIMMUNE FEATURES

RHD is the most serious complication of RF and depends on several host factors that mediate a heart tissue–driven autoimmune response triggered by a defensive immune response against *S. pyogenes*.

Genetic predisposition is one of the leading factors contributing to the development of autoimmunity. In the last 5 years, using molecular biology tools, several new single-nucleotide polymorphisms (SNPs) of genes

**FIGURE 63.2** Acute phase rheumatic lesions (A and B) and cultured intraleisional T lymphocytes. (A) Mitral valve surgical fragment obtained from a RHD patient, with verrucae lesions (arrows). (B) Immunohistochemistry of myocardium exhibiting Aschoff bodies, granulomatous structures with mononuclear cells infiltration (circle). Magnification: 200 $\times$ . (C) In vitro proliferation of infiltrating T CD4 $^{+}$  isolated from rheumatic lesions. Magnification: 200 $\times$ .

involved with the activation of both innate and adaptive immune responses were associated to the development of RF/RHD (see the “Genetic features” section).

The first genetic associations described in the 1980s focused on human leukocytes antigens (HLA) class II alleles coded by HLA-DRB1 and DQB1 genes. The HLA class II molecules are expressed in the surface of antigen-presenting cells (APCs), for example, macrophages, dendritic cells, and B lymphocytes and trigger the activation of the immune system. In the case of RF/RHD, T-cell populations activated upon specific self-antigen stimulation will trigger autoimmune reactions. The production of several inflammatory cytokines will perpetuate the heart tissue damage. These observations are corroborated by the fact that during the acute phase of disease, Aschoff bodies, a granulomatous lesion containing macrophages, Anitschkow cells, multinucleated cells, and polymorphonuclear leukocytes develop in the myocardium and/or endocardium of RHD patients. Inflammatory cytokines such as IL-1, TNF $\alpha$ , and IL-2 have been found, depending on the developmental phase of the Aschoff bodies (Fraser et al., 1997) and as mentioned above, probably initiate the inflammatory process leading to heart tissue rheumatic lesions.

More recently, other molecules were described involved with the inflammatory process such as integrins and chemokine and cytokines such as IFN $\gamma$ , IL-23, and IL-17 that play a role in the recruitment of both T and B lymphocytes leading to the autoimmune reactions observed in rheumatic heart lesions (reviewed by Guilherme et al., 2011b) (Guilherme et al., 2011a). T and B lymphocytes react against self-antigens through molecular mimicry, first in the periphery and later in the heart tissue. The mechanisms of T-cell receptor (TCR) degeneracy and epitope spreading amplify the autoimmune reactions (see the “Pathologic effector mechanisms” section). All these steps are represented in Fig. 63.2.

## GENETIC FEATURES

RF and RHD occur in 1%–5% of the untreated children with genetic predisposition. The disease is associated with several genes, some of which are related to the innate or adaptive immune response or both (Table 63.2) (Azevedo et al., 2010; Beltrame et al., 2014; Berdelli et al., 2005, 2006; Catarino et al., 2014; Chou et al., 2004; Col-Araz et al., 2013; Düzung et al., 2009; Guilherme and Kalil, 2010; Hernández-Pacheco et al., 2003b; Hirsch et al., 1996; Kamal et al., 2010; Messias Reason et al. 2006, 2009; Ramasawmy et al., 2007, 2008; Sallakci et al., 2005; Settin et al., 2007).

In order to facilitate the comprehension of the role of implicated genes, known up to now, we describe the associated genes/alleles based on their role.

## Innate Immune Response

### **MBL2 Gene**

MBL (mannan-binding lectin) is an acute phase inflammatory protein and functions as a soluble pathogen recognition receptor. It binds to a wide variety of sugars on the surface of pathogens and plays a major role in innate immunity due to its ability to opsonize pathogens, enhancing their phagocytosis and activating the complement cascade via the lectin pathway (Jack et al., 2001). Different variants of the promoter and exon 1 regions of the *MBL2* gene, which encodes MBL, have been reported in patients with RF/RHD. Interestingly, the A allele that codes for high production of MBL was associated with the development of mitral stenosis (MS) and most of these patients presented high serum levels of MBL (Messias Reason et al., 2006). In contrast, RHD patients with AR presented the O allele that codes for low production of MBL, and the patients presented low serum levels of MBL (Ramasawmy et al., 2008).

### **TLR-2 Gene**

Toll-like receptors (TLRs) are sensors of foreign microbial products, which initiate host defense responses in multicellular organisms. A polymorphism of TLR-2 at codon 753 generally leads to the replacement of arginine to glutamine. The genotype 753 Arg/Gln was more frequent in a Turkish ARF cohort when compared to controls (Berdeli et al., 2005).

### **Ficolin Gene**

Ficolin trigger the innate immune response by either binding collectin cellular receptors or initiating the complement lectin pathway (Beltrame et al., 2014; Messias-Reason et al., 2009). In Brazilian chronic RHD patients, with prolonged time of infection or repeated streptococcal infections, the haplotype G/G/A (-986/-602/-4) was found to be more frequent than in controls and was also correlated with low expression levels of this protein.

### **Fc $\gamma$ RIIA Gene**

The protein plays a role in the clearance of immune complexes by macrophages, neutrophils, and platelets (Hirsch et al., 1996). ARF patients presented histidine (H) in the codon 131, which typically encodes for arginine (A), consequently RF/RHD patients present a protein with low binding capacity to the immune complex, favoring the inflammatory response.

### **Masp2 Gene**

MBL-associated serine protease (Masp) results from this gene. It is a protease that plays a role during innate immune response process through recognition of the pathogen and complement activation. Three polymorphisms (p.371D, p.377V and p.439R) increase the susceptibility to develop RHD (Catarino et al., 2014).

### **MIF Gene**

This gene codes for a macrophage inhibitory factor (MIF), expressed in monocytes/macrophages and other type of cells and tissues and has been associated with several inflammatory diseases (Col-Araz et al., 2013). A significant increase in the frequency of MIF-173CC genotype was found in children with RF (Col-Araz et al., 2013).

## Adaptive Immune Response

The HLA system is located in the short arm of the human chromosome 6 and codes for diverse proteins; it is considered the most polymorphic system, composed by several genes with several alleles. The class I proteins are present in all nucleated cells; however, the class II are expressed only in specialized cells of the immune system (B lymphocytes, activated T lymphocytes, monocytes/macrophages, and dendritic cells). These proteins are involved with antigen recognition and presentation of self and foreign (microbes) antigens.

## Major Histocompatibility Complex: DRB1, DRB3, DQB1, DQA1 Genes

Several HLA class II alleles were described in association with RF/RHD. Patarroyo et al. (1979) described an alloantigen on the surface of B cells, designated 883, probably related to the HLA class II molecules, which was present in a high frequency in RF patients. Later, a monoclonal antibody (D8/17 MoAb) was produced against B cells from RF patients bearing the 883 alloantigen. Studies performed by Zabriskie et al., (1985) showed an increased frequency of this alloantigen in RF patients.

The susceptibility of developing RF/RHD was first associated with the alleles of HLA class II genes (*DRB1*, *DRB3*, *DQB*, and *DQA*), which are located on human chromosome 6. Briefly, HLA-DR7 was the allele most consistently associated with RF (Guilherme et al., 1991; Guédez et al., 1999; Ozkan et al., 1993; Stanevicha et al., 2003; Visentainer et al., 2000; Weidebach et al., 1994). In addition the association of DR7 with different DQB or DQA alleles seems to be related with the development of multiple valvular lesions (MVL) or mitral valve regurgitation in RHD patients (Guédez et al., 1999; Stanevicha et al., 2003). HLA-DR53 coded by the *DRB3* gene is another HLA class II molecule in linkage disequilibrium with HLA-DR4, DR7, and DR9. This allele was strongly associated with RF/RHD in two studies with Mulatto Brazilian patients (Guilherme et al., 1991; Weidebach et al., 1994), but not in Brazilian Caucasian patients (Visentainer et al., 2000). Although DR53 has not been described in previous studies, DR4 and DR9 were associated with RF in American Caucasian and Arabian patients (Ayoub, 1984; Rajapakse et al., 1987), whereas in Egyptian and Latvian patients, DR7 was associated with the disease (Guédez et al., 1999; Stanevicha et al., 2003) (Table 63.1). In Japanese RHD patients, susceptibility to MS seems to be in part controlled by the HLA-DQA gene or by genes in close disequilibrium linkage with HLA-DQA\*0104 and DQB1\*05031 (Koyanagi et al., 1996). HLA-DQA\*0501 DQB\*0301 with DRB1\*1601 (DR2) were associated with RHD in a Mexican Mestizo population (Hernández-Pacheco et al., 2003a).

The molecular mechanism by which MHC class II molecules confers susceptibility to autoimmune diseases is not clear. However, since the role of HLA molecules is to present antigens to the TCR, it is probable that the associated alleles facilitate the presentation of some streptococcal peptides that will later trigger autoimmune reactions mediated by molecular mimicry mechanisms.

### CTLA4 Gene

This gene is an essential inhibitor of T-cell responses. It is a strong candidate susceptibility gene in autoimmunity, and several studies suggest disease-associated polymorphisms (reviewed by Gough et al., 2005).

### Both Innate and Adaptive Immune Response

More recently, with new technologies that have allowed the description of gene variability by SNPs, other associations have been established that could clarify some reactions related with both innate and adaptive immune response leading the autoimmune reactions in RF/RHD.

- *TNF- $\alpha$*  gene, also located in the chromosome 6, between HLA class I and II genes, codes for a proinflammatory cytokine that plays a role during the *S. pyogenes* infection and later in the inflammatory process in the valves. Polymorphisms at -308G/A and -238G/A were associated with the susceptibility of RHD patients from several countries (Berdeli et al., 2006; Hernández-Pacheco et al., 2003b; Ramasawmy et al., 2007; Sallakci et al., 2005).
- *IL-10* gene is responsible for the production of IL-10, an antiinflammatory cytokine. The genotype -1082G/A, misrepresented in RHD patients, is apparently associated with the development of MVL and with the severity of RHD (Settin et al., 2007).
- *TGF-B1* is a gene that controls the proliferation and differentiation of cells. The polymorphism of both the SNPs 869T and -509T alleles were considered possible risk factors for the development of valvular RHD lesions in Egyptian and Taiwan RHD patients (Chou et al., 2004; Kamal et al., 2010).
- *IL-1Ra* gene, for which the most frequent alleles are 1 and 2, encodes the antagonist of IL-1 $\alpha$  and IL-1 $\beta$ , which are inflammatory cytokines. Two studies in Brazilian and Egyptian RHD patients with severe carditis showed low frequencies of allele 1, suggesting lack of inflammatory control (Azevedo et al., 2010; Settin et al., 2007).

## IN VIVO AND IN VITRO MODELS

### In Vivo Model of Myocarditis and Valvulitis

Humans are unique hosts for *S. pyogenes* infections. However, several studies have been performed to determine a suitable animal model, and numerous different species (mice, rats, hamsters, rabbits, and primates) have been tested for the development of autoimmune reactions that resemble those observed in RF/RHD patients (Unny and Middlebrooks, 1983), all with little success.

In the last decade a model that appears to be useful for the study of RF/RHD has been developed with Lewis rats. These rats have already been used to induce experimental autoimmune myocarditis and to study the pathogenesis of RF/RHD (Li et al., 2004).

Immunization of Lewis rats with recombinant M6 protein induced focal myocarditis, myocyte necrosis, and valvular heart lesions in three out of six animals. The disease in these animals included verruca-like nodules and the presence of Anitschkow cells, which are large macrophages (also known as caterpillar cells), in mitral valves. Lymph node cells from these animals showed a proliferative response against cardiac myosin, but not skeletal myosin or actin. A CD4<sup>+</sup> T-cell line responsive to both the M protein and cardiac myosin was also obtained. Taken together, these results confirmed the cross-reactivity between the M protein and cardiac myosin triggered by molecular mimicry, as observed in humans, possibly causing a break in tolerance and consequently leading to autoimmunity (Quinn et al., 2001). In another study done by the same group, Lewis rats were immunized with a pool of synthetic peptides from the conserved region of the M5 protein. Mononuclear spleen cells from these animals were able to proliferate in response to peptides from both the C-terminal region of M5 protein and the N-terminal region of a heterologous protein (M1) and myosin. These rats developed a focal infiltration of mononuclear cells predominantly in the aortic valve, although no evidence of Aschoff bodies, the hallmark of RF lesions, or Anitschkow cells was observed (Lymbury et al., 2003).

Another study immunized Lewis rats with recombinant M5 or synthetic peptides from the B- and C-regions of group A *streptococcus* (GAS) M5 (Gorton et al., 2009). Sera and T cells from these animals recognized a peptide (M5-B.6) from the B repeat of the N-terminal portion of M5 protein and induced heart lesions (Gorton et al., 2010), confirming the previous results. The immunized rats (five out of seven) developed mononuclear cell infiltration in the myocardial or valvular tissue. Histopathological analysis of valve lesions showed the presence of both CD4<sup>+</sup> T cells and CD68<sup>+</sup> macrophages (Gorton et al., 2010), consistent with human studies (Guilherme et al., 1995).

Altogether, these studies indicated that the Lewis rats could be a model of autoimmune valvulitis.

In the last decade, however, other animal models as mice and guinea pig were also used by several researchers and appear to be also useful as experimental models of RF/RHD as reviewed by Rush et al. (2014).

### In Vitro Model of Rheumatic Heart Disease Autoimmune Reactions

The major sequels of RF are heart tissue lesions that lead to chronic RHD, which is characterized by permanent valvular lesions. The heart disease starts by pericarditis, followed by myocarditis episodes in which the healing process results in varied degrees of valvular damage (Mota et al., 2009).

By isolating infiltrating T lymphocytes from damaged valvular tissue, we could establish the mechanism by which the immune response in the heart leads to autoimmune reactions (Guilherme et al., 1995). Fig. 63.2 shows a damaged mitral valve in which verrucae lesions are observed, indicative of an acute RF episode. Furthermore, the presence of Aschoff bodies in the myocardium tissue allowed for histological diagnosis of an active episode of rheumatic disease. In vitro tissue culture of small pieces of the surgical fragment allowed to the isolation of infiltrating T cells.

The in vitro analysis of these tissue-infiltrating T cells showed their ability to recognize several streptococcal-M protein peptides and self-antigens by molecular mimicry mechanisms. We identified some mitral valve-derived proteins such as vimentin, PDIA3 (protein disulfide isomerase ER-60 precursor) and HSPA5 (78 kDa glucose-regulated protein precursor) that were recognized by both peripheral and intralesional T-cell clones (Faé et al., 2008).

The identification of heart-M protein cross-reactive T cell clones directly from rheumatic valvular lesions established their involvement in the pathogenesis of the disease.

## PATHOLOGIC EFFECTOR MECHANISMS

The term of “molecular mimicry” was introduced in 1964 by Damian to define the mechanism by which self-antigens are recognized after an infection by cross-reactivity (Damian, 1964).

Pathogen and self-antigens can be recognized by T lymphocytes and antibodies through molecular mimicry by four different mechanisms. They can recognize (1) identical amino acid sequences, (2) homologous but nonidentical sequences, (3) common or similar amino acid sequences of different molecules (proteins, carbohydrates), and (4) structural similarities between the microbe or environmental agent and its host (Peterson and Fujimani, 2007).

RF/RHD is the most convincing example of molecular mimicry in human pathological autoimmunity, in light of the cross-reactions between streptococcal antigens and human tissue proteins, mainly heart tissue proteins that follow throat infection by *S. pyogenes* in susceptible individuals.

The inflammatory process that follows a *S. pyogenes* throat infection in individuals with genetic predisposition leads to intense cytokine production by monocytes and macrophages that trigger the activation of B and T lymphocytes.

Several heart-reactive antibodies, first described from 1945 (reviewed by Cunningham, 2000 and Guilherme et al., 2011b) (Guilherme et al., 2011a), also play a role in the development of the disease.

Streptococcal and heart tissue cross-reactive antibodies activate the heart tissue valvular endothelial cells increasing the expression of adhesion molecules such as VCAM1, which facilitates cellular infiltration by neutrophils, monocytes, B and T cells (Yeğin et al., 1997). The “rolling” of leukocytes through vessels is triggered by chemokines expressed by activated endothelial cells that induce the expression of integrins, selectins, and subsequent transendothelial migration. Recently, we identified increased expression of intercellular adhesion molecule (ICAM), another adhesion molecule, a few chemokines (CCL-1, CCL-3, and CCL9) (Faé et al., 2013) as well as some integrins (P- and E-selectins and) in the myocardium and valvular tissue of RHD patients. All of these molecules are involved with the inflammatory process and T and B lymphocytes infiltration leading to rheumatic valvular tissue damage.

CD4<sup>+</sup> infiltrating T cells are predominant in the heart rheumatic lesions (Kemeny et al., 1989; Raizada et al., 1983), and the first evidence of the molecular mimicry between *streptococcus* and heart tissue was obtained through an analysis of these heart tissue–infiltrating T cells. Three immunodominant regions of the M5 protein (residues 1-25, 81-103, and 163-177), heart tissue proteins (myocardium and valve-derived proteins, as well as vimentin), and synthetic peptides of the beta chain of cardiac myosin-light meromyosin region (LMM) were recognized by cross-reactivity by intralesional T-cell clones (Ellis et al., 2005; Faé et al., 2006; Guilherme et al., 1995, 2001). Peripheral T-cell clones also recognized human-purified myosin, tropomyosin, laminin, and cardiac myosin-derived peptides from LMM and S2 regions (Guilherme et al., 1995).

Employing a proteomics approach, we characterized a number of mitral valve proteins identified by molecular weight and isoelectric point (pI). Four valve-derived proteins with molecular masses ranging between 52 and 79 kDa and different pI cross-reacted with the M5 immunodominant peptides and were recognized in proliferation assays by intralesional T-cell clones from patients with severe RHD. Vimentin was one of the identified proteins, a result that reinforces the role of this protein as a putative autoantigen involved in the rheumatic lesions. Novel heart tissue proteins were also identified, including disulfide isomerase ER-60 precursor (PDIA3) protein and a 78-kDa glucose-regulated protein precursor (HSPA5). The role of PDIA3 in RHD pathogenesis and other autoimmune diseases is not clear (Table 63.3) (Faé et al., 2008).

A mass spectrometry analysis allowed the identification of several valve proteins that suffered expression alterations probably due to the autoimmune process. Briefly, we identified abundant expression of two isoforms of vimentin (45 and 42 kDa) with reduced expression of the full size of protein (54 kDa). Vitronectin was other altered protein that presented increased expression and reduced collagen VI expression (Martins et al., 2014). Immunohistochemical analysis of their distribution in valve tissue lesions was also analyzed, and a disorganized distribution of these proteins in RHD valves was found and correlates with clinical manifestations such as valve regurgitation or stenosis. Confocal microscopy analysis revealed a diverse pattern of distribution of collagen VI and lumican into RHD and myxomatous degeneration (MXD) valves (Martins et al., 2014).

The analysis of the TCRs of autoreactive T lymphocytes that infiltrate both myocardium and valves allowed us to evaluate the V $\beta$  chains usage of TCR and the degree of clonality of heart tissue–infiltrating T cells (Guilherme et al., 2000). In the heart tissue (myocardium and valves) of both chronic and acute RHD patients, several expanded T-cell populations with an oligoclonal profile were found. Such oligoclonal expansions were identified by TCRs analyses (Guilherme et al., 2000). The finding of oligoclonal T-cell populations is in contrast with the peripheral blood scenario, which contains polyclonal TCR-BV families. The fact that a high number of

Adapted from Faé, K.C., Diefenbach da Silva, D., Bilate, A.M., Tanaka, A.C., Pomerantzoff, P.M., Kiss, M.H., et al., 2008. PDIA3, HSPA5 and vimentin, proteins identified by 2-DE in the valvular tissue, are the target antigens of peripheral and heart infiltrating T cells from chronic rheumatic heart disease patients. *J. Autoimmun.*, 31(2), 136–141.

T-cell oligoclonal expansions could be found in the valvular tissue indicates that specific and cross-reactive T cells migrate to the valves and proliferate upon specific cytokine stimulation at the site of the lesions (Guilherme et al., 2000).

Cytokines are important secondary signals following an infection because they trigger effective immune responses in most individuals and probably deleterious responses in patients with autoimmune diseases. Three subsets of T helper cytokines are currently described. Antigen-activated CD4<sup>+</sup> T cells polarize to the Th1, Th2, or Th17 subsets, depending on the cytokine secreted. Th1 is involved with the cellular immune response and produces IL-2, IFN $\gamma$ , and TNF $\alpha$ . Th2 cells mediate humoral and allergic immune responses and produce IL-4, IL-5, and IL-13.

Another lineage of CD4<sup>+</sup> T cells, namely Th17 cells, produces a set of cytokines identified as IL-17, TGF $\beta$ , IL-6, and IL-23, and this subset of cells is involved with inflammatory reactions and in association with several autoimmune diseases (Volin and Shahrara, 2011).

In RHD, in both myocardium and valvular tissue, we found large numbers of infiltrating mononuclear cells secreting the inflammatory cytokines IFN $\gamma$  and TNF $\alpha$ . However, mononuclear cells secreting IL-10 and IL-4, which are regulatory cytokines, were also found in the myocardium tissue; nonetheless, in the valvular tissue, only a few cells secrete IL-4, suggesting that low numbers of IL-4-producing cells may contribute to the progression of valvular RHD lesions (Guilherme et al., 2004).

Increased numbers of Th17 cells in peripheral blood were found in a cohort of RHD patients from Turkey, in which high levels of IL-17A cytokine in the sera were observed (Bas et al., 2014). We also identified large numbers of IL-17- and IL-23-producing cells in both myocardium and valvular endothelium of RHD, confirming that Th17 cells also play an important role in the inflammatory process in RHD heart lesions.

## AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Several streptococcal and human cross-reactive antibodies have been found in the sera of RF patients and immunized rabbits and mice over the last 60 years and have been recently reviewed (Carapetis et al., 2016). N-Acetyl- $\beta$ -D-glucosamine that is present in both the streptococcal cell wall and heart valvular tissue is one of the major targets of the humoral response in RF/RHD, and antibodies against this polysaccharide displayed cross-reactivity with laminin, an extracellular matrix alpha-helical coiled-coil protein that surrounds heart cells and is also present in the valves (Cunningham, 2000; Cunningham et al., 1989).

Cardiac myosin is the most important protein in the myocardium and by using affinity purified antimyosin antibody, Cunningham's group identified a five-amino acid residue (Gln-Lys-Ser-Lys-Gln) epitope of the N-terminal M5 and M6 proteins as being cross-reactive with cardiac myosin (Cunningham et al., 1989).

The permanent rheumatic lesions that damage the valves and antibodies against vimentin, an abundant protein in the valvular tissue, probably play a role in the valvular lesions (Cunningham, 2000). In agreement with this observation the permanent rheumatic lesions that damage the valves and antibodies against vimentin, an

abundant protein in the valvular tissue, probably play a role in the valvular lesions (Cunningham, 2000). In agreement with this observation, as mentioned before, two isoforms of vimentin (45 and 42 kDa) were recently identified by proteomics approach in damaged valves probably due to the autoimmune process (Martins et al., 2014).

In conclusion, antibodies against *N*-acetyl- $\beta$ -D-glucosamine, some epitopes of cardiac myosin, vimentin, collagen, and vitronectin can be considered the immunological markers of the disease.

## CONCLUDING REMARKS—FUTURE PROSPECTS

RF/RHD is the most convincing example of molecular mimicry in which the response against *S. pyogenes* triggers autoimmune reactions with human tissues. RF/RHD lesions result from a complex network of several genes that control both innate and adaptive immune responses after a *S. pyogenes* throat infection. An inflammatory process permeates the development of heart lesions, in which adhesion molecules and specific chemokines facilitate the valvular-tissue infiltration by B and T cells. CD4 $^{+}$  T lymphocytes are the prime effectors of heart lesions. Several self-antigens such as vimentin, collagen VI, vitronectin, myosin proteins, and other human targets proteins are recognized by molecular mimicry mechanism between streptococcal immunodominant peptides, particularly in individuals with genetic predisposition. The production of inflammatory cytokines (IFN $\gamma$ , TNF $\alpha$ , IL-17, and IL-23), and low numbers of IL-4-producing cells, a regulatory cytokine, lead to local inflammation.

All these information create a new scenario for the development of RHD, opening new possibilities for immunotherapy. Molecular knowledge of the autoimmune reactions mediated by antibodies and peripheral and intra-lesional T cells will certainly assist in the choice of streptococcal protective epitopes for the construction of an effective and safe vaccine.

Anti-GAS vaccine candidates based on the M protein and other alternative streptococcal antigens, including A-CHO, C5a peptidase (SCPA), cysteine protease (Spe), binding proteins, *streptococcus* pili, and other antigens are under investigation as reviewed by Steer and Carapetis (2009).

Briefly, a recombinant N-terminal protein candidate vaccine including the 30 most prevalent *S. pyogenes* serotypes in the US strains was constructed and has entered into phase I clinical trials (Dale et al., 2011).

J8 is a candidate vaccine that incorporates a minimal C-terminal protective epitope and induced protective antibodies in mouse models (Batzloff et al., 2003). StreptInCor, composed of 55 amino acid residues is a vaccine epitope based on the selection of a large panel of human sera and peripheral blood cells. This epitope can undergo processing by APCs (monocytes and/or macrophages) and generates a universal, robust, and safe immune response (Guilherme et al., 2009, 2011b). Experimental assays using several animal models showed that the candidate vaccine induced high titers of opsonic, neutralizing, and protective antibodies (De Amicis et al., 2014; Postol et al., 2013). The immunogenicity and safety of the StreptInCor vaccine epitope was also evaluated for a period of 1 year in a model of HLA class II transgenic mice. Specific and nonautoreactive antibodies were produced without autoimmune or pathological reactions in the heart or other organs (Guerino et al., 2011).

In conclusion, of a vaccine to protect against *S. pyogenes* without triggering autoimmune reactions remains a challenge. The knowledge of the mechanisms that lead to RF and/or RHD allows and favors the construction of a safe and efficacious anti-*S. pyogenes* vaccine.

Autoimmune Features	1274	Further Reading	1284

## HISTORICAL BACKGROUND

The role of autoimmunity in cardiovascular disease has long been a topic of investigation in the clinic and the laboratory. Years of research effort were devoted to establishing a link between streptococcal infection and rheumatic heart disease based on an autoimmune response (see Chapter 63). Chagas disease is still believed to be based on a cross-reaction of antibodies to *Trypanosoma cruzi* with myocardial or cardiac conductive tissue (Coura and Borges-Pereira, 2012). Finally, postpericardiotomy syndrome and postmyocardial infarction syndrome are sometimes cited as instances of an autoimmune response instigated by damaged or necrotic tissue (Maisch et al., 1979). This chapter reviews the evidence linking autoimmunity with two important forms of heart disease, myocarditis and dilated cardiomyopathy (DCM). It must be stated, ab initio, that immunologic testing has so far not been effective in allowing a clear distinction between autoimmune and other etiologies of these diseases.

The classic description of myocarditis was given by Corvisart in 1812 (referenced in Gravanis and Sternby, 1991), but for many years, progress in studying the disease was impeded by the uncertainties of clinical diagnosis. Definitive diagnosis was dependent upon autopsy examination. Interest in the disease increased in recent years because of the introduction of antemortem diagnostic tools, especially the endomyocardial biopsy (EBM), greater understanding of the role of cardiotropic viruses, and the availability of new modalities of therapy.

## MYOCARDITIS—CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

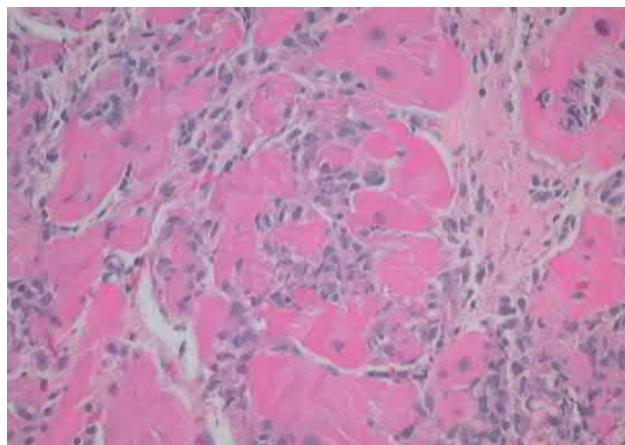

Myocarditis is inflammation of the heart muscle leading to impaired function of the myocardium. The several types of myocarditis can be classified by etiology, histology, immunohistochemistry, clinical pathology, or clinical criteria. Clinical findings can span asymptomatic cases to severe disease with associated arrhythmia and heart failure. Even in the same patient, symptoms vary as the disease progresses. The most serious manifestation of myocarditis is heart failure due to dysfunction of the left ventricle (LV) (Hufnagel et al., 2000). This dysfunction might develop gradually with mild symptoms or rapidly, leading to cardiogenic shock. Supraventricular and/or ventricular arrhythmias are other symptoms linked to myocarditis. Patients might present with palpitations, dizziness, or syncope. Conduction disturbances or serious ventricular arrhythmia suggest giant cell myocarditis, cardiac sarcoidosis, or *Borrelia burgdorferi*–associated myocarditis. Sudden cardiac death in previously healthy young adults can be caused by heart failure or severe arrhythmia. Another major symptom is angina-like chest pain. In these cases, acute coronary syndrome should be ruled out by catheterization. After further exclusion of other pathologies (such as aortic dissection, atrial or ventricular tachycardia, ulcer diseases, or severe anemia), myocarditis should be considered (Baccouche et al., 2009). After initial systolic dysfunction, about half of the cases improve spontaneously or after standard heart failure treatment. Therefore it is recommended to postpone invasive therapeutic interventions, such as the implantation of a cardioverter or defibrillator, for about 3–6 months after onset of the disease or start of treatment. Cases presenting predominantly with heart failure tend to have a worse prognosis than those presenting with arrhythmia or chest pain (Caforio et al., 2007).

The most common cause of myocarditis is viral infection. Patients may recall a recent viral illness with symptoms of malaise, chills and fever, upper respiratory or gastrointestinal symptoms, myalgia, and chest pain. Most cases, however, cannot be traced back to an obvious preceding illness. Adenovirus and enterovirus have mostly been associated with cardiomyocyte infection, and parvovirus B19 attacks cardiac endothelial cells. Today, human herpes virus 6 and HIV are the major pathogens causing myocarditis (Breinholt et al., 2010). Other causes are diverse and include bacteria, protozoa, alcohol, drugs, and toxins. In South and Central America, Chagas disease is a major cause of heart muscle inflammation. The hemoflagellate *T. cruzi* is transmitted to humans via the bite of the reduviid bug triatomine. Most patients initially have only mild, influenza-like symptoms, but 10%–30% of the infected individuals develop fulminant myocarditis.

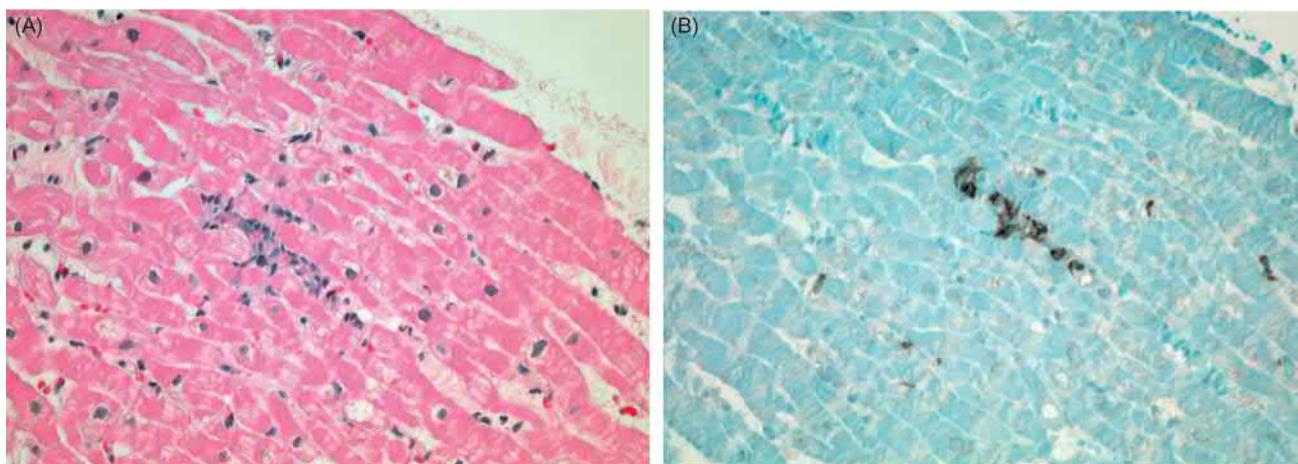

For a long time, conclusive diagnosis of myocarditis was difficult because suitable diagnostic methods were lacking. The diagnosis was supported by the exclusion of other diseases that could explain the symptoms. Today, even though our diagnostic possibilities have expanded and improved, there is still room for further modifications and more specific criteria to diagnose myocarditis. The first indication is clinical symptoms such as chest pain, heart failure, and arrhythmia. Electrocardiogram (ECG) and echocardiography are the basic diagnostic tools for the heart, but they do not provide specific signs for myocarditis. Their value lies more in excluding other causes and in assessing heart function. Even normal findings in a patient do not exclude myocarditis. Echocardiography can help to record disease progression because temporal changes in systolic function, chamber size and thickness can be evaluated regularly (Caforio et al., 2013).

The most important noninvasive method to date is magnetic resonance imaging (MRI). It is helpful in the evaluation of numerous morphological and functional aspects of myocardial impairment and allows a thorough tissue characterization (Friedrich et al., 2009; Olimulder et al., 2009; Bruder et al., 2013; Lurz et al., 2012). Tissue pathologies, such as myocardial edema and hyperemia, capillary leak, necrosis, and fibrosis as well as contraction abnormalities and pericardial effusion can be detected (Kuchynka et al., 2015). The Lake Louise criteria have been proposed to standardize the evaluation of findings in MRI and improve diagnostic accuracy (Friedrich et al., 2009). They combine three different cardiac magnetic resonance techniques and are based on myocardial edema as a sign of acute inflammation, early gadolinium enhancement linked to hyperemia and late gadolinium enhancement linked to increased myocardial necrosis or fibrosis. Late gadolinium enhancement is also an important prognostic factor as well as a significant predictor of cardiovascular mortality (Grün et al., 2012). MRI is, in general, better suited for acute cases with inflammation than chronic cases with less inflammatory activity.

Even though MRI diagnosis has improved, EBM still constitutes the gold standard in the diagnosis of myocarditis, since it is the only method for a definitive diagnosis *in vivo*. It dates to the 1980s, when the Dallas criteria were used as a standardized method to evaluate samples (Aretz et al., 1987). Today, the application of the Dallas criteria has been limited due to low sensitivity and high interobserver variability. Even though endomyocardial biopsy (EMB) is invasive and sampling errors may occur, it offers important information for diagnosis, prognosis, and therapy (Hufnagel et al., 2000; Caforio et al., 2015; Lassner et al., 2014). By immunohistochemistry,

**FIGURE 64.1** Lymphocytic myocarditis. There is a heavy infiltrate of large activated lymphocytes throughout the myocardium. Myocyte necrosis is noted in the middle of this image. Fibrosis is present on the right side of the image. (H&E 400 $\times$ ).

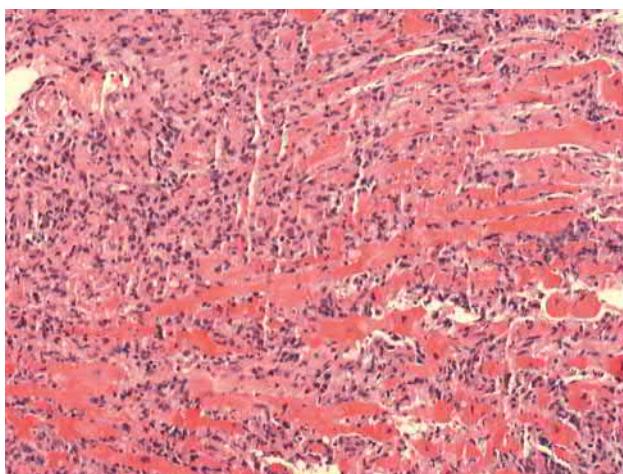

**FIGURE 64.2** Borderline myocarditis. (A) A single cluster of perivascular lymphocytes is present. No myocardial damage is identified. (H&E 400 $\times$ ). (B) A CD8 immunohistochemical stain highlights the infiltrating T lymphocytes. (H&E 400 $\times$ ).

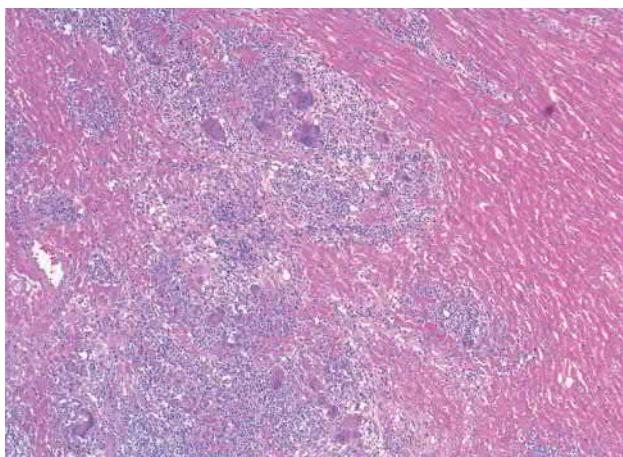

inflammatory cell infiltrates as well as activated immunological processes can be identified and characterized (Maisch and Pankuweit, 2012; Malik et al., 2015; Palecek et al., 2010). EMB allows classification of the types of myocarditis, pathogens can be detected by polymerase chain reaction, and a quantitative assessment of viral load is possible. Perforin-positive cells and human leukocyte antigen (HLA) expression can be evaluated (Figs. 64.1–64.4).

Myocarditis typically has a three-phased progression (Cooper, 2009; Kindermann et al., 2012; Dennert et al., 2008). In the first, or acute phase, viral pathogens enter cardiomyocytes via the coxsackie–adenoviral receptor under participation of the coreceptors (Noutsias et al., 2003). This phase lasts several days to weeks as the virus replicates, and a reaction of nonspecific immunity takes place. Viral and inflammatory mediators lead to myocardial impairment. Patients in this phase are often asymptomatic.

The second phase begins 2–4 weeks after onset of the disease and is characterized by a specific immune reaction with cellular and antibody-mediated response. In this phase the start of an autoimmune reaction is possible. In this reaction, antibodies against heart-specific structures such as myosin or troponin are produced, which cause additional damage to the cardiac tissue. The onset of the third phase after several weeks or months is marked either by an improvement of cardiac function or a deterioration into chronic cardiomyopathy. In between 50% and 70% of the cases the inflammation retreats and LV function increases. If improvement does not occur in this phase, a persistent dysfunction and development of postinflammatory DCM is usually the long-term consequence. Many factors, such as the degree of initial damage, intensity and duration of inflammation, and persistence of viral pathogens influence the course of the disease (Schultheiss et al., 2011; D'Ambrosio et al., 2001).

**FIGURE 64.3 Fulminant myocarditis.** The myocardium is replaced by a marked polymorphous inflammatory infiltrate composed predominantly of lymphocytes and macrophages with rarer eosinophils and neutrophils. Global myocyte injury and loss is noted. No giant cells are present. (H&E 100 $\times$ ).

**FIGURE 64.4 Giant cell myocarditis.** The myocardium is infiltrated by a patchy and diffuse inflammatory infiltrate composed primarily of lymphocytes and macrophages. Multiple collections of giant cells are seen within the infiltrate along with eosinophils. There is significant injury and loss of myocytes in areas of inflammation, while adjacent myocardium is relatively unininvolved. (H&E 50 $\times$ ).

The extent of myocardial damage in the acute phase is one of the most important factors determining the recovery of LV function in later periods (Baccouche et al., 2009; Maisch and Pankuweit, 2012; Cooper and Myocarditis, 2009; Kindermann et al., 2012; Dennert et al., 2008).

Most people do not develop continuing myocarditis after exposure to viruses, which suggests a genetic susceptibility. A higher prevalence in patients with a family history of myocarditis has also been observed, which would seem to support this theory (Hufnagel et al., 2000; Dennert et al., 2008).

## TREATMENT

With the diagnosis of myocarditis, physical activity should be limited for 6 months or until the regression of inflammation and restitution of LV function (Hufnagel et al., 2000). Standard heart failure treatment seems to have a potential positive influence on inflammatory changes and outcome of myocarditis patients and is widely recommended (Bahk et al., 2008; Saegusa et al., 2007; Yuan et al., 2004; Pauschinger et al., 2005). This includes angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers, beta blockers, and aldosterone antagonists (McMurray et al., 2012; Yancy et al., 2013a,b). However, nonsteroidal anti-inflammatory drugs

(NSAIDs) and digoxin have not been recommended. In critical cases mechanical circulatory support can aid as a temporary solution until the decision between treatment and transplantation is made. Heart transplantation is the last option in severe cases of heart failure.

Devices for treating arrhythmia should be postponed since a significant improvement of LV function and retreat of arrhythmia can often be seen after a few weeks with the regression of myocardial inflammation. The optimal treatment depends on the type of myocarditis present. This is one reason why it is important to have a classification by EMB. For giant cell myocarditis, eosinophilic myocarditis, and cardiac sarcoidosis, immunosuppressive therapy is indicated, but the dose and duration of treatment have not yet been standardized. Lu et al. (2016) have stated that immunosuppressive therapy does not affect mortality or the need for heart transplantation but has a favorable effect on the improvement of LV systolic function. The results of smaller studies still should be verified in larger, multicenter studies. Another approach is treatment with intravenous immunoglobulins and immunoabsorption, but the effect is still disputed.

In the first phase of myocarditis, antiviral treatment is used to stop viral replication and contain damage to cardiomyocytes. Interferon beta treatment seems to be beneficial in the cases of adenovirus and enterovirus infection but not necessarily in other types (Kühl et al., 2003). Specifically for enterovirus, interferon beta therapy may be associated with long-term prognostic benefit (Kühl et al., 2012).

## DILATED CARDIOMYOPATHY—CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

DCM is characterized by left ventricular dilation and contractile dysfunction with the absence of abnormal loading conditions and severe coronary artery disease. It is one of the most common causes of heart failure and the most common indication for heart transplant worldwide (Maron et al., 2006). The prevalence is estimated to be around 40 cases per 100,000 individuals with an annual incidence of 7 cases per 100,000 (Maron et al., 2006; Manolio et al., 1992; Taylor et al., 2006). Racial differences have been detected, whereas sex does not seem to make a difference in susceptibility (Manolio et al., 1992; Yancy et al., 2013a,b). About 60% of all childhood cardiomyopathies are the cases of DCM (Liupshultz et al., 2003; Nugent et al., 2003) and infants younger than 12 months have the highest incidence (Nugent et al., 2003; Towbin et al., 2006). The overall mortality is higher in children than in adults; therefore, age is an important risk factor for the deaths of DCM. Symptoms usually include congestive heart failure with excessive sweating, ankle edema, orthopnea, fatigue after mild exertion, palpitations, and syncope. Circulatory collapse, arrhythmia, and thromboembolic events are also possible. There is a risk of sudden death, particularly in infants (Nugent et al., 2003), caused by electromechanical dissociation or ventricular arrhythmia.

There are varying causes for DCM. Genetic mutations in genes for cytoskeletal, sarcomere, nuclear envelope proteins, transcriptional pathways, and mitochondrial proteins make up about 35% of the cases (Grunig et al., 1998; Michels et al., 1992). The inheritance is mostly an autosomal dominant trait (Michels et al., 1992; McNally et al., 2013). Hereditary DCM can be classified in predominantly cardiac types, mutations associated with neuromuscular diseases such as Duchenne and Becker muscular dystrophy or DCM as part of a syndrome. The most common mutations for predominant cardiac phenotypes are in titin and lamin A/C genes (Gerull et al., 2002; Fatkin et al., 1999; Parks et al., 2008).

Acquired causes include myocarditis, alcohol, drugs, and toxins. About 20% of the myocarditis patients develop a chronic DCM while the disease progresses (D'Ambrosio et al., 2001). Alcohol, cocaine, and methamphetamine abuse have a cardiotoxic effect and can lead to DCM. The same applies to anthracycline, a cytostatic used in therapy for cancer, whose cardiotoxicity can occur during treatment or many years afterward. In addition, certain metabolic and endocrine disturbances have been linked to DCM. A special case is peripartum cardiomyopathy. It can occur in the last month of pregnancy or within 5 months of delivery; however, the exact pathologic mechanisms and cause are still unknown (Pearson et al., 2000).

In DCM patients the LV assumes a spherical shape. Hypertrophy and fibrosis restrict the heart function, and ventricular relaxation and filling are reduced. There is a significant decrease in stroke volume and cardiac output. Preload and afterload as well as end-diastolic pressure are increased, resulting in elevated wall stress. Compensatory changes in the vascular system such as an increase in systemic vascular resistance, a decrease in arterial compliance, and an increase in venous pressure will usually occur. These exacerbating circumstances cause secondary neurohormonal changes, for example, an increase in sympathetic adrenergic activity and a

reduction in vagal activity further add to the wall stress and elevate myocardial oxygen demand. Myocytes incur damage, leading to a further reduction in myocardial performance.

Because of its heritability, genetic testing and screening at-risk family members is important in affected families. In patients with DCM, ECG can show nonspecific repolarization abnormalities, left ventricular hypertrophy, pathological Q waves, poor R wave progression, prolongation in the PR interval, AV block, left bundle branch block, or left anterior hemiblock. In cardiac radiography, cardiomegaly and pulmonary venous redistribution may be visible. Like ECG and radiography, echocardiography can detect abnormalities of the heart but none specific for DCM. Global LV hypokinesis is common, sometimes regional wall motion abnormalities, intracardiac thrombi, and functional mitral regurgitation due to annular dilation can occur. Doppler parameters can assist in quantifying the severity of diastolic dysfunction ([Nishimura and Tajik, 1997](#)). MRI is a noninvasive option for examining ventricular volume, wall thickness, contractile function, and tissue characterization.

Histologically, irregular myocyte hypertrophy with or without the areas of fibrosis and myocyte damage can be detected. Lymphocytic infiltrates are the regular markers of inflammation. Furthermore, specific disorders may be identified which can be helpful in choosing the correct treatment. Polymerase chain reaction is a possible method for identifying viral genome in affected patients. Biomarkers such as B-type natriuretic peptide (BNP) and N-terminal BNP play an important prognostic role as their elevation is proportional to the severity of heart failure ([Maisel et al., 2002](#)).

## TREATMENT

The most important goals in the treatment of DCM are the improvement of survival and reduction of hospital admissions. Heart failure guidelines should be applied. Standard first-line drugs are ACE inhibitors and beta blockers. Mineralocorticoid antagonists and the If-channel inhibitor ivabradine provide additional survival benefits when combined with ACE inhibitors and beta blockers ([Pitt et al., 1999](#); [Zannad et al., 2011](#); [Swedberg et al., 2010](#)). Studies have shown that sacubitril–valsartan therapy has better outcomes than treatment with enalapril. Digoxin is useful for patients with sustained atrial fibrillation or refractory heart failure symptoms. To control symptoms loop diuretics are recommended, as well as salt and fluid restriction. Other vasodilatory, natriuretic, and inotropic drugs were tested in clinical trials, but they do not seem to have a positive influence on the outcome ([Chen et al., 2013](#)). New drugs are being tested in ongoing trials. A specific genetic diagnosis might indicate additional or alternative drug therapy. Device therapy can be used for patients with arrhythmia and to prevent sudden death. Implantation of implantable cardioverter defibrillators are recommended for patients at highest risk. Patients with combined DCM and symptomatic bradycardia are eligible for biventricular pacing. Heart transplantation or implantation of long-term mechanical circulatory support such as an extracorporeal membrane oxygenation are to be seen as last measures only. For all patients with DCM an enrollment in a multidisciplinary heart failure service is advised. Its primary function is in educating patients about their disease and giving advice for living with DCM, as well as offering support and monitoring at-risk patients.

## AUTOIMMUNE FEATURES

In recent years, autoimmunity has been accepted as a significant contributing factor in the pathology of inflammatory cardiovascular diseases. Patients suffering from classic autoimmune diseases have a higher risk for developing cardiovascular diseases ([Jastrzebska et al., 2013](#)), which emphasizes the connection between autoimmunity and cardiovascular diseases.

Cardiac autoantibodies have many different points of origin; they can be directed against contractile elements, stress (“heat shock”) proteins, mitochondrial and extracellular matrix antigens, and cardiac receptors. At present, antibodies against cardiac myosin, troponin, the  $\beta_1$ -receptor and muscarinic 2-receptor (M2-receptor) are thought to have the greatest impact in the development of cardiomyopathies ([Satta and Vuilleumier, 2015](#); [Bornholz et al., 2017](#); [Müller et al., 2016b](#); [Caforio et al., 2008a,b](#); [Lappé et al., 2008](#); [Nussinovitch and Shoenfeld, 2010, 2012, 2013a,b](#); [Kaya et al., 2010](#)). They can be divided into two types of autoantibodies. The first ones are classic autoantibodies, which signal an immune response that injures the target tissue. Relevant antibodies are directed against cardiac myosin and cardiac troponin. The second class is “functional autoantibodies.” They are directed against G-protein-coupled receptors (GPCR) and influence receptor-mediated signal cascades by binding to the receptor

and acting as ligands. They thus have an impact on physiological functions similar to the physiologically specific receptor ligand but usually without appropriate controlling feedback mechanisms. In cardiomyopathy patients, GPCR-autoantibodies (GPCR-AABs) are associated primarily with electrical cardiac abnormalities, arrhythmia, ventricular tachycardia, sudden death, and myocarditis (Caforio et al., 2008a; Root-Bernstein and Fairweather, 2015; Wallukat et al., 1992; Chiale et al., 1995; Brisinda et al., 2012; Iwata et al., 2001). Mainly  $\beta_1$ -adrenergic and M2-receptor autoantibodies seem to play an important role in cardiomyopathy.

$\beta_1$ -Autoantibody effects ( $\beta_1$ -AABs) cause the activation of the adenylate cyclase (cAMP increase) (Dandel et al., 2012), activation of protein kinase A (Krause et al., 1996), elongation of the action potential, increase of the L-type calcium ion current (Christ et al., 2001), change of mitochondrial structure and membrane potential (Wang et al., 2013), induction of apoptosis and cell death (Staudt et al., 2003; Jane-wit et al., 2007; Haberland et al., 2011), and maturation and degranulation of cardiac mast cells (Okruhlikova et al., 2007).  $\beta_1$ -AABs also activate the mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK) pathway. They may contribute to cardiac hypertrophy (Tutor et al., 2007). Changes in T-cell proliferation and secretion have also been observed (Du et al., 2012).

M<sub>2</sub>-Autoantibody effects (M2-AABs) are associated with a negative chronotropic effect and the blocking of cardiac parasympathetic innervation (Wallukat et al., 1999; Goin et al., 1997) by inhibiting the L-type calcium ion channels. This could explain electric abnormalities often observed in the heart in the presence of these antibodies (Lazzerini et al., 2008; Hong et al., 2009; Dobrev et al., 2004). M2-AABs also seem to influence the regulation of COX-2 and iNOS mRNA, hereby possibly contributing to proinflammatory conditions (Ganzinelli et al., 2009).

The first autoantibodies in DCM patients were identified in 1992, with the detection of IgG class antibodies directed against alpha- and beta-myosin heavy chains (Caforio et al., 1992). Similar antibodies were found in some patients with Chagas cardiomyopathy (Ballinas-Vedugo et al., 2003) and women with peripartum cardiomyopathy (Haghikia et al., 2015). Myosin is a motor protein in the contractile apparatus of the cardiomyocyte. It consists of two heavy chains and four light chains. For the heavy chain two isoforms exist, the alpha-myosin heavy chain and beta-myosin heavy chain. The beta-myosin heavy chain is not heart specific; it appears in the heart muscle as well as in the skeletal muscle, whereas alpha-myosin heavy chain can, to our knowledge, only be found in the myocardium. Therefore anti-alpha-myosin autoantibodies are heart specific (Becker et al., 2017). In 2007 antocardiac troponin I autoantibodies were detected in patients with DCM, in the following years also in patients with Chagas cardiomyopathy and peripartum myopathy. In animal models, those antibodies were generated and administered to mice resulting in dilatation and dysfunction of the heart (Okazaki et al., 2003).

Treatment strategies against functional autoantibodies show promising results in early clinical trials. Patients with  $\beta_1$ -AABs showed benefits from immunoabsorption for antibody removal (Dandel et al., 2012). To detect and measure GPCR-AABs, two groups of assays have been applied (Bornholz et al., 2017). The first group (bioassay) uses changes of a second messenger signal in (living) cells that occur after the binding of GPCR-ABs to the receptor. The second method, enzyme-linked immunosorbent assay (ELISA), is used to directly detect GPCR-AABs after binding to epitope mimics. ELISA provides information about the type or amount of antibodies in a sample but cannot measure their functionality. For both assays data about sensitivity and specificity are often unclear and validation and standardization deficient. Therefore numbers for the prevalence of autoantibodies in cardiomyopathy patients and healthy subjects vary from study to study. Antimyosin antibodies were found in up to 5% of healthy individuals (Caforio et al., 2008a; Nussinovitch and Shoenfeld, 2013a,b), whereas DCM patients had a prevalence of 50%–66%. In comparison, patients with ischemic or valvular cardiomyopathy showed the same prevalence of anti-c myosin-AABs as healthy individuals (Caforio et al., 1992; Konstadoulakis et al., 1993). For  $\beta_1$ -AABs and M2-AABs a prevalence of around 10% in healthy individuals is estimated, increasing with age. A coexistence of both antibodies was detected in 65% of healthy subjects (Liu et al., 1999). Different studies delivered a wide range for the presence of  $\beta_1$ -AABs in DCM patients between 26% and 95% (Störk et al., 2006), again with a high coexistence of M2-AABs (Hoebke et al., 1994). Myocarditis patients even had a prevalence of up to 96%. In contrast, ischemic cardiomyopathy patients had a prevalence of  $\beta_1$ -AABs lower than 15% (Nussinovitch and Shoenfeld, 2013a,b; Störk et al., 2006; Nikolaev et al., 2007). Levels of  $\beta_1$ -AABs were correlated with a negative prognosis, higher mortality and increased risk for electric abnormalities and sudden death in some studies (Caforio et al., 2008b; Nussinovitch and Shoenfeld, 2013a,b). However, other studies could not prove this connection. It is unclear if antibody titers can give information about the severity of the disease progression. For the detection of functional  $\beta_1$ -AABs a new screening technology is currently being tested in the Etiology, Titre-Course, and Survival (ETiCS) study on patients with EMB-proven new-onset myocarditis. This assay is called functional fluorescence energy transfer and uses novel cAMP sensors (Nikolaev et al., 2007; Deubner et al., 2010; Beavo and

Brunton, 2002; Staudt et al., 2004). M2-AABs were found in 15%–50% of DCM patients (Nussinovitch and Shoenfeld, 2012). The occurrence of M2-AABs in DCM patients is associated with electric abnormalities (Lazzerini et al., 2008; Lee et al., 2011). The data are based on bioassay and ELISA measurements. About half of the patients with Chagas cardiomyopathy were tested positive for anti-c myosin and anti-c troponin T autoantibodies, but about the same amount of Chagas patients presenting without cardiac symptoms were also positive for these antibodies  $\beta_1$ - and M2-AABs are frequently found in Chagas heart patients (Talvani et al., 2006). A correlation between levels of autoantibodies and severity of the disease was not found.

Because of the high prevalence of autoantibodies in DCM patients, treatment options which target pathogenic autoantibodies are promising. Autoantibodies can be removed from the patients' circulation or attacked and destroyed in vivo. Unselected plasmapheresis (therapeutic plasma exchange, TPE) and apheresis technologies (immunoabsorption) have been proposed. During TPE the patients' blood is transferred to a device that separates plasma and blood cells. The cells are returned to the patients' circulation, and the plasma, which contains the autoantibodies, is replaced by donor plasma or a plasma surrogate. TPE is a common technique in the treatment of autoimmune disorders [Joint United Kingdom (UK) Blood Transfusion and Tissue Transplantation Services Professional Advisory Committee]. In DCM patients TPE was so far only used in case studies. These did, however, show good results. Immunoabsorption also begins with connecting the patients' circulation to a machine that separates plasma and blood cells. The plasma is passed through a column containing ligands that enable the binding of immunoglobulins, specific IgG subclasses, or specific antibodies. The targeted molecules are left behind while the cleared plasma joins the blood cells and is transferred back into the patients' circulation. With this method, specific antibodies can be filtered from the plasma. Immunoabsorption was first applied to DCM patients in 1996 (Wallukat et al., 1996). Of the 8 patients 7 showed benefits and shifted to lower NYHA classes. Follow-up studies demonstrated an increase in LV ejection fraction, cardiac index, and stroke volume index immediately after immunoabsorption (Felix et al., 2000, 2002; Mobini et al., 2003). In addition, lasting positive effects such as increased cardiac function, decreased diastolic diameter, improved echocardiographic and cardio-pulmonary exercise parameters, and improved endothelial function for months or even years following treatment were documented (Reinthalter et al., 2015; Müller et al., 2000; Cooper et al., 2007; Knebel et al., 2004; Staudt et al., 2006a,b; Herda et al., 2010; Bulut et al., 2010, 2011, 2013; Doesch et al., 2009, 2010; Trimpert et al., 2010). For patients who benefited from immunoabsorption a significant increase in regulatory T-cells was observed, which was associated with long-term patient health improvement (Bulut et al., 2010, 2011, 2013). The studies mentioned above focused primarily on  $\beta_1$ -AABs. Subgroup analysis revealed that mostly patients with high levels of autoantibodies benefit from immunoabsorption therapy (Dandel et al., 2012). Therefore it is important in clinical practice to differentiate between cardiomyopathy patients who tested positive or negative for cardiac autoantibodies to make adequate therapy decisions. Immunoabsorption is a relatively expensive procedure, but worth the gain in patient benefits and survival rate. New therapeutic possibilities that directly attack and neutralize autoantibodies in vivo are being tested. Methods such as intravenous IgG treatment, B-cell depletion and aptamer-based neutralization of GPCRs might offer more therapy options for DCM patients in the future.

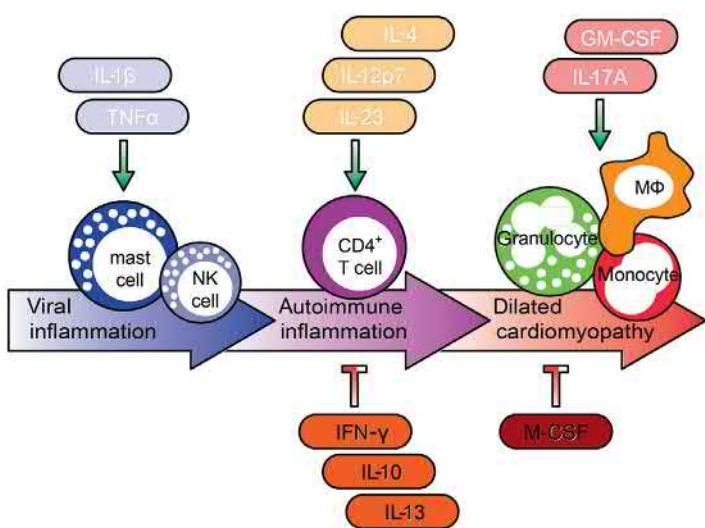

## GENETIC FEATURES

Because of the possible autoimmune origin of myocarditis and DCM in humans, and the well-documented association of experimental myocarditis with the major histocompatibility complex (MHC) in mice (Rose et al., 1988), a number of studies to determine the relationship with the human MHC (HLA) have been carried out. Anderson et al. (1984) reported that DCM patients had an increased frequency of HLA-DR4 and a decreased frequency of HLA-DR6. These findings were corroborated by Limas et al. (1990), who also demonstrated an increased frequency of HLA-DR4 in DCM patients. A genetic predisposition toward cardiac autoimmunity was demonstrated, in that 72% of HLA-DR4 + patients had anti- $\beta_1$  adrenergic receptor antibodies compared with 21% of HLA-DR4 – patients. In the largest study to date, Carlquist et al. (1991) reconfirmed these findings and also found that the DR4-DQw4 haplotype conferred heightened risk of disease. In a metaanalysis of five studies, they confirmed that the DR4 association with myocarditis was sustained among different patient populations. No differences in disease phenotypes have been reported. The availability of EBMs has allowed genetic studies of CVB3 infection in viral myocarditis in humans. Tschopp et al. (2017) reported that non-obese diabetic 2 (NOD2), a nucleotide-binding domain, mediates viral uptake and inflammation in the heart.

## ANIMAL MODELS

Since enteroviruses are often implicated in human myocarditis and DCM, these agents have been widely used to investigate the pathogenic mechanisms. Although infections by CVB3 are relatively common, the development of clinically significant, ongoing myocardial disease in humans is relatively uncommon, suggesting that differences in host response play a critical role in disease susceptibility. These differences are likely to be genetically determined and may relate to the expression of virus-specific receptor on heart tissue or to the immune response of the host. Because it is difficult to examine the role that genetic polymorphisms play in humans, investigators have developed models of coxsackievirus-induced myocarditis in mice, for which many genetically different, inbred strains are available. A model of the time course of viral myocarditis is illustrated in Fig. 64.5.

All strains of mice tested developed acute myocarditis starting 2 or 3 days after CVB3 infection. Viral disease reached its peak on day 7 and gradually resolved so that by day 21 the heart was histologically normal. No infectious virus was found after day 9. In a few strains of mice, however, the myocarditis persisted (Rose et al., 1987; Cihakova and Rose, 2008), but the histologic picture shifted. The first phase was characterized by the focal necrosis of myocytes and accompanying a focal acute inflammatory response with a mixed cell infiltrate consisting of polymorphonuclear and mononuclear cells. In those mice that developed the second phase of disease, the inflammatory process was diffuse rather than focal and consisted mainly of mononuclear interstitial infiltrates, including both T- and B-lymphocytes and little or no myocyte necrosis. In the mice that developed the second phase of disease, heart-reactive autoantibodies were present and shown to be specific for the cardiac isoform of myosin (Neu et al., 1987a). This finding suggested that the second phase represented an autoimmune response initiated by the viral infection. Direct evidence to support this hypothesis was produced by immunizing the susceptible strains of mice with purified cardiac myosin and showing that they developed a very similar histologic picture of myocarditis (Neu et al., 1987b). No heart disease was found in animals immunized in a similar manner with skeletal myosin, and none appeared in the strains of mice that were not genetically susceptible to the second phase of virus-induced myocarditis. Further evidence that the disease was due to an immune response to cardiac myosin was assembled by inducing specific tolerance to cardiac myosin (Wang et al., 2000; Fousteri et al., 2011). The finding first suggested that the second phase represents an autoimmune response initiated by molecular mimicry between viral and heart antigens (Cunningham et al., 2004). Other evidence showed that the autoimmune response depends upon virus-induced damage to the heart. (Horwitz et al., 2000) found that transgenic mice expressing interferon gamma (IFN- $\gamma$ ) in their pancreatic cells failed to produce CVB3-induced myocarditis, even though the virus proliferated greatly in other sites. The virus infection may serve as an adjuvant for cardiac antigens that have been expressed or liberated during the viral infection of the heart (Rose, 2000). Other viruses unrelated to coxsackieviruses such as cytomegalovirus produce a similar autoimmune myocarditis following infection. The experiments showing that myocarditis can be produced by immunization with cardiac myosin in animals with no viral infection establish that the disease does not depend upon persisting virus even though it is possible to demonstrate traces of viral RNA.

**FIGURE 64.5** Schematic of the pathogenesis of viral myocarditis.

Unless subjected to exercise stress, most mice survived autoimmune myocarditis whether induced by virus infection or by immunization with cardiac myosin. Gradually the disease waned in severity (Cihakova and Rose, 2008; Rose and Hill, 1996). In some mice, however, the histologic picture changed to produce a mainly fibrotic disease. As the process continued, there was a thinning of the ventricular cell walls and a large increase in size of the left ventricle. By day 35, after infection or immunization, there were definite signs of cardiac insufficiency and by day 60, most of the animals died of heart failure. This form of the disease, whether induced by viral infection or myosin autoimmunity, replicated the major characteristics of DCM, suggesting that DCM can represent an end stage of autoimmune myocarditis.

A striking finding in the investigations described above was that strains of mice highly susceptible to the autoimmune myocarditis following viral infection were susceptible to the myosin-induced disease. Other strains were resistant to both forms of myocarditis. These observations indicated that the susceptibility to autoimmune myocarditis was under a large measure of genetic control. As in most autoimmune diseases, genes of the MHC have an important influence on the development and course of autoimmune disease (Li et al., 2008a). In both the viral and myosin-induced models the H-2s, H-2a, and H-2b alleles were associated with increased morbidity of autoimmune myocarditis, whereas other H-2 alleles were associated with low susceptibility. The genetic findings in the mouse can be related to human myocarditis through experiments by Hayward et al. (2006) and Taneja and David (2009), who demonstrated a spontaneous myocarditis model in NOD mice carrying the transgenically introduced human HLA-DQ8 allele associated with greater susceptibility to human DCM. Like most autoimmune diseases, non-MHC genes play a determining role in susceptibility to myocarditis. Genome-wide linkage analysis revealed at least two prominent loci that had significant effects on susceptibility to autoimmune myocarditis. A putative susceptibility gene, eam1, was located on the proximal end of chromosome 1 and eam2 on the distal region of chromosome 6 (Guler et al., 2005; Li et al., 2008b). Both chromosomal segments bore genes determining susceptibility to a number of other autoimmune diseases such as autoimmune encephalomyelitis and autoimmune arthritis as well as spontaneous diabetes.

In addition to lending themselves to genetic studies the experimental models of autoimmune myocarditis provide the opportunity of following the inflammatory process from the beginning to the end (Rose, 2011). The first major question to be considered was the basis of the susceptibility to autoimmune myocarditis following the virus infection. Studies show that two critical cytokines, IL-1 $\beta$  and TNF- $\alpha$ , were both necessary and sufficient for the progression from viral myocarditis to autoimmune myocarditis (Lane 1992). Blocking either one of these two cytokines prevented the transition from viral to autoimmune myocarditis. Even more significant was the demonstration that providing either of these two cytokines in recombinant form to genetically resistant mice caused them to develop the autoimmune myocarditis. Early signs of susceptibility to autoimmune myocarditis become evident early in the course of viral infection. Significantly, the elevations of IL-1 $\beta$  were found as early as 8 hours after viral infection (Fairweather et al., 2004a; Fairweather et al., 2004b). The innate immune response to the virus determined later susceptibility to autoimmune disease. Adoptive transfer experiments using myosin or myosin peptide-induced disease have shown that the induction of autoimmune myocarditis depends upon myosin-specific CD4 T-cells (Smith and Allen, 1991; Chen et al., 2012; Li et al., 2008b).

The course of the inflammation during autoimmune myocarditis can be traced to the relative proportions of certain key cytokines emanating from different CD4 T-cell families. Differing forms of autoimmune myocarditis are associated with greater production of IL-12p35 P40 (a Th1 signal), IL-4 (a Th2 signal), and IL-23p19p40 (a signal of the Th17 response) (Rose, 2011). For example, IFN- $\gamma$ , a signature of Th1 responses, retards the development of myocarditis, and its deficiency produces a particularly severe form lymphocytic disease. A rapidly developing, fatal form of eosinophilic myocarditis occurs in the absence of both IFN- $\gamma$  and IL-17A (Barin et al., 2013). These findings are striking examples of the cytokine "interactome"; they further suggest that a balance of cytokines affects not only the severity but the profile of inflammation. IL-4 promotes a particularly severe form of giant-cell myocarditis in mice, and eosinophil-derived IL-4 drives progression of myocarditis to DCM (Diny et al., 2017). IL-17A, a cytokine associated with neutrophilic inflammation, has little impact on the severity of overall inflammation in the myosin-induced autoimmune disease. It is, however, critical for the later progression to DCM; animals deprived of IL-17A fail to develop postmyocarditis cardiac remodeling and the subsequent fibrotic disease (Baldeviano et al., 2010). The disease can be prevented by administering antibody to IL-17A earlier during inflammation. This key role of IL-17 may be related to its established ability to increase granulocyte proliferation as well as to activate macrophages. Wu et al. (2014) found that IL-17A stimulates cardiac fibroblasts to produce GM-CSF, which, in turns, stimulates both leukocytes and Ly6Chigh-bearing monocytes/macrophages. Similar studies in humans supported the rationale for targeting Th-17-related cytokines for the treatment of DCM (Myers et al., 2016). An issue critical to understanding the pathogenesis of autoimmune myocarditis is the dynamic

balance of mediators tending to favor inflammation and cardiomyocyte injury with mediators that reduce or retard inflammation.

As mentioned previously, other cardiac-specific antigens can induce autoimmune myocarditis. Goser et al. (2006) demonstrated the provocation of an autoimmune response to cardiac troponin I, which induces severe inflammation in the myocardium of mice followed by fibrosis and heart failure, with marked mortality. These investigators identified two sequence motifs of cardiac troponin I that induced inflammation and fibrosis in the myocardium (Kaya et al., 2008). Interestingly, these same animals eventually developed immunity to cardiac myosin following at least 90 days of inflammation. Thus autoimmune myocarditis, like most autoimmune diseases, is characterized by the production of multiple organ-specific autoantibodies.

## PERSPECTIVES

When the first edition of "The Autoimmune Diseases" was published in 1985, research on the inflammatory cardiopathologies was taking on new life. Cardiac transplantation and EBM focused greater attention on the details of histopathology of the heart muscle and years of study of cardiotropic coxsackievirus melded into an opportunity to appraise a recurrent question in the investigations of many autoimmune diseases: how could a viral infection trigger an autoimmune disorder? Myocarditis has proven to be an accessible model for studying the question. The disease can be reasonably replicated in the mouse with the candidate virus, and viral peptides were defined that tracked the course of virus-induced myocarditis. The door was opened to trace the inflammatory process with respect to both cellular composition and mediator balance from initiation of the immune response to heart failure. Together, these studies are leading to promise of earlier diagnosis and more specific therapies. The lessons learned may well be applied to other immune-mediated disorders.

## HISTORICAL BACKGROUND

Vasculitis is inflammation of blood vessel walls (Jennette et al., 2013a). Major categories of systemic vasculitides are based on the predominant type of vessels involved (and the pattern of initial injury), that is, large-vessel vasculitis (chronic granulomatous arteritis), medium-vessel vasculitis (necrotizing arteritis), and small-vessel vasculitis (necrotizing polyangiitis) (Fig. 65.1 and Box 65.1).

Necrotizing arteritis was first recognized because of the grossly discernible segmental inflammatory nodular lesions that occur along major arteries (Kussmaul and Maier, 1866). Small-vessel vasculitis (SVV) was first recognized because of the palpable purpura that is caused by inflammation of dermal venules (Willan, 1808).

### Necrotizing Arteritis

Kussmaul and Maier (1866) provided the first definitive pathologic and clinical description of a patient with necrotizing arteritis. They reported the case of a 27-year-old journeyman tailor, who developed a fulminant disease characterized by fever, anorexia, muscle weakness, paresthesias, myalgias, abdominal pain, and oliguria. Kussmaul and Maier (1866) introduced the term *periarteritis nodosa* (PAN) as a reference to the major findings identified during this patient's autopsy, that is, multiple inflammatory nodules affecting medium-sized arteries. For years after the original description, the generic term PAN was given to any patient with necrotizing vasculitis

**FIGURE 65.1** Major categories of systemic vasculitis include large-vessel vasculitis, medium-vessel vasculitis, and small-vessel vasculitis. A substantial overlap with respect to arterial involvement can be observed in all three major categories. The aorta, a large artery, medium artery, small artery/arteriole, capillary, venule, and vein are shown from left to right. ## BOX 65.1

**NAME FOR VASCULITIDES PROPOSED BY THE 2012  
INTERNATIONAL CHAPEL HILL CONSENSUS CONFERENCE ON THE  
NOMENCLATURE OF VASCULITIDES**

- Large-vessel vasculitis (LVV)
  - Takayasu arteritis (TAK)
  - Giant cell arteritis (GCA)
- Medium-vessel vasculitis (MVV)
  - Polyarteritis nodosa (PAN)
  - Kawasaki's disease (KD)
- Small-vessel vasculitis (SVV)
  - Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV)
    - Microscopic polyangiitis (MPA)
    - Granulomatosis with polyangiitis (Wegener's) (GPA)
    - Eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (EGPA)
  - Immune complex SVV
    - Antiglomerular basement membrane (anti-GBM) disease
    - Cryoglobulinemic vasculitis (CV)
    - IgA vasculitis (Henoch–Schönlein) (IgAV)
    - Hypocomplementemic urticarial vasculitis (HUV) (anti-C1q vasculitis)
- Variable vessel vasculitis (VVV)
  - Behcet's disease (BD)
  - Cogan's syndrome (CS)
- Single-organ vasculitis (SOV)
  - Vasculitis associated with systemic disease
    - Lupus vasculitis
    - Rheumatoid vasculitis
    - Others
  - Vasculitis associated with probable etiology
    - Hepatitis C virus-associated cryoglobulinemic vasculitis
    - Hepatitis B virus-associated vasculitis
    - Drug-associated immune complex vasculitis
    - Drug-associated ANCA-associated vasculitis
    - Cancer-associated vasculitis
    - Others

*Modified from Jennette, J.C., Falk, R.J., Bacon, P.A., Basu, N., Cid, M.C., Ferrario, F., et al., 2013a. 2012 Revised international Chapel Hill consensus conference nomenclature of vasculitides. Arthritis Rheum.* 65 (1), 1–11.

([Jennette and Falk, 1997](#)). The name later evolved into the more pathologically correct term of PAN, as it became clear that the inflammation arose in the walls of arteries rather than in the perivascular tissue.

By the 1950s, distinction of PAN and a *microscopic form* of the disease was gradually recognized ([Chung and Seo, 2010](#)). Although [Wohlfwill \(1923\)](#) described a variant of PAN that was characterized by the involvement of small-vessels, Davson and Zeek were probably the first to suggest the separation of PAN into different disorders based on the presence of widespread glomerular inflammation (glomerulonephritis, GN) ([Davson et al., 1948; Zeek et al., 1948](#)). Today, the *microscopic form* of PAN is designated as microscopic polyangiitis (MPA) ([Jennette et al., 1994](#)).

In 1931, medical student Heinz Klinger published the first case of a patient with granulomatosis with polyangiitis (GPA) ([Klinger, 1931](#)). The detailed features of this multisystemic disorder were provided initially by the German pathologist Friedrich Wegener ([Wegener, 1939](#)). A few years later, the diagnostic triad of Wegener's granulomatosis was identified, that is, systemic necrotizing angiitis, necrotizing inflammatory involvement of the respiratory tract, and necrotizing GN ([Godman and Churg, 1954](#)).

[Churg and Strauss \(1951\)](#) described a series of 13 patients with asthma, eosinophilia, necrotizing vasculitis, and granulomatous inflammation. Three years later, [Godman and Churg \(1954\)](#) concluded that this disease, now designated as eosinophilic GPA (EGPA), the *microscopic form of periarteritis nodosa* (MPA), and Wegener's granulomatosis (GPA), were all pathologically and clinically distinct from PAN and probably have a related etiology and pathogenesis. This concept has been borne out by the discovery that GPA, MPA, and EGPA are associated with, and are probably caused by, antineutrophil cytoplasmic autoantibodies (ANCAs), whereas PAN is not ([Jennette and Falk, 1997; Jennette et al., 2013a](#)).

[Kawasaki \(1967\)](#) discovered an additional form of necrotizing arteritis that was associated with the mucocutaneous lymph node syndrome. This disease has been called *infantile polyarteritis nodosa* because it almost always occurs in young children ([Magilavy et al., 1977](#)); however, the clinical, pathologic, and pathogenetic features of Kawasaki's disease (KD) are clearly distinct from those of PAN ([Jennette et al., 2013a](#)).

## Purpura and Small-Vessel Vasculitis

Purpura was the first manifestation of SVV that was described in the medical literature. The term probably derives from the Greek *porphyra*, which refers to the purple color produced by the mollusk *Purpura lapillus* (Jones and Tocantins, 1933). English dermatologist Willan (1808) was one of the first to separate purpura caused by systemic febrile infections from noninfectious purpura, which were associated with systemic diseases.

Schönlein (1837) and Henoch (1868) described the occurrence of purpura in children in association with arthralgias and arthritis, abdominal pain, nephritis, and small visceral hemorrhages (Henoch, 1868; Schönlein, 1837). Osler (1895, 1914) recognized that peripheral neuropathy, pulmonary hemorrhage, epistaxis, iritis, and rapidly progressive renal disease were all symptoms caused by necrotizing inflammation of small vessels (Jennette and Falk, 1997; Osler, 1914). In 1919 Goodpasture reported a patient with pulmonary hemorrhage and rapidly progressive GN (pulmonary–renal syndrome) who had hemorrhagic alveolar capillaritis and vasculitis of glomerular capillaries as main pathology findings (Goodpasture, 2009).

By the 1950s, the pathologic features in SVV of extensive acute inflammation with numerous neutrophils and conspicuous leukocytoclasia had been well described (Jennette and Falk, 1997). Similarity of these findings with the injury pattern of the *Arthus* reaction in addition to the association of some cases of necrotizing vasculitis with serum sickness or exposure to certain drugs led to the suggestion of a possible “hypersensitivity” or allergic cause for vasculitis (Alarcon Segovia and Brown, 1964; Winkelmann, 1958; Zeek et al., 1948).

In the 1960s, the widespread application of immunofluorescence microscopy revealed that certain forms of SVV had substantial vascular localization of immunoglobulins and complement, suggesting an immune complex pathogenesis. Landmark discoveries using this technique include the identification of linear deposits of immunoglobulin along glomerular and pulmonary capillary basement membranes in a subset of patients with pulmonary–renal syndrome (Sturgill and Westervelt, 1965), later shown to be pathogenic autoantibodies directed against basement membrane collagen (Lerner et al., 1967); the demonstration of granular deposits of IgM, IgG, and complement in vessels walls of patients with cryoglobulinemic vasculitis (CV) (Meltzer and Franklin, 1966; Meltzer et al., 1966), and the finding of deposits of IgA and C3 in dermal venules and glomerular capillaries of children with Henoch–Schönlein purpura (now termed IgA vasculitis) (Faille-Kuyper et al., 1976).

By the end of the 1970s, there was a widespread belief that most if not all SVV was mediated by immune complexes (Fauci et al., 1978). However, evaluation of a wide range of vasculitides failed to identify substantial vessel wall deposition of immunoglobulins or complement. This was especially true in cases of GPA, MPA, and EGPA (Ronco et al., 1983; Weiss and Crissman, 1984). Davies et al. (1982) reported a new type of autoantibody that reacted with neutrophil cytoplasm in eight patients with pauci-immune necrotizing GN and SVV. Three years later, van der Woude et al. (1985) identified these autoantibodies in patients with GPA and suggested its value as a diagnostic and prognostic marker. Numerous subsequent studies documented that ANCAs were closely associated with GPA, MPA, and EGPA. The two major antigen specificities in patients with ANCA vasculitis were described by Falk and Jennette (1988), and Niles et al. (1989), that is, antimyeloperoxidase (MPO) ANCA (MPO-ANCA) and antiproteinase 3 (anti-PR3) (PR3-ANCA) (Falk and Jeneette 1988; Jennette and Nachman, 2017; Niles et al., 1989). In addition to the diagnostic value of these autoantibodies there is now strong evidence that ANCA participate in disease pathogenesis by direct activation of neutrophils (Jennette et al., 2013a).

## POLYARTERITIS NODOSA

### Definition

PAN is a systemic necrotizing arteritis of medium-sized or small arteries without GN or vasculitis in arterioles, capillaries, or venules. PAN is typically not associated with ANCAs (Jennette et al., 2013a).

### Epidemiology

The annual incidence of PAN in European countries is approximately 2–10 cases per million population. Prevalence has been estimated between 2 and 31 cases/million (Mahr et al., 2004; Mohammad et al., 2007; Watts and Scott, 2004). The peak incidence occurs in the sixth decade of life (Mahr et al., 2004; Mohammad et al., 2007; Watts and Scott, 2004).

## Clinical Features and Disease Association

Presentation includes constitutional symptoms, such as fever, weight loss, arthralgia, and myalgia (30%–93% of the cases); tender erythematous nodules, livedo reticularis, and ulcers caused by dermal and subcutaneous arteritis (28%–49%); peripheral neuropathy (e.g., mononeuritis multiplex) caused by arteritis in epineural arteries (38%–74%); and gastrointestinal manifestations, that is, abdominal pain, bowel bleeding, or perforation (14%–38%) (Hernandez-Rodriguez et al., 2014; Pagnoux et al., 2010). Kidney involvement is observed in 15% of the patients and is the result of tissue infarction or rupture of renal arterial aneurysms rather than GN. Signs and symptoms of renal involvement are renal insufficiency, new-onset hypertension, hematuria, or low-level proteinuria (Agard et al., 2003; Pagnoux et al., 2010). Less common complications of PAN include myocardial infarction, orchitis, and ischemic retinopathy.

A PAN-like disease caused by deficiency of adenosine deaminase 2 (DADA2) has been described. DAD2 is a monogenic autoinflammatory disorder characterized by early-onset polyarteritis, recurrent ischemic or hemorrhagic strokes, livedo reticularis, fever, elevation of acute phase reactants, and in some cases peripheral neuropathy, gastrointestinal ischemic symptoms, and hypogammaglobulinemia (Navon Elkan et al., 2014; Zhou et al., 2014).

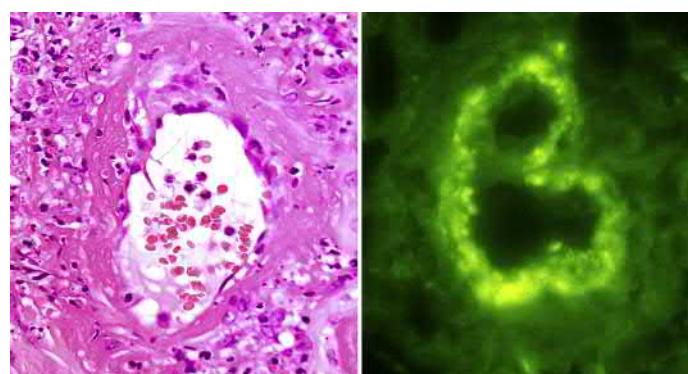

## Pathological Features

The hallmark of PAN is transmural inflammation and necrosis of muscular arteries (Fig. 65.2). The vascular inflammation initially contains predominantly neutrophils, but within a few days, the infiltrates contain predominantly monocytes, macrophages, and T-lymphocytes (Jennette, 2002). Typically, lesions are observed at arterial branching sites with acute necrotizing vasculitis usually coexisting with chronic vascular fibrotic changes. Segmental inflammation and necrosis may produce pseudoaneurysms by eroding through the vessel wall into the surrounding tissue. Thrombosis can cause acute ischemia, including infarction. Rupture of pseudoaneurysms results in hemorrhage, which may be severe and life threatening. The histopathological features of newly described DADA2 are indistinguishable from those of classic PAN (Caorsi et al., 2016).

## Pathogenesis

The pathogenesis of PAN remains poorly understood. It is probable that both humoral and cellular inflammatory systems participate in the development of necrotizing arteritis (Ozen, 2017). In a particular subset of patients, that is, those with hepatitis B virus–associated PAN (HBV-PAN), deposition of immune complexes is believed to play a role (Fig. 65.2). When arterial wall immune complexes are present, they cause inflammation by activating the complement, kinin, plasmin, and coagulation humoral systems, and the neutrophil, mononuclear phagocyte, lymphocyte, and platelet cellular systems. This complex interplay between the innate and adaptive immune systems results in the influx of inflammatory cells (especially neutrophils), necrosis, and sometimes thrombosis.

ADA2 acts as a growth factor for endothelial and hematopoietic cells and also participates in monocyte proliferation and macrophage differentiation (Zavialov et al., 2010). In this sense deficiency of this enzyme has been associated with compromised vascular endothelial integrity and with defects in the differentiation of M2 antiinflammatory monocytes, leading to an increased polarization of M1 proinflammatory cells (Caorsi et al., 2016; Zhou et al., 2014). In addition DADA2 may lead to an increased neutrophil activation (Caorsi et al., 2016; Zhou et al., 2014).

**FIGURE 65.2** Left panel: Light microscopy of necrotizing arteritis consistent with PAN in the wall of the small intestine (hematoxylin and eosin). The muscular media of the artery has been destroyed and replaced by fibrinoid material with admixed leukocytes and leukocyte nuclear debris (leukocytoclasis). Right panel: Direct immunofluorescence photomicrograph demonstrating granular IgG deposits in an artery from the subcutaneous tissue of a patient with hepatitis B–associated polyarteritis nodosa, showing granular vessel wall staining for C3. *PAN*, periarteritis nodosa.

## Autoimmune Features

Most patients with PAN do not have recognized evidence for an autoimmune pathogenesis. Exceptions are the few patients with systemic lupus erythematosus (SLE) who have a vasculitis that is pathologically similar to idiopathic PAN (lupus arteritis) (Korbet et al., 1984). ANCAs are typically absent in PAN patients (Jennette et al., 2013a).

## Environmental Influences and Genetic Features

There is a strong association between PAN and HBV, as approximately one-third of PAN cases are secondary to this infectious disease (Guillevin et al., 2005; Pagnoux et al., 2010). In comparison with the idiopathic form of this vasculitis HBV infected patients usually exhibit a more severe phenotype, frequently involving the gastrointestinal and peripheral nervous system and the heart (Pagnoux et al., 2010). Anecdotal reports of PAN-like vasculitis associated with hepatitis C virus (HCV), human immunodeficiency virus (HIV), parvovirus B19, cytomegalovirus, Mediterranean fever, and hematological neoplasias have been published (Hasler et al., 1995; Ozen et al., 2001).

There is no evidence that genetic factors play a substantial role in the development of classic PAN neither than genetic features of HBV correlates with the induction of the disease. In contrast DADA2 is clearly associated with a genetic defect, that is, loss-of-function homozygous or compound heterozygous mutations in CECR1 gene (Caorsi et al., 2017).

## Animal Models

Pearl Zeek, who was one of the pioneers in delineating the clinical and pathologic features of PAN, studied an animal model of systemic arteritis that resembled PAN and that was induced by implanting pieces of silk in the perirenal tissue of rats (Zeek et al., 1948). More recently, necrotizing inflammation of mesenteric, pancreatic, and testicular arteries has been reported to occur spontaneously in certain rodent strains and in transgenic rats carrying the *env-pX* gene of human T-cell leukemia virus type I (Fugo et al., 2002; Yoshiki, 2002). The relevance of these models to PAN in patients is not clear because these experimental animals often have involvement of small-sized vessel (e.g., GN), as well as the presence of several pathogenic autoantibodies that are not observed in most patients with PAN (e.g., anti-DNA and antinuclear antibodies) (Fugo et al., 2002).

## Diagnostic Procedures

Biopsies from muscle, peripheral nerve, or skin (subcutaneous tissue) may document necrotizing arteritis. Conventional angiography is an alternative to biopsy (Hernandez-Rodriguez et al., 2014; Pagnoux et al., 2010). Typical findings include multiple aneurysms (pseudoaneurysms), and stenosis of mesenteric, renal, and hepatic arteries. The diagnosis PAN is supported by the serologic identification of HBV (Agard et al., 2003; Janssen et al., 2004). The diagnosis of PAN in a patient with necrotizing arteritis requires the exclusion of other diseases with arteritis, such as KD or ANCA vasculitis (Agard et al., 2003; Jennette et al., 2013a; Mahr et al., 2004). In this sense the presence of GN, alveolar capillaritis, or positive MPO-ANCA or PR3-ANCA rule out a diagnosis of PAN and indicate some form of SVV, for example, MPA or GPA (Agard et al., 2003; Jennette et al., 2013a).

## Treatment

Patients with nonorgan and non-life-threatening disease may be treated with glucocorticoids (GC) alone. A recent clinical trial showed that the addition of azathioprine to GC for remission-induction of nonsevere PAN did not improve remission rates or lower the relapse risk of these patients (Puechal et al., 2017). Under this category are included those who present with constitutional symptoms, mild cutaneous involvement or those who lack any of the poor prognostic variables described in the five factor score (FFS), that is, renal insufficiency, proteinuria >1 g/day, cardiac involvement, central nervous system involvement, or gastrointestinal involvement. Half of these patients will require an additional immunosuppressant for remission-maintenance (Samson et al., 2014). Moderate or severe manifestations, that is, one or more features of the FFS, presence of mononeuritis multiplex, or limb ischemia, are treated with high-dose GC in combination with cyclophosphamide (Gayraud et al.,

2001; Guillemin et al., 1995). Cases with HBV-associated PAN should receive antiviral therapy with interferon (IFN)- $\alpha$  or lamivudine in addition to immunosuppressive agents (Guillemin, 1999; Han, 2004; Janssen et al., 2004).

Experience treating DADA2 is limited. High-dose GC, tumor necrosis factor (TNF)-blockers, and enzymatic replacement therapy have all reported to be of benefit (Caorsi et al., 2016).

## KAWASAKI'S DISEASE

### Definition

KD is an acute vasculitis of childhood associated with the mucocutaneous lymph node syndrome that predominantly affects medium and small arteries. Coronary arteries are often involved (Jennette et al., 2013a).

### Epidemiology

In the United States, the estimated incidence of KD among children <5 years of age is in the range of 19–25 cases per 100,000 (Watts and Scott, 2004). Incidence varies by race, being markedly more frequent in East Asia, particularly in Japan. Approximately 90% of the patients are between ages 6 months and 5 years, with a male-to-female ratio of 1.5:1 (Yanagawa et al., 1995). In children from developed countries KD is the leading cause of acquired heart disease (Newburger and Fulton, 2004).

### Clinical Features and Disease Associations

Major clinical manifestations (also considered diagnostic criteria) include persistent fever in combination with (1) extremity changes (50%–85% of the cases), that is, erythema and edema of the palms and soles, periungual desquamation; (2) nonexudative bilateral conjunctivitis (70%–90%); (3) cutaneous involvement (70%–90%), that is, maculopapular eruption, diffuse erythroderma, or erythema multiforme-like rash; (4) oral mucosal lesions (90%), that is, erythema and cracking of the lips, “strawberry tongue,” or erythema of pharyngeal mucosa; and (5) cervical lymphadenopathy (25%–70%) (Fukushige et al., 1994; Kawasaki, 1967; McCrindle et al., 2017; Newburger and Fulton, 2004; Ozdemir et al., 2010). Cardiovascular complications, the major determinant of long-term prognosis, include coronary artery aneurysms, myocardial infarction, myocarditis, and valvular abnormalities (McCrindle et al., 2017).

### Pathological Features

The vasculitis of KD involves medium-sized and small arteries, most notably the coronary arteries. KD arteriopathy usually evolves from an acute necrotizing arteritis, characterized histologically by segmental mural necrosis with infiltration by predominantly mononuclear leukocytes with less conspicuous neutrophils, to a subacute vasculitis with infiltration of lymphocytes, plasma cells, and eosinophils, that is followed by myofibroblastic proliferation that may result in narrowing of the lumen, arterial stenosis, and ischemia (Jennette, 2002; McCrindle et al., 2017). Pseudoaneurysms are most common in the proximal coronary arteries and may be occluded by thrombus, resulting in myocardial infarction. In addition to the coronary arteries, renal, iliac, mesenteric, hepatic, and peri-pancreatic arteries may be involved (Cohen and Sundel, 2016). In comparison with PAN less fibrinoid material, more edema, and more macrophages are observed in necrotizing lesions of KD (Jennette, 2002).

### Pathogenesis

As in PAN, activation of both the innate and adaptive immune systems may play a role in KD. Previous studies have demonstrated a marked increase in serum concentration of proinflammatory cytokines IL-1 $\beta$ , IL-6, IL-8, IL-17, and TNF- $\alpha$  during the acute phase of KD (Franco et al., 2010; Matsubara et al., 2005; Sohn et al., 2003; Wang et al., 2013). In addition KD patients have a deficit of regulatory T cells and increased activity of CD4+ T-lymphocytes (Hirabayashi et al., 2013; Sohn et al., 2011). Although not fully verified, antiendothelial cell antibodies have been incriminated in the pathogenesis of vascular injury in patients with KD (Grunebaum et al., 2002; Kaneko et al., 2004; Leung et al., 1986a, 1986b, 1989).

## Autoimmune Features

Autoantibodies that react with activated endothelial cells and cardiac myosin have been identified in patients with KD (Cunningham et al., 1999; Grunebaum et al., 2002; Kaneko et al., 2004; Leung et al., 1986a, 1986b, 1989). The relevance of this finding is still to be determined.

## Genetic Features and Environmental Influences

Infectious, environmental, and genetic factors have been implicated in the development of KD. An infectious etiology of KD has been suggested on the basis of the temporal clustering and seasonality of reported cases and the similarity of clinical presentation with childhood febrile exanthems. Although several microorganisms have been incriminated, that is, coxsackie virus, cytomegalovirus, parainfluenza virus, novel RNA viruses, or bacterial superantigens, none has been confirmed (Burns et al., 2005). Proposed associations with environmental factors include dust mites or pollen exposure, residence near standing water, and large-scale wind currents originating from Asia (Cohen and Sundel, 2016; McCrindle et al., 2017; Rodo et al., 2011).

A role for genetic factors in the pathogenesis of KD is supported by the observation that children of parents who had KD in childhood are at greater risk for developing the disease (Uehara et al., 2003). In addition a child is at 10-fold greater risk of developing the disease within 1 year of onset of the disease in a sibling (Fujita et al., 1989). Genome-wide association studies (GWAS) and family linkage studies have identified an increased susceptibility for the development of KD in the presence of single-nucleotide polymorphisms of several genes that are involved in the regulation of immune response, that is, BLK, CD40, ITPKC, CASP3, and FC $\gamma$ R2A (Lee et al., 2012; McCrindle et al., 2017; Onouchi et al., 2008, 2012).

## Animal Models

Takahashi et al. (2004) have developed an animal model of vasculitis that has a remarkable pathologic similarity to the arteritis of KD. They injected a *Candida albicans* extract intraperitoneally for 5 consecutive days into a variety of mouse strains. Arteritis developed in 66% of the CD-1 mice and most often affected the coronary arteries and aortic root close to the orifice of coronary arteries. The gross distribution and histologic pattern of injury closely mimics coronary arteritis in patients with KD. Not all strains of mice developed disease, indicating a genetic susceptibility in certain strains. Duong et al. (2003) have described a similar mouse model of coronary arteritis induced by the injection of *Lactobacillus casei* cell wall extract.

## Diagnostic Procedures

Diagnosis of KD and incomplete (atypical) forms is based on clinical criteria and exclusion of other systemic vasculitis and infectious conditions (McCrindle et al., 2017). Leukocytosis, anemia, and raised erythrocyte sedimentation rate (ESR) and C-reactive protein are common during the first days of disease. Echocardiography of coronary arteries should be performed in all patients (McCrindle et al., 2017). Until now, no autoantibodies have been recognized that can be used for routine diagnosis of KD (Newburger and Fulton, 2004).

## Treatment

Management of KD is aimed to prevent the development of coronary aneurysms. Recommended initial treatment includes the administration of a single dose of intravenous gamma-globulin (IVIg, 2 g/kg) in addition to high-dose aspirin (Furusho et al., 1984; McCrindle et al., 2017; Nagashima et al., 1987; Newburger and Fulton, 2004). After normalization of fever and in the absence of coronary aneurysms, low-dose aspirin should be continued for 4–6 weeks.

Patients who are refractory to initial IVIg dose (10%–20% of the cases) have an increased risk of developing aneurysms. For these children, options include a repeated infusion of IVIg, infliximab, GC, cyclosporine, cyclophosphamide, or plasma exchange (McCrindle et al., 2017).

## ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY VASCULITIS

### Definition

ANCAAs are autoantibodies specific for antigens located in the cytoplasmic granules of neutrophils and lysosomes of monocytes (Jennette and Nachman, 2017). The main autoantigen targets of ANCAAs are MPO (MPO-ANCA) and PR3 (PR3-ANCA). ANCA vasculitis is characterized by necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels, that is, capillaries, venules, arterioles, and small arteries (Jennette et al., 2013a). ANCA vasculitis has three major clinicopathologic expressions, that is, GPA (formerly called Wegener's granulomatosis), MPA, and EGPA (formerly Churg–Strauss syndrome) (Jennette et al., 2013a) (Box 65.1). GPA has necrotizing granulomatous inflammation superimposed on the vasculitis. EGPA has asthma, eosinophilia, and granulomatous inflammation in addition to the vasculitis. MPA has only the vasculitis, without granulomatous inflammation, asthma, or eosinophilia (Jennette et al., 2013a).

### Epidemiology

The overall incidence and prevalence of ANCA vasculitis has been estimated at 13–23 cases/million adults per year and 46–184 cases/million, respectively (Mohammad et al., 2007, 2014; Watts et al., 2015; Watts and Scott, 2004). The annual incidence in 1,000,000 adults ranges from 2 to 12 for GPA, from 3 to 12 for MPA, and from 1 to 3 for EGPA (Watts et al., 2015). Reported prevalence of GPA is 24–160 cases/million inhabitants, between 9 and 94 for MPA, and 2 and 38 for EGPA (Mohammad et al., 2007, 2014; Watts et al., 2015; Watts and Scott, 2004). GPA is more prevalent in Nordic countries, whereas MPA is the most common ANCA vasculitis in Southern Europe and Japan (Ntatsaki et al., 2010). Mean age at disease onset is 45–60 years for GPA, 55–74 for MPA, and 38–52 for EGPA (Guillevin et al., 1999; Smyth et al., 2004).

### Clinical Features and Disease Associations

Constitutional symptoms such as fever and arthralgias are observed in a large majority of patients (Agard et al., 2003). Small vessels in any organ or tissue can be affected (Table 65.1). Frequent examples include vasculitis affecting dermal venules causing palpable purpura; necrotizing arteritis in small dermal and subcutaneous arteries causing ulcers, and nodules; vasculitis affecting small epineurial arteries and arterioles causing peripheral neuropathy (usually mononeuritis multiplex or sensory neuropathy); vasculitis of the small vessels of the eye causing scleritis and uveitis; and vasculitis in small vessels in the gastrointestinal mucosa and submucosa causing abdominal pain and blood in the stool (Jennette and Nachman, 2017).

Inflammation of glomerular capillaries causes focal and segmental, necrotizing, crescentic GN, and pulmonary capillaritis causes pulmonary hemorrhage (Jennette and Falk, 1997). Vasculitis of small vessels in the upper respiratory tract, present in approximately 90% of the GPA patients, causes sinusitis, otitis, bloody nasal discharge, or collapse of the nasal septum causing saddle nose deformity (Hoffman et al., 1992). A smaller proportion of MPA patients have upper respiratory tract inflammation that is less destructive than that of GPA.

Patients with GPA may have clinical manifestations of necrotizing granulomatous inflammation, that is, pulmonary nodules and cavities, subglottic stenosis, orbital masses, and nasolacrimal duct obstruction (Hoffman

**TABLE 65.1** Differential Diagnostic Features of Several Forms of Small-Vessel Vasculitis (SVV).

	MPA	GPA	EGPA	IgAV	Cryo V	PAN
SVV signs and symptoms	Yes	Yes	Yes	Yes	Yes	No
IgA-dominant deposits	No	No	No	Yes	No	No
Cryoglobulins	No	No	No	No	Yes	No
Necrotizing granulomas	No	Yes	Yes	No	No	No
Asthma and eosinophilia	No	No	Yes	No	No	No

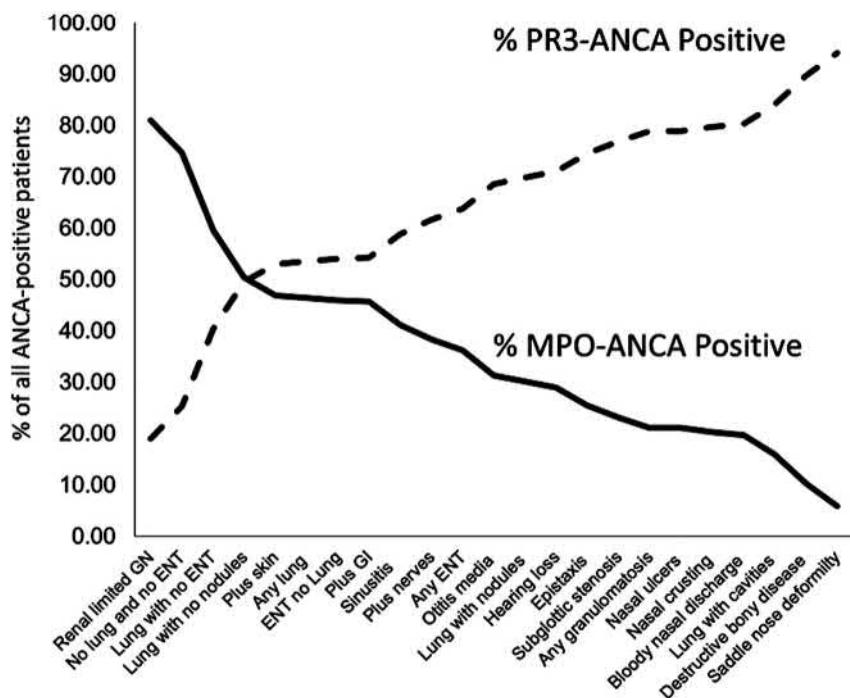

All these SVVs can manifest any or all of the shared features of SVV, such as purpura, nephritis, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence, and just as importantly the absence, of certain specific features. Both ANCA vasculitis and PAN can cause arteritis, but PAN lacks features of SVV and ANCA. GPA and EGPA are distinguished from MPA by granulomatous inflammation, and EGPA is distinguished by asthma and blood eosinophilia. ANCA, Antineutrophil cytoplasmic autoantibody; GPA, granulomatosis with polyangiitis; EGPA, eosinophilic granulomatosis with polyangiitis; PAN, periarteritis nodosa.

et al., 1992), whereas those with EGPA may suffer from organ damage associated with eosinophilic infiltration, for example, cardiomyopathy, or gastroenteritis (Comarmond et al., 2013).

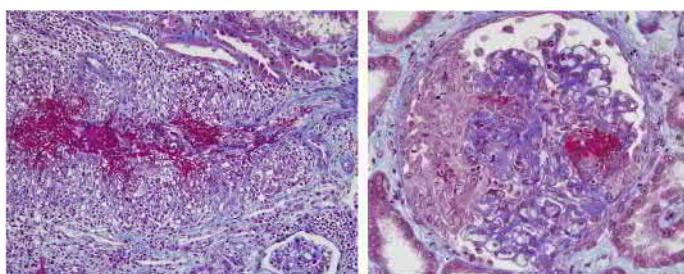

The frequency of different organ system involvement, and the clinical signs and symptoms of disease, are influenced by the ANCA antigen specificity (serotype), that is, whether the patient has MPO-ANCA or PR3-ANCA (Lionaki et al., 2012). As noted earlier, this also is influenced by geography. Fig. 65.3 demonstrates the correlation of organ system involvement with ANCA serotype in a cohort of patients from the southeastern United States (Jennette and Nachman, 2017). Note that patients with renal-limited disease have predominantly MPO-ANCA, whereas patients with evidence for destructive upper respiratory tract disease have predominantly PR3-ANCA.

## Pathological Features

Patients with all clinicopathologic expressions of ANCA vasculitis share a common pathologic manifestation of small-vessel inflammation (Jennette, 1991, 2002). The acute vascular lesion is similar in all vessels and is characterized by mural fibrinoid necrosis with karyorrhexis and infiltrating leukocytes (Fig. 65.4) (Jennette et al., 2013b). Neutrophils predominate in early lesions and are later replaced by inflammation with a

**FIGURE 65.3** Frequency of PR3-ANCA and MPO-ANCA positivity in ANCA-positive patients with a particular organ system involvement in an inception cohort of 502 ANCA vasculitis patients with MPA, GPA, or RLV evaluated at the University of North Carolina Kidney Center (excluding patients with EGPA). Organ groupings are not mutually exclusive. 'No lung and no ENT' has vasculitis in some other organs. Plus means there is vasculitis in an additional organ. **FIGURE 65.4** (A, left panel) Necrotizing arteritis in a small artery and (B, right panel) necrotizing glomerulonephritis in a patient with microscopic polyangiitis. The artery and glomerulus have bright red staining for fibrinoid necrosis with a Masson trichrome stain. The artery and adjacent tissue are infiltrated by neutrophils and mononuclear leukocytes. The glomerulus has a cellular crescent on the left and segmental fibrinoid necrosis on the right.

predominance of monocytes, macrophages, and T-lymphocytes. Late-stage lesions have fibrotic scars (Jennette et al., 2013b). Acute and chronic vasculitic lesions usually coexist in tissue samples as a result of ongoing waves of new acute lesions superimposed on earlier lesions.

Focal segmental necrotizing GN with crescent formation is a frequent lesion in patients with ANCA vasculitis (Fig. 65.4). By immunofluorescence microscopy, the absence or paucity of staining for immunoglobulin distinguishes ANCA GN from immune complex GN.

In addition to SVV, GPA is characterized by the presence of necrotizing granulomatous inflammation that most often affects the upper and lower respiratory tract (Jennette et al., 2013a). Earliest granulomatous lesions are histologically characterized by the presence of a neutrophil-rich inflammatory infiltrate that resembles abscess formation (Gaudin et al., 1995; Travis et al., 1991). As the lesion progresses, geographic necrosis, palisading elongated macrophages, and scattered multinucleated giant cells are observed (Travis et al., 1991). More chronic lesions have extensive fibroblastic proliferation and interstitial deposition of collagen. In contrast to GPA the necrotizing granulomas of EGPA have more intense infiltration of eosinophils along with neutrophils.

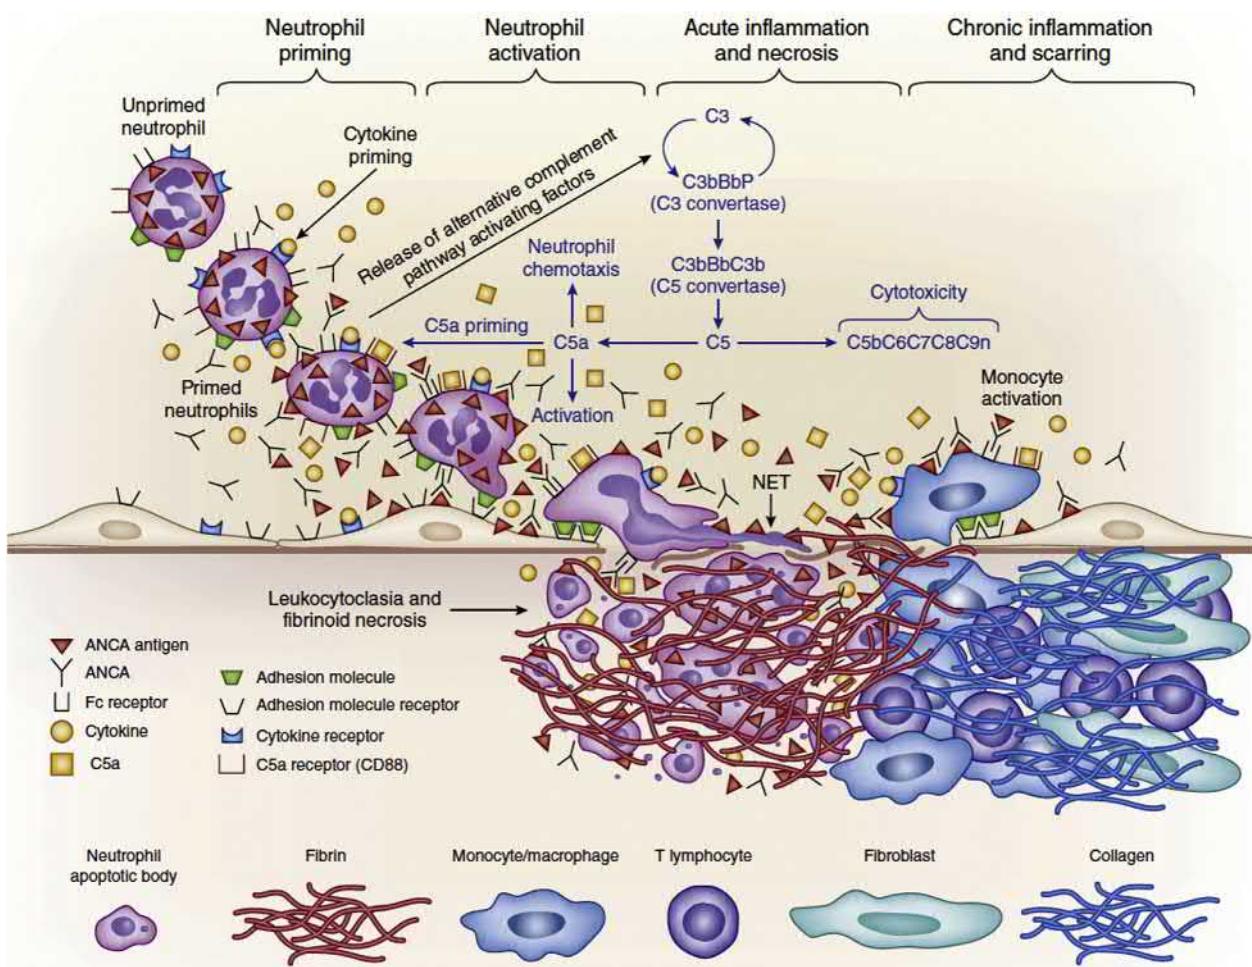

## Pathogenesis

The leading theory of the pathogenesis of vascular inflammation in ANCA vasculitis proposes that interaction of ANCAs with antigens (PR3 and MPO) expressed at the surface of cytokine-primed neutrophils causes full neutrophil activation [through both FcR engagement and F(ab')2 attachment to antigens] with generation of proinflammatory cytokines, oxygen radicals, destructive enzymes, and extrusion of neutrophil extracellular traps, in addition to the activation of the alternative complement pathway, resulting in the attachment to, injury and death of vascular endothelial cells, and other vessel wall components (Fig. 65.5) (Jennette and Nachman, 2017).

Extensive in vitro evidence supports this scenario (Jennette and Falk, 1998; Rarok et al., 2003; Williams et al., 2005). Incubation of ANCA IgG with primed neutrophils induces the release of toxic reactive oxygen species and lytic granule enzymes (Falk et al., 1990b). Neutrophil priming, as occurs with exposure to certain cytokines, results in the expression of small amounts of ANCA antigens at the surface of neutrophils where they can interact with ANCA (Falk et al., 1990b). In vitro ANCA-activated neutrophils are able to kill primed endothelial cells (Ewert et al., 1992; Savage et al., 1992). Also, exposure to ANCA IgG causes rolling neutrophils to adhere to endothelial cells in culture through integrin-mediated adhesion (Radford et al., 2000). Further, it has been demonstrated that MPO-ANCA and PR3-ANCA antigens may become planted in vessel walls by a charge-dependent mechanism, allowing their interaction with ANCA to form immune complexes *in situ* (Vargunam et al., 1992). If the latter occurs *in vivo*, the magnitude of vessel wall immune complex formation must be substantially less than in conventional immune complex disease because of the absence or paucity of staining for immunoglobulin in vessel walls in ANCA SVV.

In addition to in vitro experimental data, clinical observations and *in vivo* models (see the “Animal models” subsection of “Antineutrophil cytoplasmic autoantibody vasculitis” section) strongly support the pathogenic potential of ANCAs (Jennette and Falk, 2014). Clinical evidence include the report of a neonate who developed pulmonary hemorrhage and nephritis following transplacental transfer of maternal MPO-ANCA IgG; the presence of ANCA in the circulation and the correlation in *some* patients of ANCA titers with disease activity and recurrences of disease; the efficacy of anti-B-cell therapy (rituximab) and plasma exchange; and the induction of ANCA and pauci-immune SVV by drug exposure (Bansal and Tobin, 2004; Falk and Jennette, 2010; Han et al., 2003; Kallenberg et al., 1994). In addition it is interesting to note that approximately 90% of the patients report a “flu-like illness” shortly before the onset of the signs and symptoms of ANCA vasculitis (Falk et al., 1990a). An inflammatory process, such as a viral respiratory tract infection, may cause increased levels of circulating cytokines, which in turn prime neutrophils to interact with circulating ANCAs to induce vasculitis (Jennette and Falk, 1998). Experimental support for this hypothesis is provided by the observation that injection of bacterial lipopolysaccharide (LPS) into mice prior to induction of GN with anti-MPO IgG causes more severe injury (Huugen et al., 2005).

The pathogenic mechanisms involved in the development of extravascular granulomatous lesions observed in GPA are unknown. One hypothesis proposes that these lesions are consequence of an exaggerated antigen-independent innate response, that is, activation of primed-neutrophils by ANCAs located in the extravascular compartment results in an intense localized necrotizing inflammation that attract an influx of mononuclear cell, later evolving into more typical granulomatous inflammation (Jennette and Falk, 2014; Jennette et al., 2013b). An alternative proposal suggest that ANCA granulomatosis is induced by an antigen-specific T-cell immune response directed against PR3 or MPO (Lamprecht and Gross, 2007).

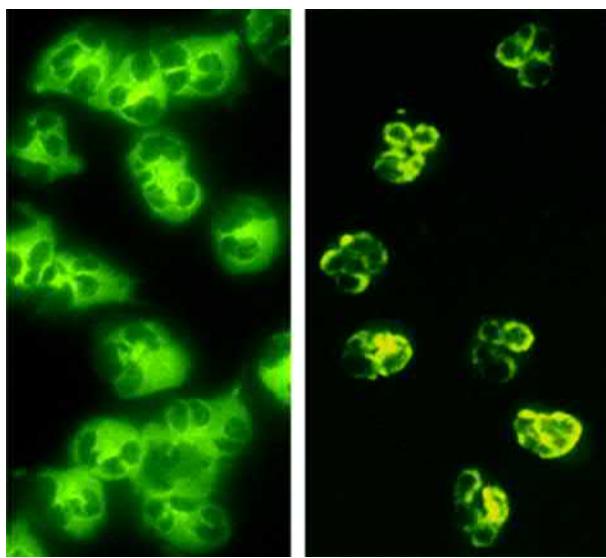

**FIGURE 65.5** Putative pathogenic mechanisms for ANCA-induced vasculitis. ANCA antigens (granule proteins) that are normally within the cytoplasm of neutrophils are transferred to the surface by cytokine priming, where they can interact with ANCAs. Some antigens also are released and can bind to endothelial cells and other vessel wall structures. These free and bound antigens can also react with ANCAs. The interaction of neutrophils with ANCAs, especially Fc receptor engagement, induces full activation with respiratory burst and degranulation, which releases factors from ANCA-activated neutrophils that activate the alternative pathway of complement activation. The resultant inflammation causes vascular injury (vasculitis). The response to this injury results in chronic inflammation and scarring. ANCA, antineutrophil cytoplasmic autoantibody. ## Autoimmune Features

Over 90% of the patients with active untreated GPA or MPA, and approximately 45% of the EGPA have circulating ANCAs (Falk and Jennette, 2010; Finkelman et al., 2007; Jennette and Falk, 1997). Standard methods for the detection of ANCAs include indirect immunofluorescence (IIF) microscopy and enzyme-linked immunosorbent assays (ELISA) (Lim et al., 1999; Savige et al., 1999). When detected by IIF using alcohol-fixed neutrophils as substrate, the two major antigen specificities cause two different staining patterns: cytoplasmic (C-ANCA) and perinuclear (P-ANCA) (Fig. 65.6). The perinuclear pattern is an artifact of substrate preparation caused by diffusion of antigens from the cytoplasm to the nucleus (Charles et al., 1989). When analyzed by specific immunoassays, the most frequent C-ANCA antigen specificity is for PR3 (PR3-ANCA) (Goldschmeding et al., 1989; Jennette et al., 1990; Niles et al., 1989), and the most frequent P-ANCA specificity is for MPO (MPO-ANCA) (Jennette and Nachman, 2017). ANCA specificity is a major determinant of clinical presentation, independently of the clinicopathologic variant (Lionaki et al., 2012) (Fig. 65.3); therefore a diagnosis for ANCA vasculitis should include both the serotype as well as the phenotype, for example, PR3-ANCA MPA.

It is important to realize that a minority of patients with typical clinicopathologic features of ANCA vasculitis are ANCA-negative using clinical serologic assays (Eisenberger et al., 2005). This may change with the

**FIGURE 65.6** Indirect immunofluorescence microscopy photomicrograph of (A) C-ANCA and (B) P-ANCA—staining patterns on alcohol-fixed human neutrophils; produced, respectively, by PR3-ANCA and MPO-ANCA. C-ANCA, cytoplasmic antineutrophil cytoplasmic autoantibody; MPO, myeloperoxidase; P-ANCA, perinuclear antineutrophil cytoplasmic autoantibody; PR3, proteinase 3.

development of more sensitive and activity-specific assays. For example, using an epitope-specific assay, Roth et al. were able to detect MPO-ANCA with very restricted epitope specificity in many patients who were ANCA-negative by conventional clinical assays (Roth et al., 2013). In addition they identified three categories of MPO-ANCA epitope specificity: (1) epitope specificity confined to ANCA-associated vasculitis patients with active disease, (2) epitope specificity detected in patients with active disease and in remission, and (3) epitope specificity that was seen in patients as well as in very low titer in healthy controls (natural ANCA) (Roth et al., 2013).

Approximately 5%–15% of the ANCA-vasculitis patients have concurrent antiglomerular basement membrane (anti-GBM) antibodies (Jennette, 2003; McAdoo et al., 2017; Rutgers et al., 2005). When both autoantibodies are present, a patient is at risk for manifesting vasculitic features of ANCA-associated disease that do not occur with anti-GBM disease alone, such as cutaneous, skeletal muscle, or gut vasculitis. In addition these patients have a worse prognosis than those with ANCA alone (Jennette, 2003; McAdoo et al., 2017; Rutgers et al., 2005). The presence of antiplasminogen antibodies is associated with venous thrombotic events in patients with PR3-ANCA vasculitis (Bautz et al., 2008). In addition antibodies directed against lysosomal membrane protein 2 have been reported in some patients with ANCA-necrotizing GN (Kain et al., 2008).

## Genetic Features and Environmental Influences

The precise etiology of the autoimmune response that causes pathogenic ANCAs is unknown, but evidence suggests that multiple environmental and genetic factors may play a relevant role in this process (Jennette et al., 2013b). Several infections have been implicated in the induction of ANCA vasculitis, for example, Ross River virus, *Entamoeba histolytica*, and *Staphylococcus aureus* (Stegeman et al., 1996). Some authors suggest that molecular mimicry between microbial proteins and self-antigens is responsible for the induction of the autoimmune ANCA response (Kain et al., 2008). Another theory proposes that pathogens can initiate an antibody response through induction of an appropriate antibody response to microbial proteins that have an amino acid sequence that mimics the antisense sequence (complementary sequence) of the autoantigen (Pendergraft et al., 2004). These antibodies to the complementary peptide in turn induce antiidiotypic antibodies that cross-react with the autoantigen (i.e., are autoantibodies). In support of this theory patients with PR3-ANCA disease have circulating antibodies that react with peptides that have an amino acid sequence that is complementary to PR3, and these antibodies react with anti-PR3 antibodies as an antiidiotypic pair. Further, immunization of mice with a complementary PR3 peptide induces not only an antibody response to the complementary PR3 peptide but also to native PR3. Interestingly, *S. aureus*, Ross River virus, and *E. histolytica*, which have been associated with PR3-ANCA disease, contain proteins with amino acid sequences that mimic complementary peptides of PR3 (Pendergraft et al., 2004).

ANCA disease can also be caused by a variety of drugs, including propylthiouracil, allopurinol, minocycline, hydralazine, or cocaine contaminated with levamisole (Choi et al., 2000; Pendergraft and Niles, 2014). Other environmental exposures that have been associated with the development of ANCA vasculitis include silica, mercury, and lead exposure (Albert et al., 2004; Hogan et al., 2001; Lane et al., 2003).

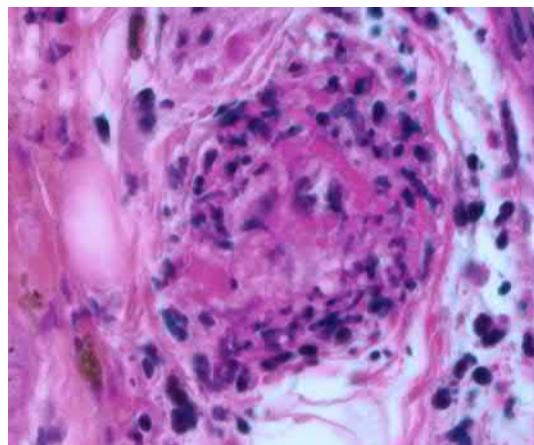

A GWAS of a large cohort of European patients has revealed a genetic influence on ANCA disease that correlated best with MPO-ANCA and PR3-ANCA autoantigen specificity rather than clinicopathologic phenotype (Lyons et al., 2012). In this study PR3-ANCA was associated with the human leukocyte antigen (HLA)-DP and genes encoding  $\alpha$ 1-antitrypsin (SERPINA1) and PR3 (PTRN3). MPO-ANCA was associated with HLA-DQ. Similar results were recently obtained in a North American cohort of GPA/MPA patients, where additionally a gene variant of PTPN22 was associated with an increasing susceptibility to ANCA disease (Merkel et al., 2017).

The predilection for the disease in white persons and the low prevalence in African Americans suggests that a genetic background contributes to disease induction. A previous study showed that African Americans with PR3-ANCA ANCA vasculitis had 73.3-fold higher odds of having HLA-DRB1\*15 alleles than healthy controls. Interestingly, DRB1\*1501 protein binds with high affinity to amino acid sequences of both sense-PR3 and anti-sense (complementary) PR3, suggesting that the major histocompatibility complex (MHC) antigen binding site is important in disease induction (Cao et al., 2011).

Epigenetic factors can also influence ANCA pathogenesis. Epigenetic modification of ANCA autoantigen-encoding genes results in aberrant overexpression of PR3 and MPO in neutrophils of ANCA patients (Ciavatta et al., 2010).

## Animal Models

Xiao et al. (2002) described the first convincing animal model of ANCA-induced SVV. This model is based on the passive transfer of purified anti-MPO IgG or splenocytes, obtained from MPO-deficient mice immunized with murine MPO, into wild-type or immunodeficient  $Rag2^{-/-}$  mice (lacking functional T and B cells) (Xiao et al., 2002). Over the course of 6 days, all mice that received anti-MPO developed necrotizing and crescentic GN that closely mimic human disease. In addition some mice exhibited extrarenal systemic SVV, for example, pulmonary capillaritis or necrotizing granulomatous inflammation, leukocytoclastic angiitis in the skin, or necrotizing arteritis in multiple viscera (Fig. 65.7). Studies using this model, or its variants, have demonstrated that (1) MPO-ANCA antibodies alone, in the absence of functional T cells, are sufficient to cause acute disease, (2) neutrophils are the mainstay effectors of disease induction, (3) bone marrow-derived cells are sufficient and necessary to induce ANCA GN, (4) genetic background plays an important role in the susceptibility and severity of disease, (5) circulating proinflammatory cytokines are able to exacerbate ANCA disease, (6) FC receptors are involved in pathogenesis and disease modulation, and (7) activation of alternative complement pathway is required to induce ANCA-associated GN (Huugen et al., 2005; Schreiber et al., 2006; Xiao et al., 2002, 2005, 2007, 2013).

**FIGURE 65.7** Necrotizing arteritis in a small artery in the dermis of a mouse 6 days after intravenous injection of mouse antimyeloperoxidase IgG. There is a central area of deeply eosinophilic fibrinoid necrosis surrounded by leukocytes with leukocytoclasis (H&E stain).

**TABLE 65.2** Clinicopathologic Phenotypes (RLV = Renal Limited Vasculitis, MPA = Microscopic Polyangiitis, GPA = Granulomatosis With Polyangiitis) and Serotypes [MPO-ANCA (Antineutrophil-Cytoplasmic-Autoantibody—Myeloperoxidase), PR3-ANCA (Proteinase-3—Antineutrophil-Cytoplasmic-Autoantibody)] of 502 ANCA-Positive Patients From an Inception Cohort Evaluated at the University of North Carolina Kidney Center (Excluding Patients With Eosinophilic Granulomatosis With Polyangiitis, EGPA)

Phenotype	MPO-ANCA (%)	PR3-ANCA (%)	
RLV ( <i>n</i> = 121)	81	19	
MPA ( <i>n</i> = 264)	59	41	
GPA ( <i>n</i> = 117)	26	74	
Serotype	RLV (%)	MPA (%)	GPA (%)
All ( <i>n</i> = 502)	24	53	23
MPO-ANCA ( <i>n</i> = 283)	35	55	11
PR3-ANCA ( <i>n</i> = 219)	10	50	40

## Diagnostic Procedures

Diagnosis of ANCA vasculitis is based on a combination of compatible clinical manifestations, positive laboratory test results, supportive radiology findings, and, when possible, the pathology confirmation of SVV (Table 65.2) (Jayne, 2009). As an SVV, ANCA vasculitis must be distinguished from other forms of SVV that can cause similar signs and symptoms, and have similar pathologic lesions by light microscopy. Immunopathologic features in tissue and serum are important in distinguishing among different forms of SVV (Table 65.1). ANCA vasculitis can involve arteries causing lesion that are indistinguishable histologically for the arteritis of PAN; however, PAN does not cause venulitis and capillaritis and is not associated with ANCA.

Laboratory workup for suspected ANCA vasculitis must include serum creatinine levels and urinalysis in all cases, in addition to determination of ANCA, antinuclear, and anti-GBM antibodies. Although one approach to ANCA testing is to first perform a screening by IIF and if positive (or inconclusive) to test for MPO-ANCA/PR3-ANCA by ELISA (Bossuyt et al., 2017; Savige et al., 1999), there is increasing evidence that high-quality immunoassays may be used for the primary screening, without the categorical need of IIF (Csernok et al., 2016; Damoiseaux et al., 2017). In addition epitope-specific assays may be a future option for the diagnosis and follow-up of these patients (Roth et al., 2013).

Serology alone cannot make the distinction between MPA, GPA, EGPA, or isolated pauci-immune crescentic GN because each syndrome can be associated with either C-ANCA (PR3-ANCA) or P-ANCA (MPO-ANCA) (Lim et al., 1999; Savige et al., 1999). However, the relative frequencies of ANCA specificities vary among the disease variants. For example, most patients with GPA have C-ANCA (PR3-ANCA), and most patients with renal-limited disease or MPA have P-ANCA (MPO-ANCA) (Table 65.2). Dual positivity is usually observed in drug-induced ANCA vasculitis (Savige et al., 2000). Diseases other than pauci-immune SVV can be associated with ANCAs, especially with ANCAs that are not specific for MPO or PR3, for example, autoimmune hepatitis, rheumatoid arthritis, ulcerative colitis, or sclerosing cholangitis (Bartunkova et al., 2002; Jennette and Falk, 1993).

Radiologic evaluation of the chest, orbits, brain, or ear, nose, and throat (ENT) structures may add diagnostic information and may be useful during follow-up. Computed tomography is preferred for evaluation of ANCA-associated lung disease. Typical findings include multiple, bilateral nodules, masses, and cavitations in cases of GPA and ground-glass opacities, usually reflecting alveolar hemorrhage, in patients with MPA (Cordier et al., 1990). Pulmonary fibrosis may be observed in approximately 7%–10% of these patients, particularly those with MPO-ANCA (Alba et al., 2017). Additional procedures may be performed if clinically indicated, for example, nerve-conduction studies, bronchoscopy, or ophthalmologic examination.

## Treatment

Treatment of ANCA vasculitis is composed of a remission induction phase with administration of highly potent immunosuppressants followed by a remission-maintenance period that aims to prevent relapses, still present in 40%–50% of the patients, and accrual of damage associated with vasculitis activity (Yates et al., 2016).

Remission-induction therapy of organ- or life-threatening disease consists in a combination of high-dose GC and either rituximab or cyclophosphamide (de Groot et al., 2009; Stone et al., 2010). Plasma exchange needs to be considered in patients with rapidly progressive GN and serum creatinine level >5.6 mg/dL, concomitant anti-GBM autoantibodies, or in those with severe diffuse pulmonary hemorrhage (Jayne et al., 2007; Klemmer et al., 2003; Yates et al., 2016). Methotrexate and mycophenolate mofetil are alternatives for less severe disease, for example, GPA with limited ENT involvement or patients with cutaneous or articular involvement (De Groot et al., 2005; Han et al., 2011). EGPA patients with nonorgan or life-threatening manifestations are usually managed with GC alone (Groh et al., 2015). The addition of IL-5 antagonist mepolizumab is effective in relapsing/refractory EGPA disease (Wechsler et al., 2017).

Current therapy strategies achieve remission of approximately 80%–90% of the patients, usually within 3–6 months after the initiation of treatment (Holle et al., 2011). Once remission is induced, patients are switched to maintenance therapy with low-dose GC in combination with rituximab, azathioprine, or methotrexate (Jayne et al., 2003; Pagnoux et al., 2008, 2015). The optimal duration of this phase is unknown. Ideally, extent of maintenance therapy should be individualized and should take into account aspects such as age, previous morbidity, or the presence of factors that have been associated with a relapsing course, for example, ANCA-PR3 seropositivity, lung or ENT involvement, or a clinical diagnosis of GPA (Hogan et al., 2005).

Despite the efficacy of immunosuppressive therapy, morbidity remains common in ANCA vasculitides. Patients are at increased risk of cardiovascular events and malignancy in addition to development of end-stage renal disease or treatment-associated adverse effects, for example, osteoporosis or opportunistic infections (Westman et al., 2015).

## CRYOGLOBULINEMIC VASCULITIS

### Definition

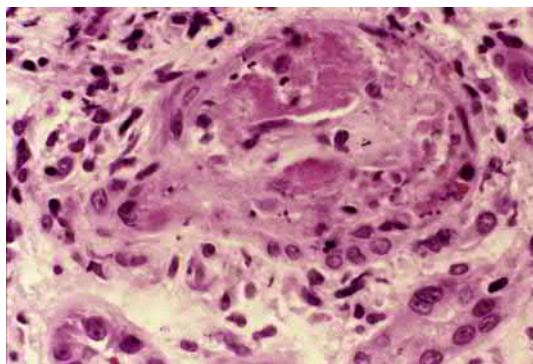

Cryoglobulins are circulating immunoglobulins that precipitate at cold temperatures and dissolve with rewarming. CV is defined as vasculitis with cryoglobulin immune deposits that affects small vessels (predominantly capillaries, venules, or arterioles) with associated serum cryoglobulins (Jennette et al., 2013a).

### Epidemiology

CV is more common in southern Europe than in northern Europe or North America and is closely associated with HCV infection (Ferri et al., 2004). Cryoglobulins are detected in 12%–50% of the HCV-infected patients, although less than 30% develop overt systemic vasculitis. HCV antibodies and RNA are detected in the serum of 75%–95% of the patients with vasculitis and GN caused by mixed cryoglobulins (D'Amico and Fornasieri, 1995; Ferri et al., 2004; Ramos-Casals et al., 2012). CV is most frequent in middle-aged individuals, predominantly women (female-to-male ratio 3:1) (Ferri et al., 2004).

### Clinical Features and Disease Associations

The clinical picture of CV may overlap with those of other systemic SVV (Table 65.1) and ranges from mild involvement of the skin and joints to potentially life-threatening disease, for example, alveolar hemorrhage. Patients with type I cryoglobulinemia (see the “Autoimmune features” subsection of “Cryoglobulinemic Vasculitis” section) may develop symptoms of vascular occlusion, for example, acrocytosis, livedo reticularis, skin necrosis, digital gangrene, or manifestations suggestive of hyperviscosity syndrome, that is, blurred vision, mucosal bleeding, headache, confusion, hearing loss, or heart failure (Harel et al., 2015; Terrier et al., 2013). Features of mixed CV (type II/III cryoglobulinemia) include constitutional symptoms (weakness, fever), palpable purpura, cutaneous ulcers, arthralgia/arthritis, mononeuritis multiplex, or distal sensory peripheral neuropathy; and kidney involvement, which usually presents as microscopic hematuria with proteinuria and less frequently as acute renal failure, nephrotic syndrome, or systemic hypertension. Sicca syndrome and abnormal liver function tests are common in HCV-associated CV.

**FIGURE 65.8** Cryoglobulinemic vasculitis affecting a small artery in the kidney. The deeply acidophilic material in the vessel probably is a mixture of thrombus, fibrinoid necrosis, and aggregated cryoglobulins. The vessel wall and adjacent tissue are infiltrated by leukocytes with leukocytoclasis.

## Pathological Features

CV is characterized pathologically by inflammation in small vessels that is associated with deposits of cryoglobulins and complement in vessel lumens and walls (Fig. 65.8). CV affects vessels of many types, including postcapillary venules (e.g., in the dermis), capillaries (e.g., glomerular and rarely pulmonary alveolar capillaries), arterioles, and rarely small arteries (Ferri et al., 2004). Immunofluorescence microscopy reveals granular deposits of immunoglobulins and complement in vessel walls, and sometimes luminal aggregates of cryoglobulins and complement. Type I membranoproliferative GN is observed in 70%–80% of the kidney biopsies; highly cellular glomerular infiltrates, thickening of GBM, hyaline intraluminal thrombi (precipitated cryoglobulins), and subendothelial dense deposits are typical features (D'Amico et al., 1989; Sinico et al., 1988).

## Pathogenesis

The pathogenic effect of cryoglobulins is the result of two different mechanisms, that is, immunoglobulin precipitation in the microcirculation, and deposition of mixed cryoglobulins in small vessels (Ramos-Casals et al., 2012). In the latter acute inflammation of blood vessels develops when immune complexes, composed of mixed cryoglobulins, activate the complement cascade, particularly the classic pathway (Sansonno et al., 2009). Of interest, it has been previously reported that immune complexes in HCV-associated CV contain nonenveloped nucleocapsid proteins and whole HCV virions (Sansonno and Dammacco, 2005). In this regard although mechanisms of cryoglobulin induction by HCV are not fully elucidated, one hypothesis proposes that infection of B cells by HCV triggers the production of polyclonal and monoclonal rheumatoid factors (RFs) that participate in cryoglobulin formation (D'Amico and Fornasieri, 1995). Another proposes that HCV lipoprotein induces an IgM response that is initially reactive with a virus-self complex but subsequently mutates to have RF activity (Agnello, 1995).

## Autoimmune Features

Cryoglobulins are divided into three major types: monoclonal (type I, either IgM or IgG), mixed monoclonal–polyclonal (type II, monoclonal IgM in combination with polyclonal IgG), and polyclonal (type III) (Brouet et al., 1974). Type I cryoglobulinemia (6% of the cases) is associated with B-cell lymphoproliferative disorders. Type II cryoglobulinemia (62% of the cases) is almost always caused by chronic HCV infection, although HBV and HIV are detected in a small percentage. Type III cryoglobulinemia (32% of the cases) is caused by HCV, lymphoproliferative malignancies or autoimmune diseases such as Sjögren syndrome or SLE (Monti et al., 1995).

Monoclonal cryoglobulins are not effective activators of inflammatory mediator systems and, therefore, rarely cause overt vasculitis, and morbidity is primarily by precipitation within vessels with the resultant occlusion (Muchtar et al., 2017). In contrast mixed cryoglobulins are immune complexes that are capable of activating inflammatory mediators and, therefore, characteristically cause systemic vasculitis (Muchtar et al., 2017). Most type II/III cryoglobulins contain autoantibodies directed against immunoglobulins, that is, RFs (Ferri et al., 2004; Sansonno and Dammacco, 2005).

## Genetic Features and Environmental Influences

As described previously, there is a strong association between CV and HCV infection, though not all patients with HCV develop cryoglobulinemia (D'Amico and Fornasieri, 1995; Ferri et al., 2004; Sansonno and Dammacco, 2005). The likelihood of developing circulating cryoglobulins is closely linked to the duration of HCV infection and the presence of certain HLA polymorphisms (Amoroso et al., 1998; Congia et al., 1996).

## Animal Models

The production of high titers of IgG-RF by secreting hybridomas was the base of two experimental mouse models of CV (Gyotoku et al., 1987; Kikuchi et al., 2002). In the first model investigators established monoclonal IgG-RF-secreting hybridomas from MRL/lpr mice (Gyotoku et al., 1987). These monoclonal RF antibodies were capable of forming cryoglobulins, and, when injected into normal mice, caused peripheral vasculitis and GN resembling that seen in patients with mixed cryoglobulinemia. In an alternative model mice were implanted with a hybridoma that secreted an IgG3 anti-IgG2a RF. These animals developed circulating cryoglobulins, acute GN, and cutaneous leukocytoclastic vasculitis (Kikuchi et al., 2002).

## Diagnostic Procedures

Classification criteria for CV have been proposed (De Vita et al., 2011). The laboratory hallmark of CV is the detection of cryoglobulins in the circulation (Table 65.2). Blood collection for cryoglobulin identification should be performed in prewarmed tubes. The type of cryoglobulins is later identified by immunoelectrophoresis and immunofixation (Ferri, 2008). Hypocomplementemia, characteristically low C4 but normal or near normal C3, is typically observed in mixed cryoglobulinemia as is the presence of high titers of RF (Ferri, 2008). Evaluation for possible HCV infection is mandatory. Additional work-up in selected cases may include HBV and HIV testing and determination of antinuclear, anti-DNA, and anti-Ro/La antibodies (Ramos-Casals et al., 2012). Tissue samples of the skin, peripheral nerve, or kidney may confirm the presence of a SVV.

## Treatment

Treatment of type I cryoglobulinemia is directed against the underlying lymphoproliferative disease (Muchtar et al., 2017). In patients with hyperviscosity syndrome plasma exchange may be of benefit. Management of noninfectious mixed cryoglobulinemia consists in the administration of high-dose GC and rituximab (Terrier et al., 2012). In organ- or life-threatening disease combination of intravenous methylprednisolone, rituximab (or cyclophosphamide), and plasmapheresis is recommended (D'Amico and Fornasieri, 1995).

Suppression of vascular inflammation and clearance of HCV are necessary in patients with HCV-associated CV. In these cases GC and rituximab are used in combination with pegylated IFN-ribavirin or preferentially, direct-acting antiviral agents, for example, sofosbuvir, simeprevir, or daclatasvir (Gragnani et al., 2016; Saadoun et al., 2017; Sise et al., 2016; Sneller et al., 2012). The choice of hepatitis C antiviral therapy should follow international guidelines (2016).

## IgA VASCULITIS (HENOCH–SCHÖNLEIN PURPURA)

### Definition

IgA vasculitis is a systemic vasculitis with IgA-dominant vascular immune deposits affecting small vessels. The disease occurs commonly in children and often involves the skin, the gastrointestinal tract, and the kidneys (Jennette et al., 2013a).

### Epidemiology

IgA vasculitis is the most common form of vasculitis in children. The disease has an incidence of 13–20 per 100,000 and is observed more frequently in patients of 4–7 years old (Gardner-Medwin et al., 2002). Male-to-

female ratio is about 1.5–1.8 to 1 (Gardner-Medwin et al., 2002; Hocevar et al., 2014). IgA vasculitis is less common in adults, that is, annual incidence of 3.4 new cases per million inhabitants (Watts et al., 1998).

## Clinical Features and Disease Associations

The classic manifestations of IgA vasculitis include palpable purpura, abdominal pain, arthritis/arthralgia, and nephritis. Purpura is typically symmetric and involves the lower extremities and buttocks. In adults purpura may show necrotic or hemorrhagic areas (Audemard-Verger et al., 2017). Arthritis of IgA vasculitis is typically nonerosive, migratory, and oligoarticular. Gastrointestinal involvement may present as nausea and vomiting, abdominal pain, bleeding, or, uncommonly, perforation or intussusception. Renal involvement is usually manifested as microscopic hematuria with low-level proteinuria, although nephrotic-range proteinuria, hypertension, and renal failure may occur. In contrast to the excellent overall prognosis observed in children 10%–30% of the adult patients suffer from more severe kidney involvement that may progress to end-stage renal disease (ESRD) (Coppo et al., 2006; Pillebout et al., 2002; Shrestha et al., 2006). In addition approximately 20% of adult patients have chronic relapsing disease (Coppo et al., 2006; Pillebout et al., 2002; Shrestha et al., 2006). As in other SVV, alveolar hemorrhage and peripheral neuropathy may be observed.

## Pathological Features

IgA vasculitis predominantly affects capillaries, venules, or arterioles (Jennette et al., 2013a). Immunofluorescence microscopy of dermal venules and renal glomeruli reveals granular vessel wall deposits of predominantly IgA1 and C3, with variable amounts of IgG and IgM, supporting a pathogenic mechanism that involves IgA-dominant immune deposits and activation of the alternative pathway of the complement system (Heineke et al., 2017).

## Pathogenesis

IgA vasculitis is an immune-mediated vasculitis that probably results from a dysregulated mucosal immune response, possibly initiated by environmental or infectious stimuli in a genetically predisposed individual (Heineke et al., 2017). IgA1-dominant immune complex deposits in vessel walls are the putative mediators of the inflammation. The IgA1 deposits may contain predominantly self-aggregated IgA1 or IgA1 complexed with anti-IgA1 autoantibodies (Heineke et al., 2017). Human IgA1 has an O-glycosylated hinge region not present in other immunoglobulin classes, and this hinge region has reduced galactosyl residues in patients with IgA nephropathy and IgA vasculitis (Allen et al., 1998; Heineke et al., 2017; Lau et al., 2007; Suzuki et al., 2009). This reduced galactosylation may be due to a functional defect in plasma cell  $\beta$ -1,3-galactosyltransferase. The abnormal glycosylation alters IgA1 structure and function, resulting in IgA1 aggregation, greater affinity for matrix proteins in vessel walls (including glomerular mesangium), and greater complement activation, which could result in localization of pathogenic IgA1-dominant deposits in vessel walls with resultant complement activation and vasculitis. Increased serum levels of IgA antiphospholipid antibodies (APA) directed against cardiolipin and  $\beta$ 2-glycoprotein have been reported in some patients (Kawakami et al., 2006; Yang et al., 2000, 2012). These antibodies are able to induce complement-dependent lysis of endothelial cells (Heineke et al., 2017).

## Autoimmune Features

Several antibodies have been detected in the serum of children and adults with active IgA vasculitis nephritis and IgA nephropathy, for example, antibodies directed against abnormally glycosylated IgA1, IgA anti- $\alpha$ -galactosyl, IgA antiendothelial cell antibodies, and APA (Davin et al., 1987; Heineke et al., 2017; Kawakami et al., 2006; Yang et al., 2000, 2012). The precise role of these antibodies in the pathogenesis of this vasculitis remains uncertain.

## Genetic Features and Environmental Influences

IgA vasculitis has a multifactorial etiology in which both genetic and environmental factors are probably involved. An infectious etiology of IgA vasculitis has long been suspected due to the seasonal pattern of the

disease, and the finding that approximately 40%–50% of the affected children suffered from an upper respiratory tract infection near the time of disease onset (Gonzalez-Gay et al., 2004; Masuda et al., 2003; Saulsbury, 2002; Ting and Hashkes, 2004). In this sense group A *Streptococcus*, methicillin-resistant *S. aureus*, and *Helicobacter pylori* have all been implicated as potential triggers for IgA vasculitis. In addition anecdotal cases have reported the association of this vasculitis with certain drugs, vaccination, and malignancy (Podjasek et al., 2014). Infections and other mucosal immune stimuli may be able to incite the production of pathogenic IgA1 that is not dependent on an antigen-specific immune response.

There is evidence from family studies that there may be a genetic predisposition for having circulating potentially pathogenic abnormally glycosylated IgA1 (Boyd and Barratt, 2011; Kiryluk et al., 2011). More importantly, a recent GWAS performed in 308 European patients identified that polymorphisms of HLA-DRB1 gene were associated with IgA vasculitis susceptibility (Lopez-Mejias et al., 2017). These findings are in line with previous studies that reported an increased prevalence of HLA-DRB1 and IL-1 allele polymorphisms in IgA vasculitis patients (Amoli et al., 2004).

## Animal Models

There is no good animal model for IgA vasculitis, although there are several animal models of IgA nephropathy, which is the glomerular lesion of IgA vasculitis. Many of these involve oral or nasal immunization with dietary or infectious antigens (Amore et al., 2004). Uteroglobin gene knockout and uteroglobin antisense transgenic mice develop pathologic features of human IgA nephropathy, but the relevance of this to human disease is unclear (Coppo et al., 2002; Lin et al., 2015; Zheng et al., 1999). Okazaki et al. (2012) used ddY mice as a model of spontaneously developing IgA nephropathy and have shown that aberrant IgA glycosylation influences the progression of kidney disease.

## Diagnostic Procedures

The immunohistologic identification of IgA-dominant immune deposits in vessels is currently the only accepted diagnostic marker for IgA nephropathy and is a defining feature of IgA vasculitis (Table 65.1) (Jennette et al., 2013a). Although a kidney biopsy may confirm the diagnosis, these are reserved for patients (usually adults) with nontypical presentations or those with severe involvement. The amount of circulating abnormally glycosylated IgA1 or IgG autoantibodies specific for abnormally glycosylated IgA1 may become a useful diagnostic marker in the future (Heineke et al., 2017). Differential diagnosis of IgA vasculitis includes other SVV, viral infections, thrombocytopenic purpura, and SLE. Patients with SVV that has vascular IgA-dominant immune deposits who have unusually aggressive vasculitis or GN should be evaluated for concurrent ANCA disease.

## Treatment

In children, IgA vasculitis usually is a mild, self-limited, vasculitis that does not warrant corticosteroid or cytotoxic therapy (Heineke et al., 2017; Robson and Leung, 1994). Some patients will require symptomatic relief of articular or abdominal pain with nonsteroidal antiinflammatory drugs. Colchicine and dapsone may be used in cases with chronic purpuric lesions (Audemard-Verger et al., 2015). Approximately 5% of the IgA vasculitis patients will develop organ- or life-threatening disease, for example, rapidly progressive GN, significant gastrointestinal bleeding or severe central nervous system (CNS) disease. In these cases high-dose methylprednisolone should be administered; cyclophosphamide, cyclosporine, rituximab, or plasmapheresis may be tried as adjuvant therapy (Audemard-Verger et al., 2015; Gedalia, 2004; Niaudet and Habib, 1998; Pillebout et al., 2010; Tarshish et al., 2004; Ting and Hashkes, 2004).

## CONCLUDING REMARKS—FUTURE PROSPECTS

A variety of pathogenic immunologic mechanisms, including autoimmune processes, mediate necrotizing arteritis and SVV. Clinically, and even pathologically, identical disease can be produced by distinctly different etiologies and pathogenic mechanisms, and a given etiology can produce more than one clinical and pathologic pattern of vasculitis. Because different organs can be affected in different patients, the clinical manifestations of

even relatively specific types of vasculitis are extremely variable among patients. Therefore the diagnosis of systemic vasculitis, including autoimmune vasculitis, is difficult and requires knowledgeable and skillful integration of clinical, pathologic, and laboratory data. Although difficult, precise diagnosis is essential for proper management, because the prognosis and appropriate treatment vary substantially among different categories of vasculitis. As knowledge of pathogenic immunologic mechanisms and inflammatory mediator systems increases, more effective treatments for autoimmune-mediated vasculitis will emerge, which will make precise diagnosis even more important.

## VASCULITIDES OF LARGE AND MEDIUM-SIZED BLOOD VESSELS

Vasculitides, inflammatory diseases of blood vessels, are recognized for their potential to rapidly progress to serious, and at times life-threatening, complications. Accordingly, arteritides of medium-sized and large arteries that cause aortitis and aortic branch vasculitis are considered medical emergencies that require prompt diagnosis and therapeutic management. Whereas the vasculitides of the capillaries and small arterioles may result in tissue damage, large-vessel vasculitis (LVV) puts the host at risk for fatal complications. One outcome is the inflammatory destruction of the vessel wall, leading to dissection, aneurysm formation, rupture, and hemorrhage (Weyand and Goronzy, 2003b). Alternatively, arteritis promotes luminal stenosis with subsequent occlusion, tissue ischemia, and infarct.

Inflammation in venous vessels is rare, whereas the layered wall structure of large arteries is a preferred site for granulomatous vasculitis, such as giant-cell arteritis (GCA) and Takayasu's arteritis (TA) (Table 66.1). The overlap of GCA and TA in affected vascular territories is only partial, and each entity also manifests in unique

**TABLE 66.1** Principal Features of Giant Cell Arteritis and Takayasu's Arteritis

	Giant cell arteritis	Takayasu's arteritis
Clinical	Subacute disease onset Restricted to individuals older than 50 years Highest incidence in individuals with Northern European ancestry Often combined with polymyalgia rheumatica	Subacute disease onset 90% of patients are female Highest risk in Asian and South American populations Systemic inflammatory syndrome with malaise, fever, arthralgias, and chest pain
Vascular component	Extracranial branches of the carotid artery Subclavian–axillary junction Aorta	Aorta Innominate, carotid, subclavian Mesenteric, renal arteries
Extravascular component	Hepatic acute phase response Elevated IL-6 Polymyalgia rheumatica Malaise Weight loss Anemia	Hepatic acute phase response Elevated innate cytokines (e.g., IL-6) Myalgias Arthralgias Fever Failure-to-thrive
Severe complications	Blindness Stroke Aortic aneurysm	Stroke Pulselessness Visual impairment Aortic regurgitation Hypertension
Pathogenesis	Loss of the artery's immune privilege Deficiency of immunosuppressive CD8 T regulatory cells in the periphery Aberrant expression of Jagged1 on adventitial microvascular cells Breakdown of the immuno-protective PD-1 checkpoint Intramural granulomatous lesions: <ul style="list-style-type: none"> <li>• Arterial wall dendritic cells</li> <li>• Tissue-injurious macrophages</li> <li>• Multiple lineages of effector T cells (Th1, Th17, Th9, Tfh, etc.)</li> </ul> Trigger of immune-mediated vascular inflammation unknown	Peripheral immune defects unknown Key cellular elements in the vascular lesions: <ul style="list-style-type: none"> <li>• Perforin-producing T cells</li> <li>• Natural killer cells</li> </ul> Instigator of vessel wall inflammation unknown

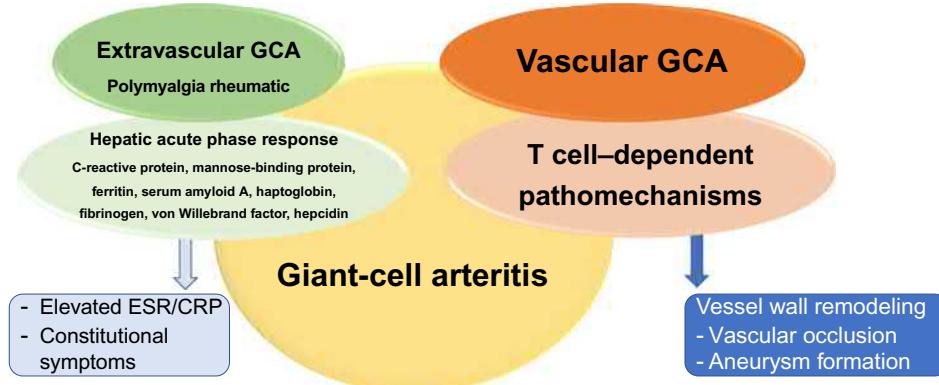

arterial beds. In rare cases, aortitides can be associated with other syndromes, such as relapsing polychondritis, sarcoidosis, inflammatory bowel disease, connective tissue disease, and infection (Rojo-Leyva et al., 2000). Some patients with aortitis, typically diagnosed from resected tissue after aortic repair, cannot be assigned to an underlying syndrome and appear to have isolated aortic disease. Noninvasive imaging modalities have greatly expanded diagnostic approaches in suspected large and medium-vessel vasculitis. Most patients require immunosuppressive therapy over prolonged periods and the prevailing paradigm of therapy-induced remission is being challenged and replaced by recognition that most patients have persistent smoldering vessel wall inflammation.

This chapter will focus on GCA and TA, the most frequent types of aortitis and aortic branch vasculitis. A singular etiologic agent for GCA or TA has not been identified, but affected patients have defined abnormalities in their innate and adaptive immune responses. Typical features include the assembly of granulomatous infiltrates within the vessel wall; the importance of host age (the young are exclusively susceptible to TA, the old exclusively develop GCA); the chronicity of inflammation; and the combination of vascular autoimmunity with an extravascular component. While GCA, TA, and atherosclerosis share the tissue tropism for medium and large arteries and have some overlap in pathogenic mechanisms, they differ in the intensity of inflammation and in the patterning of ischemic complications.

## GIANT CELL ARTERITIS

GCA has two major disease components, vascular GCA leading to aneurysm formation and arterial stenotic disease and extravascular GCA, characterized by an intense hepatic acute phase response and systemic inflammation (Fig. 66.1). The relationship of both disease components is not entirely understood, but emerging data suggest that the two components may be distinct in pathogenesis and therapeutic responsiveness.

Vascular GCA occurs due to the breakdown of the natural immune privilege that protects medium and large arteries from inflammatory attack. The immune-privileged niche of the vessel wall. Walls of medium and large arteries are composed of three layers; the intima, a thin endothelial cell layer; the media, built from contractile smooth-muscle cells; and the adventitia, a supportive structure containing the only microvascular access to the wall. An endogenous population of dendritic cells is placed at the adventitia–media border. Due to the vital function of large arteries, the wall is an immuno-privileged niche, naturally protected from inflammatory attack. Innate and adaptive immune responses are often associated with bystander damage to host tissue. Such damage is acceptable if it outweighs the risk of infection or malignancy. Since damage to the aorta and its large branches is incompatible with host survival, it is in the host's best interest to forgo immune responses that threaten vital structures. Named immune privilege, this principle is enforced by multiple mechanisms and applies to such vital organs as the eye and the myocardium. In the case of GCA, vital arteries have lost this protective mechanism, rendering them susceptible to inflammation. Typical histomorphologic lesions of GCA are granulomatous infiltrates composed of T cells and macrophages that invade into the wall layers of the aorta and its second to fifth branch vessels. It is now understood that immune cells gain access through the adventitial vasa vasorum. Once in the arterial wall, T cells interact with tissue-resident dendritic cells (DC) and differentiate into multiple functional linages. Activated by interferon- $\gamma$  (IFN- $\gamma$ )-producing T cells, macrophages release a broad portfolio of effector molecules, ranging from cytokines to proteases, growth and angiogenesis factors, and reactive oxygen species. Inflammatory damage to the wall elicits a maladaptive remodeling program, culminating in the hyperplasia of the intimal layer, luminal occlusion, and tissue ischemia. Since the upper

**FIGURE 66.1** Disease components of giant cell arteritis. Extravascular GCA is characterized by an intense hepatic acute phase response causing elevation of ESR and CRP. Vascular GCA manifests as transmural granulomatous vasculitis. Vasculitic effector T cells activate multiple macrophage subpopulations. Downstream consequences include cellular injury, neoangiogenesis, and intimal hyperplasia causing aneurysm formation in the aorta and luminal occlusion in aortic branches. CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GCA, giant cell arteritis.

extremity and cranial branches of the aorta are at highest risk, ischemic complications occur in the eye [ischemic optic neuropathy (ION)], the brain (vertebrobasilar strokes), and the subclavian-axillary bed (pulselessness). Almost all patients are older than 50 years of age, thus susceptible to immune aging and associated complications (Goronzy and Weyand, 2017). The highest incidence has been reported in persons of Northern European ancestry. If diagnosed early and treated appropriately, the clinical outcome is excellent (Weyand and Goronzy, 2003a,b). While extravascular GCA is promptly responsive to immunosuppression, vascular GCA appears more refractory, persisting long-term in a smoldering form (Maleszewski et al., 2017). It is currently unknown whether and to which degree such smoldering vasculitis requires treatment. The diagnosis can be made by biopsy of the temporal artery and given the potential side effects of long-term immunosuppressive therapy, diagnostic confirmation by histology should be sought whenever possible.

## Historic Background

Horton et al. (1932) reported on two patients admitted to the Mayo Clinic with “fever, weakness, anorexia, weight loss, anemia and painful, tender areas over the scalp and along the temporal vessels.” Histomorphology of the removed temporal artery described periarteritis and arteritis with granulation tissue in the adventitia. Horton recognized that this type of arteritis was distinct from all other vasculitic syndromes and named it “temporal arteritis.” Later the vasculitis also became known as cranial arteritis, granulomatous arteritis, polymyalgia arteritis, and Horton’s disease. Prior descriptions of temporal artery disease suggest that GCA may be a very old disease. The English surgeon Hutchinson (1890) described a patient with a red and swollen temporal artery who had difficulties wearing his hat. In the grave of Pa-Aton-Ern-Hebs, built during the Amarna period (around 1350 AD), a blind harpist was shown with nodularity and swelling of the temporal artery. And Ali Ibn Isa (940–1010 BC), an ophthalmologist in Baghdad, recommended removal of the temporal artery not only to treat headaches, but also inflammation of the scalp muscles associated with blindness (Henriet et al., 1989).

Horton deserves credit for recognizing the coexistence of the constitutional symptoms and the arteritis of the temporal vessels and for introducing temporal artery biopsy as a diagnostic test.

## Clinical, Pathologic, and Epidemiologic Features

The clinical manifestations of vascular GCA are a consequence of stenosis or occlusion of the artery’s lumen, which leads to impaired blood flow, ischemia, and tissue infarction. In case of aortic involvement, the damage pattern is that of dissection and aneurysm formation, often requiring emergency aortic repair (Table 66.2). In contrast, extravascular GCA presents with constitutional symptoms related to systemic inflammation, such as anorexia, weight loss, malaise, depression, and failure-to-thrive. In some patients, fever is the presenting symptom. Predictably, such constitutional symptoms are associated with laboratory abnormalities indicative of an intense hepatic acute phase response; for example, elevated C-reactive protein (CRP), serum amyloid A (SAA), fibrinogen (Fig. 66.1) (Evans and Hunder, 2000; Weyand and Goronzy, 2003a). Traditionally, systemic inflammatory manifestations were believed to precede vascular inflammation. A novel paradigm conceptualizes vascular and extravascular GCA as parallel processes or places extravascular GCA as downstream of the vascular pathology. In that model, vascular inflammation and remodeling could progress in the absence of systemic inflammation and both disease domains would require a differential diagnostic and therapeutic approach. For clinical purposes, it is helpful to subdivide vascular GCA into different subtypes, including cranial and large-vessel GCA, and separate these subtypes from PMR, a typical manifestation of extravascular disease.

Cranial GCA results from vasculitis in the head- and neck-supplying branches of the aorta. Most often affected are the superficial temporal artery, the vertebral artery, the ophthalmic and posterior ciliary arteries, and, less frequently, the internal and external carotid artery. Clinical consequences include headaches, scalp tenderness, claudication of the masseter muscles, and vision loss due to ischemia in the visual pathway (Table 66.2). The headaches are often intense, throbbing, and sharp in character, at times combined with temporal tenderness. On physical examination, temporal vessels are thickened, nodular, and pulseless. Other scalp arteries can be involved. Occlusion in branches of the ophthalmic artery leads to ION that causes sudden and pain-free blindness. Amaurosis fugax can precede complete vision loss. Blindness in one eye indicates high risk to suffer additional visual loss in the other eye. Vascular insufficiency of the orbital arteries can cause a wide spectrum of ophthalmic complications, but ION remains the most frequent ophthalmic manifestation (Chan et al., 2005).

**TABLE 66.2** The Clinical Profile in Giant Cell Arteritis (GCA)

Sign/symptom	Frequency (%)	Pathology
<b>VASCULAR GCA</b>		
Headaches	80	Vascular stenosis, ischemia
Scalp tenderness	70	
Jaw claudication	30	Vascular stenosis, ischemia
Ocular symptoms (blindness, amaurosis fugax, motor deficit)	<20	Vascular stenosis, ischemia
Painful dysphagia	<10	Vascular stenosis, ischemia
Cough	<10	Vascular stenosis, ischemia
Limb claudication	10	Vascular stenosis, ischemia
Absent pulses	<10	Vascular stenosis, ischemia
Asymmetrical blood pressure readings	<10	Vascular stenosis, ischemia
CNS ischemia	<5	Vascular stenosis, ischemia
Peripheral neuropathy	<5	
Aortic regurgitation	<5	Vascular dilatation
Synovitis	<5	
<b>EXTRAVASCULAR GCA</b>		
Intense acute phase response (elevated ESR, CRP, IL-6)	90	Systemic inflammation
Anemia	70	
Polymyalgia rheumatica	40	
Wasting syndrome	30	

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IL-6, interleukin 6; CNS, central nervous system.

Intermittent claudication of the masseter and temporal muscles are relatively disease-specific but only affect a fraction of patients (Smetana and Shmerling, 2002). Typically, chewing or prolonged talking induces jaw claudication. Tongue claudication and painful dysphagia can occur. Impaired blood flow in the vertebrobasilar and carotid arteries causes ischemia of the central nervous system, for example, transient ischemic attacks, or stroke. Chronic nonproductive cough has been attributed to vasculitis of pulmonary artery branches.

In a subset of patients, the primary targets of vasculitis are the subclavian, axillary, and carotid arteries, and the aorta itself (Brack et al., 1999; Salvarani, 2003). Presenting symptoms of upper extremity vasculitis are arm claudication, loss of pulses, paresthesias, and, rarely, frank gangrene. Temporal artery biopsies can be negative, and, in most patients, symptoms indicative of cranial ischemia are lacking (Brack et al., 1999). Aortitis can coexist with cranial arteritis or large-vessel involvement and predominantly manifests in the thoracic aorta. Silent aneurysm, aortic dissection, or rupture is a consequence of destruction of the elastic membranes (Evans et al., 1994; Lie, 1995). Not unusual, histomorphologic evidence of vasculitis is found during surgical repair of an aortic aneurysm. Aortic involvement is typically a late complication of GCA, suggesting a smoldering disease process and is associated with increased mortality (Kermani et al., 2012).

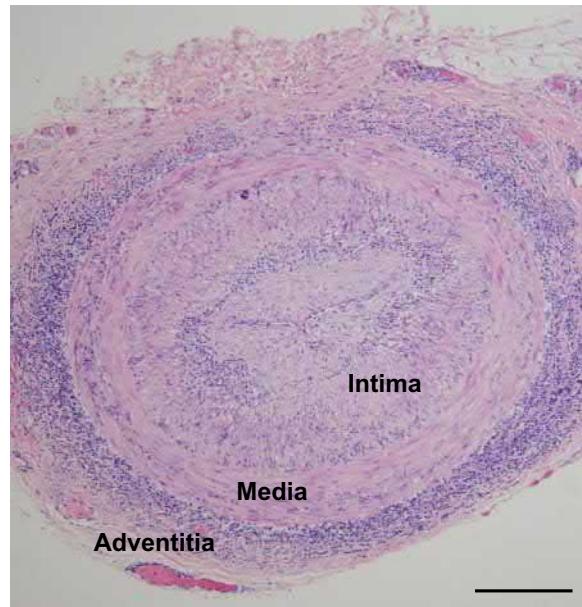

The extravascular component of GCA can appear in isolation, with the vascular component remaining subclinical (Fig. 66.1; Table 66.2). Such patients are diagnosed with PMR due to the predominance of muscle pain and stiffness. PMR is about twofold to threefold more frequent in incidence than GCA (Doran et al., 2002; Kermani and Warrington, 2013). Alternatively, patients present with fever-of-unknown-origin and wasting. Malaise, depression, anorexia, and weight loss are frequent complaints (Weyand and Goronzy, 2003a). Signs and symptoms of impaired blood flow are missing, and clinical findings are dominated by myalgias and stiffness.

The precise relationship between the extravascular and the vascular component of GCA is not understood. Vascular GCA is diagnosed by tissue histology and in some cases by typical involvement pattern of LVV of aortitis captured by noninvasive imaging. The challenge of diagnosing the extravascular component is much higher.

Lead symptoms are those of shoulder girdle and pelvic girdle pain and stiffness. Synovitis of hip and shoulder joints has been described in some patients with PMR and recent provisional classification criteria have been expanded to include cases with bursitis and synovitis (Dasgupta et al., 2012). The diagnosis of PMR remains founded on nonspecific findings, such as pain and, in some cases, inflammation in joint-related structures. A dominant laboratory finding is that of an intense hepatic acute phase response, that leads to elevated acute phase proteins, elevated erythrocyte sedimentation rate (ESR), and elevated CRP. All of these findings are nonspecific, likely to occur in multiple clinical settings, particularly in individuals older than 50 years of age. Urgent need exists to replace the nonspecific clinical classification criteria with objective, histological, and molecularly based criteria. Until that goal is reached, PMR remains a diagnosis of exclusion and includes an assortment of conditions. Patients with diffuse myalgias associated with statin therapy may also fulfill the criteria for PMR (de Jong et al., 2012). Patients and physicians need to be aware of the provisional character of this diagnosis and stay alert for the possibility of an alternate disease processes.

## The Vascular Lesion

In its typical form, GCA is a panarteritis with T lymphocytes and macrophages infiltrating into all layers of the vessel wall (Fig. 66.2) (Maleszewski et al., 2017). In about half of the cases, granulomatous formations are seen. Giant cells, which give the name to the syndrome, are not necessarily present. They tend to accumulate at the media-intima border, often close to the fragmented internal elastic lamina. Inflammatory infiltrates are usually segmental but can be circumferential. Focal placement of lesions produces the so-called skip pattern of vasculitis. In some patients, the infiltrates are predominately composed of lymphocytes without granuloma formation, particularly so after corticosteroid therapy (Maleszewski et al., 2017). The intima is hyperplastic, obstructing the lumen. T cells and macrophage infiltrates are also encountered in the adventitia, which is the port-of-entrance for inflammatory cells. Small clusters of lymphocytes and macrophages in the adventitia may not be indicative of a vasculitic process and, in isolation, should not be considered sufficient to make the diagnosis (Bjornsson, 2002). In the early stages of vasculitis the small vessels in the adventitia may be the primary target for the inflammatory infiltrates, and microvascular networks in the adventitia have recently been shown to provide instructive cues for circulating T cells (Chatelain et al., 2008; Wen et al., 2017).

**FIGURE 66.2** Giant cell arteritis. Cross-section of the temporal artery from a 76-year-old patient. Transmural inflammation with granuloma formation in the media and along the medial–intimal junction. Dense T-cell infiltrates at the adventitia–media border. Multinucleated giant cells positioned along the fragmented lamina elastic interna. Complete occlusion of the lumen by hyperplastic intima.

## Epidemiology

Among the vasculitic syndromes, GCA is the most frequent in the Western world. Age is the most significant risk factor; the disease almost exclusively occurs in individuals older than 50 years of age, and susceptibility increases with age (Machado et al., 1988; Salvarani et al., 2004), reaching highest incidence rates in those 71–80 years old (Mohammad et al., 2015). The female-to-male ratio of patients is 3:1. A characteristic feature of GCA is pronounced geographical variations in prevalence. The range of incidence rates spans between 1 and 25 cases per 100,000 persons aged 50 years and older. Highest incidence rates have been reported in Northern Europe, including Iceland, Denmark, and Sweden (Baldursson et al., 1994; Nordborg et al., 2003), as well as in areas of North America settled by populations of Scandinavian origin (Machado et al., 1988), such as Minnesota. Conversely, blacks and Hispanics are infrequently affected (Gonzalez et al., 1989; Smith et al., 1983).

A diagnosis of GCA does not impair long-term survival, and mortality rates are not increased in chronic patients (Hill et al., 2017; Mohammad et al., 2015). In a high-incidence Swedish population, 15% of GCA patients and 10.8% of a matched-reference cohort had large-vessel involvement diagnosed by noninvasive imaging studies (Naderi et al., 2017). In this patient population, 18 of 840 GCA patients had complete unilateral or bilateral vision loss, similar to data from Olmsted County, Minnesota, where seven of 204 patients suffered vision loss (Singh et al., 2015), confirming that the feared complication of complete vision loss is fortunately infrequent.

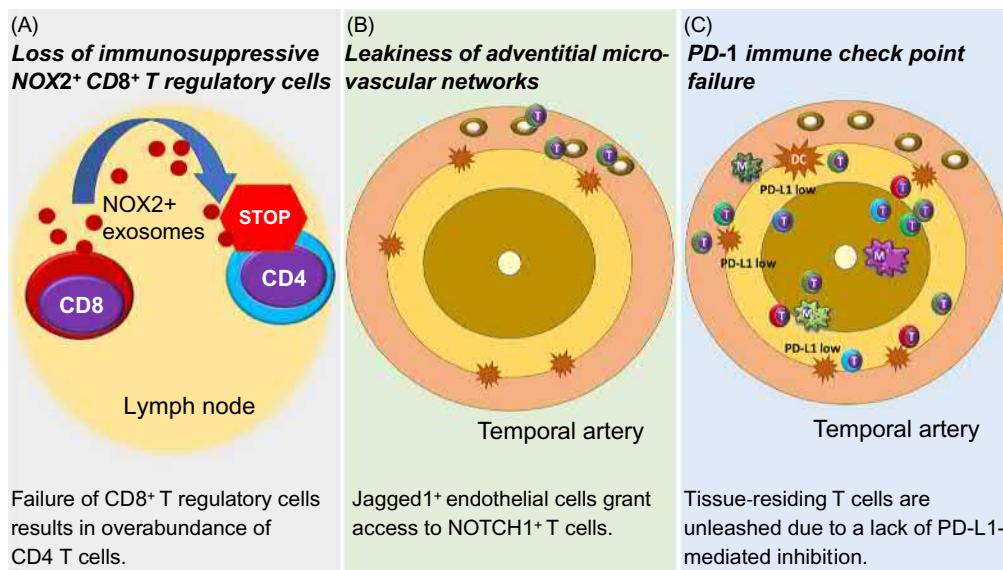

## Genetic Features

GCA is an human leukocyte antigen (HLA) class II–associated disease (Weyand et al., 1992, 1994a), as recently confirmed in a large scale genetic analysis (Carmona et al., 2015). HLA-DR4 confers the highest risk to develop arteritis. Several allelic variants of HLA-DRB1\*04 are overrepresented among affected individuals. Sharing of sequence polymorphisms in the antigen-binding groove of HLA-DR molecules have been cited as evidence for a role of antigenic peptides in disease initiation. Minor effects of polymorphisms in multiple non-HLA genes, such as corticotrophin-releasing hormone, CCL5 (RANTES), intracellular adhesion molecule 1, and interleukin (IL)-6, have been reported and larger studies are awaited to confirm or refute such associations (Alvarez-Rodriguez et al., 2011; Rodriguez-Rodriguez et al., 2011a,b). A genome-wide association study has identified risk alleles in plasminogen and P4HA2, molecules involved in vascular remodeling and angiogenesis (Carmona et al., 2017).

## Pathogenic Mechanisms

Progress has been made in deciphering the pathogenic mechanisms relevant for the inflammatory injury of the vessel wall (Weyand, 2000; Weyand and Goronzy, 2003b; Weyand et al., 2012). Data on the extravascular component, representing an intense upregulation of hepatic acute phase responses, remain limited. Acute-phase serum amyloid A can enhance IL-6 and IL-8 production and amplify tissue remodeling (O'Neill et al., 2015). However, it is unresolved whether the hepatic acute phase response, including the production of CRP, mannose-binding protein, ferritin, serum amyloid A, haptoglobin, fibrinogen, von Willebrand factor, hepcidin, etc., lies upstream or downstream of the vasculitis and may simply be an indicator of a nonhealing tissue lesion.

Principally, in vascular GCA, granulomatous lesions composed of T cells and macrophages occupy the vascular wall niche and elicit a maladaptive repair response, ultimately leading to neointima growth and luminal occlusion (Fig. 66.2). Studies in GCA patients are supporting a disease model that conceptualizes the vasculitis as a failure of a physiologic wall-protective mechanism. Given the life-sustaining functions of medium and large arteries, nature has created a high threshold for inflammatory attack, as the risks to the host are disproportional to potential benefits (Fig. 66.1). The immune privilege of arteries as vital organs is multipronged, combining a series of tolerance mechanisms to prevent vasculitis. Recent studies have revealed that the arterial-wall immune privilege fails in GCA patients on at least three levels (Fig. 66.3): (1) GCA patients lack suppressive mechanisms in peripheral immunity, resulting in uncontrolled CD4 T-cell reactivity (Wen et al., 2016) (Fig. 66.3A); (2) microvascular endothelial cells (mvEC) in the adventitia of inflamed arteries actively engage T cells, enabling T-cell invasion into a protected tissue niche (Wen et al., 2017) (Fig. 66.3B); (3) the immunoinhibitory PD-1 checkpoint is defective in GCA, allowing for unopposed T-cell activity (Zhang et al., 2017) (Fig. 66.3C). Obviously, all three mechanisms render T cells more responsive. Antigens recognized by intralesional T cells continue to be undefined; possibly, multiple antigens function as enablers. Age represents the dominant risk factor to develop GCA and may contribute through the process of immune aging (Goronzy and Weyand, 2017; Wen et al., 2016) as well as vascular

**FIGURE 66.3** Immune defects in GCA. Left panel: the T-cell zones of lymph nodes are populated by specialized CD8 T cells that carry NOX2 in their membranes. CD8<sup>+</sup> NOX2<sup>+</sup> T cells release NOX2<sup>+</sup> exosomes and transfer them to neighboring CD4 T cells. This provides a strong negative signal, preventing CD4 T cell expansion. Patients with GCA lack such immunosuppressive CD8 Treg cells. Middle panel: in GCA patients, adventitial microvessels (*vasa vasorum*) express Jagged1. Jagged1<sup>+</sup> endothelial cells directly communicate with Notch1<sup>+</sup> T cells, granting such T cells access to the otherwise inaccessible and immunoprivileged tissue site. Right panel: in healthy arteries, the immunoinhibitory ligand PD-L1 is highly expressed. In GCA arteries, PD-L1 expression on dendritic cells is low; paralyzing negative signals that stop T-cell activation in the tissue niche. Wall-infiltrating T cells are unleashed and are capable of multiple inflammatory effector functions. *GCA*, giant-cell arteritis; *NOX2*, NADPH oxidase 2; *DC*, dendritic cell.

aging. In population-based prospective health cohorts, GCA was predicted by a low body mass index (Jakobsson et al., 2015), compatible with long-term effects in disease susceptibility.

## T CELLS AND ANTIGEN-PRESENTING CELLS IN GIANT CELL ARTERITIS

The vast majority of lesional T cells are CD4<sup>+</sup> memory cells (Andersson et al., 1987). CD4<sup>+</sup> T cells enter the vessel wall through the *vasa vasorum* and infiltrate into the adventitia recruited by chemokines that derive from DCs positioned at the adventitia–media border (Krupa et al., 2002), an indigenous vessel wall cell population (Ma-Krupa et al., 2004). Vascular DC forms a circumferential ring along the lamina elastica externa. They express typical DC markers, such as CD11c, fascin, and S-100, but lack CD1a and thus are distinct from Langerhans cells in the skin. Functional profiling has demonstrated that they possess Toll-like receptors (TLR) and respond to pathogen-associated molecular patterns (Pryshchev et al., 2008). Different arterial beds in the human body carry vascular DC with distinct profiles of pattern recognition receptors (Pryshchev et al., 2008), providing a molecular basis for target tissue variations and a possible mechanism for the unusual patterning of GCA.

TLR are characteristically found on cells of the innate immune system and typical ligands are lipopolysaccharides, flagellin, viral RNA, bacterial DNA, and heat-shock proteins. TLR triggering initiates the maturation of immature DCs. Mature DCs switch their chemokine receptor profile, become migratory, and travel via lymphatic vessels to lymph nodes. Homing to the T-cell zones, they become stationary, produce T cell-attracting chemokines, and upregulate antigen-presenting HLA molecules and costimulatory molecules.

The physiological role of adventitial DCs and what they are checking for is unknown. Implantation of human temporal arteries into immunodeficient mice revealed that adventitial DCs respond to blood-borne lipopolysaccharide (LPS) (Ma-Krupa et al., 2004). Lesional DCs are highly activated, resemble lymph node-positioned DCs (Krupa et al., 2002), produce high amounts of chemokines, are no longer migratory, and can present antigen to T cells. A major abnormality of lesion-residing DC is the lack of PD-L1 expression (Weyand et al., 2018; Zhang et al., 2017). PD-L1 is an immunoinhibitory ligand that binds the PD-1 receptor on T cells, thereby sending

negative signals and inhibiting T-cell activation. Cancer cells abuse this immune tolerance mechanism to evade antitumor T-cell immunity and the PD-1 checkpoint is targeted by the revolutionary checkpoint inhibition therapies (Davies and Duffield, 2017). Tissue-resident and circulating DC in GCA patients express low amounts of PD-L1 and PD-L1 expression inversely correlates to disease activity (Watanabe et al., 2017b). Essentially, vessel-wall DC in GCA patients favor T-cell activation over T-cell suppression. Molecular mechanisms underlying this defect are unknown.

DC activation is a very early step in the disease process as evidenced by studies in PMR patients whose arteries lack T-cell infiltrates but contain activated DC. If appropriate T cells are made available, they will invade the wall and undergo *in situ* activation (Ma-Krupa et al., 2004). Thus, PMR patients appear protected from frank vasculitis, unless additional tolerance mechanisms fail.

A mechanism protecting the artery's immune privilege appears to lie in the control of cellular access to the wall. The earliest lesion captured by noninvasive imaging reveals adventitial thickening, where microvascular vasa vasorum networks grant access for inflammatory cells. The tissue transcriptome of GCA-affected aorta and temporal artery contains high expression levels of Jagged1, a ligand for the NOTCH receptor. Jagged1 expression was localized to the mvEC in the adventitia; the NOTCH receptor was located to CD4 T cells. In mechanistic studies, Jagged1-expressing mvEC triggered T-cell activation, activating mTOR-dependent signaling events, thereby opening the gate for incoming T cells and educating circulating T cells (Wen et al., 2017).

Once CD4<sup>+</sup> T cells have made their entrance into the immuno-protected microenvironment of the arterial wall, they undergo local activation (Brack et al., 1997; Weyand et al., 1994b). Studies in bilateral temporal artery specimens from the same patient have shown that identical T-cell clonotypes emerge in physically separated lesions (Weyand et al., 1994b), providing strong support for antigen-driven selection (Weyand and Goronzy, 1995). It is now clear that several functional T-cell lineages participate in the vasculitic lesions (Watanabe et al., 2017a). A major subset of tissue-infiltrating CD4 T cells are IFN- $\gamma$ -producing Th1 cells (Deng et al., 2010; Samson et al., 2012; Terrier et al., 2012; Wagner et al., 1996). In contrast to Th17 cells, lesion-residing Th1 cells are relatively resistant to standard immunosuppression, as indicated by the persistent IFN- $\gamma$  production in long-term treated patients (Deng et al., 2010; Maleszewski et al., 2017). How exactly T-cell effector molecules other than IFN- $\gamma$  and IL-17, for example, IL-9 and IL-21, contribute to the disease process has not been clarified (Table 66.3). Almost all T cells assembled in the granulomatous lesions are PD-1 positive (Zhang et al., 2017), yet are neither exhausted nor inhibited. Considering the diversity of T-cell effector populations in the lesions, the infiltrates are not suggestive for a single antigen-driving vasculitogenic immunity. Rather, vasculitogenic T cells appear unopposed, uninhibited by suppressive immune checkpoints that prevent uncontrolled and tissue damaging immunity (Weyand et al., 2018).

The lack of appropriate inhibition holds true for peripheral T cells as well. GCA patients lack a population of regulatory CD8 T cells (Wen et al., 2016) that are positioned in secondary lymphoid tissues. Such CD8 Tregs express on their surface the NADPH oxidase-2 (NOX2), package this enzyme into microvesicles and transfer NOX2-containing exosomes onto neighboring CD4 T cells. NOX2 inhibits the T-cell receptor activation cascade in close-by CD4 T cells, resulting in dampened CD4 T-cell expansion. Ultimately, NOX2<sup>+</sup> CD8 Tregs control

**TABLE 66.3** T-Cell Effector Functions in the Vascular Lesions

T-cell effector functions in the vascular lesions	
Functional lineage	Effector pathway
TH1; IFN- $\gamma$	Activation of macrophages, endothelial cells, fibroblasts, etc.
TH17; IL-17	Activation of immune and nonimmune cells
TH9; IL-9	??
TFH; IL-21	??
TH0; IL-2	T-cell survival, expansion
TH22	??

the size of the host's CD4 compartment and thus the propensity for CD4-dependent immune responses. The availability of NOX2<sup>+</sup> CD8 Tregs is closely linked to age, connecting immune aging and GCA susceptibility (Wen et al., 2016).

In essence, multiple defects in adaptive T-cell immunity are combined to predispose individuals for the development of GCA. Uncontrolled expansion of peripheral CD4 T cells, failure of barriers protecting the vessel wall, and breakdown of inhibitory signals in the tissue microenvironment are all permissive to allow T cells to infiltrate into the wall layers and establish granulomatous lesions.

## MACROPHAGES IN GIANT CELL ARTERITIS

There are no data to suggest that T lymphocytes accumulating in the vasculitic infiltrates have direct involvement in wall injury. Rather, a critical effector function of tissue-invasive T cells is the regulation of macrophage recruitment and differentiation. Macrophages rely on IFN- $\gamma$ -dependent signals, and the intensity of tissue IFN- $\gamma$  has been correlated to disease manifestations. IFN- $\gamma$ -high patients have more intense intimal hyperplasia, more visual symptoms, and cranial ischemia. Patients with distinctly lower tissue IFN- $\gamma$  often lack vessel occlusion and tend to present with fever of unknown origin (Weyand et al., 1997). Multiple pathways have been identified through which macrophages mediate tissue damage (Table 66.4). Macrophage function is closely related to the positioning in the wall, suggesting a tight interaction between infiltrating macrophages and the matrix components they encounter in the tissue niche (Weyand et al., 1996).

Adventitial macrophages focus on the production of proinflammatory cytokines, such as IL-1 $\beta$  and IL-6. Tumor necrosis factor (TNF)- $\alpha$  has been reported to be present in inflamed arteries with the staining pattern, suggesting production in the media (Hernandez-Rodriguez et al., 2004). Medial macrophages specialize in generating reactive oxygen intermediates (Rittner et al., 1999b). Toxic aldehydes, products of lipid peroxidation, have been detected in the smooth-muscle cell layer (Rittner et al., 1999b). The formation of nitrotyrosine, a marker of nitrosative stress, has also been localized to the media (Borkowski et al., 2002), where endothelial cells of medial neovessels are affected by nitrotyrosine formation. A noteworthy aspect of the medial oxidative stress is the induction of protective mechanisms, such as the induction of aldose reductase, a ketoreductase with a role in metabolizing toxic aldehydes (Rittner et al., 1999a). Blocking aldose reductase in GCA lesions increased apoptosis rates of smooth-muscle cells, identifying a protective role of the enzyme. It is unknown whether patients vary in the induction of such protective mechanisms, making them more or less susceptible to oxidative damage.

Other functional properties of media-located macrophages include the secretion of matrix metalloproteinases (MMPs) (Sorbi et al., 1996; Tomita and Imakawa, 1998). CD68-expressing macrophages close to the lamina elastica interna are prone to produce MMP-2 and MMP-9. Such metalloproteinases produce the typical fragmentation

**TABLE 66.4** Macrophage Effector Functions in the Vascular Lesions

Effector molecule	Functional impact
Chemokine production	Assemble granulomatous lesions
Cytokine production (IL-1, IL-6, TNF- $\alpha$ etc.)	Amplify inflammation
Reactive oxygen species	Oxidative tissue damage
Aldose reductase	Antioxidant defense
Growth factors (PDGF, FGF)	Proliferation of myofibroblasts-neointima
Angiogenesis factors (VEGF)	Neoangiogenesis
Metalloproteinases (MMP-2, MMP-9)	Digestion of collagen and elastic membranes

*IL*, Interleukin; *MMP*, matrix metalloproteinase; *PDGF*, platelet-derived growth factor; *FGF*, fibroblast growth factor; *TNF*, tumor necrosis factor; *VEGF*, vascular endothelial growth factor.

of the elastic membranes and digest collagen but may have pathogenic potential beyond their elastinolytic and gelatinolytic activities. So far, macrophages captured in the intima have not been assigned to particular injury pathways (Weyand et al., 1996). They have been described to stain positive for NOS-2, but downstream effects of nitrosative stress have not been detected in the intima itself.

Progress in macrophage biology has led to the identification of functionally different macrophage populations, including proinflammatory M1 macrophages and reparative M2 macrophages. IL-33, a cytokine associated with M2 polarization, has been localized in temporal artery biopsies (Ciccia et al., 2013). Why tissue-damaging macrophages functions dominate the vasculitic lesions remains unexplored.

## NEOANGIOGENESIS OF MICROVASCULAR NETWORKS AND INTIMAL HYPERPLASIA

Blockage of the vascular lumen by hyperplastic intima is the mechanism through which GCA causes vascular insufficiency and tissue ischemia (Fig. 66.2). Proliferating myofibroblasts create an expanding neointimal layer and deposit matrix. They migrate to the intima from deeper wall layers, either the media or the adventitia. Factors regulating myofibroblasts migration and differentiation thus have gatekeeper function in vascular remodeling. Disarming the PD-1 immune checkpoint increased the neointima thickness, directly implicating T cells in the regulation of this process (Zhang et al., 2017).

Inflamed temporal artery walls produce platelet-derived growth factor, which derives from at least two cell types, CD68<sup>+</sup> macrophages and resident wall cells (Kaiser et al., 1999). Numerically, the most important sources are medial macrophages, followed by multinucleated giant cells. Fibroblast growth factor has been described to be present in vasculitic lesions; its function is unexplored.

Wall remodeling, including neointimal expansion, needs to be supported by the formation of new blood vessels (Cid, 2002; Kaiser et al., 1998). Neoangiogenesis typically affects the adventitia, where new capillaries sprout out of vasa vasorum. Once wall remodeling has progressed, microvessels appear in the otherwise avascular media and intima. Multinucleated giant cells have been found to secrete vascular endothelial growth factor (VEGF) (Kaiser et al., 1998), implicating tissue-infiltrating macrophages in the restructuring of the arterial wall. Interestingly, VEGF production is correlated with IFN- $\gamma$  production, thereby connecting adaptive, innate, and tissue repair immunity. Dismantling of the PD-1 checkpoint accelerates formation of neovascular lumina, placing T cells at the pinnacle of the vasculitis-induced maladaptive tissue repair process (Zhang et al., 2017).

## IMMUNO-STROMAL INTERACTIONS IN VASCULITIS

While the immune system participates in vasculitic responses through a multitude of mechanisms, the blood vessel wall is not just an innocent bystander. Vascular cells, including vascular smooth-muscle cells (VSMC) and endothelial cells, contribute to the intramural inflammation. Receptors and ligands of the NOTCH–NOTCH ligand family appears to be particularly important in facilitating the communication between immune, mesenchymal, and endothelial cells. In GCA patients, circulating and wall-invading T cells spontaneously express NOTCH1, enabling them to interact with VSMC (Piggott et al., 2011) as well as mvEC (Wen et al., 2017). Endothelial cell–T-cell interactions have been implicated in “opening the gate” for CD4 T cells to enter the tissue. Once in the wall, NOTCH ligand-expressing VSMC could regulate the functional activity and the survival of NOTCH1<sup>+</sup> T cells.

## EXTRAVASCULAR GIANT CELL ARTERITIS

Mechanisms driving the systemic inflammatory component of GCA are less well understood. Patients with PMR in whom vascular inflammatory infiltrates are undetectable by standard histology are equally affected by systemic inflammation as GCA patients with full-fledged vasculitis (Wagner et al., 1994; Weyand et al., 1999). Thus, extravascular GCA is not simply a “spillover” from the vasculitis. In most cases, PMR presents as an isolated problem, making it unlikely that the cytokine storm of extravascular GCA induces wall inflammation.

Typical findings include a massive acute phase response with downstream effects in multiple-organ systems (Weyand and Goronzy, 2003a). Abnormalities in hematopoiesis, such as anemia and thrombocytosis, are not unusual. The liver function is often abnormal and shows elevation of alkaline phosphatase levels. By affecting the

central nervous system, the acute phase response causes fever, malaise, and depression. Profound elevation of the ESR, a typical laboratory marker of GCA, is also a consequence of excessive production of acute phase proteins.

Innate cytokines, including IL-6, IL-8, IL-12p70, MCP-1, MIP-1 $\beta$ , eotaxin, and pentraxin 3, are known to induce acute phase proteins in hepatocytes. It has long been known that IL-6 is highly elevated in the sera of PMR and GCA patients (Roche et al., 1993; Wagner et al., 1994; Weyand et al., 2000). Circulating monocytes in GCA and PMR patients are spontaneously activated and produce IL-6 (Wagner et al., 1994). Pentraxin 3 is abundant in the serum of GCA patients (Baldini et al., 2012), but the cellular origin is unresolved. Upstream signals leading to the production of innate cytokines remain unknown. Elegant studies in interstitial fluids collected from PMR-affected muscles have shown local enrichment of proinflammatory cytokines and pain-inducing substances, such as glutamate and PGE<sub>2</sub> (Kreiner and Galbo, 2011; Kreiner et al., 2010).

Extravascular GCA can exist without a vasculitic component and presents as PMR. Evidence for a causative role in the inflammatory response affecting the arterial wall is lacking, suggesting parallel pathogenic cascades that may require separate therapeutic interventions.

## Treatment, Monitoring, and Outcome

The gold standard for treatment of GCA is the use of corticosteroids. Patients respond explicitly well, with prompt and substantial improvement of symptoms within 24–48 hours. Initial doses of 60 mg of prednisone (or approx. 1 mg/kg body weight) have been found to be effective in almost all patients. Current discussions center on the question of whether at least some patients could be successfully treated with lower doses. Corticosteroids are fast and effective in suppressing the extravascular component, whereas vessel wall inflammation may require more chronic therapy (Maleszewski et al., 2017).

Once patients are stabilized on high doses of corticosteroids, daily prednisolone doses should be tapered. A reduction of 10%–20% every 2 weeks has proven to be a clinically useful guidance. Both clinical symptoms and laboratory markers of inflammation are monitored to guide the tapering process. A frequent clinical dilemma is a discrepancy between clinical and laboratory findings. To avoid overutilization of corticosteroids, it has been recommended that treatment decisions should not be solely based on laboratory results.

Many patients develop signs of flaring disease when corticosteroids are reduced. Fortunately, severe manifestations, such as sight-threatening ischemic complications, appear to be rare (Martinez-Lado et al., 2011; Weyand et al., 2000). Instead, most disease flares present as PMR or constitutional symptoms, indicative for hepatic acute phase responses and extravascular GCA. Dose adjustments of corticosteroids can effectively recapture disease control.

Corticosteroids can be discontinued in many patients after about 2 years of therapy. There is evidence that the disease process does not enter remission but continues with smoldering activity (Uddhammar, 2000; Weyand et al., 2000, 2012). Importantly, inflammatory infiltrates in the vessel wall appear to be long-lasting. Whether chronic-smoldering vasculitis requires continued immunosuppression or can be managed by watchful monitoring remains a matter of discussion.

One of the serious long-term consequences of GCA is the development of large-vessel involvement, including aortic aneurysm and dissection (Evans et al., 1994; Kermani et al., 2012; Naderi et al., 2017). In a high-incidence Swedish population, 15% of patients and 10.8% of a reference cohort had imaging evidence for large-vessel involvement, which developed after an average of 3.7 years (Naderi et al., 2017). Patients need to be informed about this complication, and monitoring for aortic wall thickness and aortic dimensions is recommended. Differences in the temporal artery histomorphology in patients with and without aortic involvement are suggestive for distinct disease pathways. Whether continuous immunosuppression can avoid this complication is entirely unclear.

With an average age of almost 75 years at disease onset and the duration of therapy for several years, patients are prone to show steroid side effects (Proven et al., 2003). Monitoring of blood glucose and blood pressure is obvious. Also, bone-sparing therapy with calcium, vitamin D substitution, bisphosphonates, etc. should be a fixed component of management.

Given the high rate of steroid side effects, efforts have been made to identify steroid-sparing therapies. In an experimental model of GCA with human temporal arteries implanted into immunodeficient mice, aspirin effectively suppressed IFN- $\gamma$  production and augmented the antiinflammatory effects of corticosteroids (Weyand et al., 2002). In contrast to other chronic inflammatory diseases, patients with GCA seem to have little benefit from methotrexate as an immunosuppressant. A meta-analysis has suggested a mild steroid-sparing effect of methotrexate (MTX) after 48 weeks of combination therapy for female but not for male patients

(Mahr et al., 2007). Similar modest effects have been reported for azathioprine as a steroid-sparing agent (De Silva and Hazleman, 1986). While anti-TNF biologics provide powerful immunosuppression in patients with rheumatoid arthritis, clinical trials testing the use of a combination therapy with corticosteroids plus infliximab compared to corticosteroids alone have been disappointing (Hoffman et al., 2007; Salvarani et al., 2007), and TNF- $\alpha$  blockade is not considered a first-line therapy in this vasculitis.

In a recent clinical trial, patients were treated with tocilizumab, an IL-6 receptor-alpha inhibitor while rapidly tapering corticosteroids. A total of 52% of tocilizumab-treated patients, but only 14% in the placebo group, were glucocorticoid-free at week 52 (Stone et al., 2017). Longer follow-up studies are necessary to determine the durability of the steroid-sparing effect and the safety of tocilizumab. The most important question is whether IL-6 blockade can suppress the vascular component of GCA or whether its effect is restricted to inhibiting the hepatic acute phase response. IL-6 blockade promptly suppresses ESR and IL-6, eliminating these two biomarkers for the monitoring of disease load. Tissue studies are needed to quantify the effect of IL-6 blockade on vascular GCA.

Difficulties in assessing disease activity in the vascular wall are exemplified by a recent study utilizing high-resolution positron emission tomography (PET). Based on FDG-PET scans, most patients with LVV in clinical remission had active disease (Grayson et al., 2018).

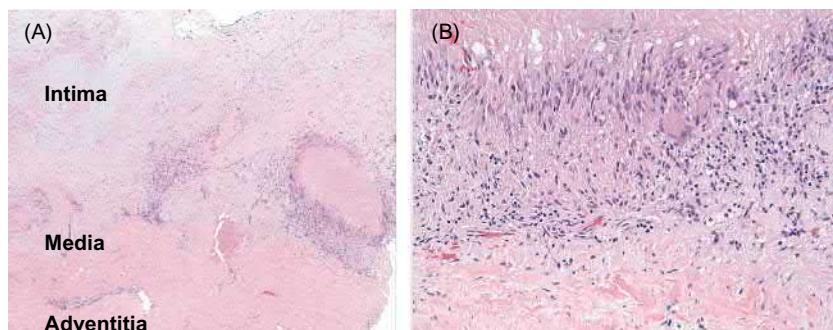

Despite concerns about the persistence of vasculitis, the overall outcome of GCA is good. In a cohort of 840 patients with biopsy-proven GCA the long-term survival was not impaired (Mohammad et al., 2015).

## TAKAYASU'S ARTERITIS

TA is a systemic arteritis that predominantly manifests in the aorta and its major branches. It is also known as pulseless disease or occlusive thromboarthritis. The typical patient is a female of Asian or South American origin presenting with vascular insufficiency and generalized inflammation in the second or third decades of life. But care must be taken not to miss the diagnosis in males and middle-aged individuals and in non-Asian populations. Inflammatory infiltrates in the wall of large elastic arteries induce thickening of the adventitia, destruction of the media, and hyperplasia of the intima (Fig. 66.4) (Gravanis, 2000). Recently, diagnosis and management of TA have benefited from advances in noninvasive imaging methods and more aggressive use of surgical procedures (Luqmani, 2012). Over the last decade, the prognosis of TA has continued to improve with more rapid diagnosis, more aggressive immunosuppression and less vaso-occlusive complications (Kim and Beckman, 2018; Ohigashi et al., 2012).

### Historic Background

In 1830, Yamamoto reported the first case of TA. In 1905, M. Takayasu was the first to describe peculiar optic fundus abnormalities with coronal anastomosis (Takayasu, 1908), which 40 years later were interpreted as neovascularization and anastomosis secondary to ischemia caused by the occlusion of cervical vessels. Shimizu and Sano (1951) described a cohort of 31 cases and made the connection between pulselessness, coronal anastomosis of retinal vessels, and carotid abnormalities, and called it pulseless disease.

**FIGURE 66.4** Takayasu's arteritis. Cross-section of a surgical specimen from the aorta of a 24 year-old female. (A) Inflammatory infiltrates in all wall layers. Massive fibrosis of the adventitia. Loss of medial smooth-muscle cells intimal thickening. The media is destroyed and the intimal is thickened. (B) Detailed view of highly activated histiocytes and multinucleated giant cells.

## Clinical, Pathologic, and Epidemiologic Features

TA is a rare disease with incidence rates of 1–2 cases in 1 million individuals per year (Watts et al., 2009). The most significant risk factors are female sex, age less than 40 years, and selected ethnic origin. The highest prevalence rates have been reported for Asian countries, including Japan, Korea, China, India, Thailand, and Turkey (Koide, 1992). South American countries, such as Mexico, Brazil, Columbia and Peru, are now also considered higher incidence areas (Dabague and Reyes, 1996). The disease does occur in Whites, can affect males, and needs to be kept in mind as a differential diagnosis in older individuals with aortitis or LVV.

Prominent histomorphologic findings include the thickening of the aortic wall which may involve all three layers (Fig. 66.4) but often is most significant in the adventitia (Bjornsson, 2002; Gravanis, 2000). Extension of inflammatory infiltrates and fibrosis into the periaortic tissues may occur. Most often, the aortic lumen is compromised, but stenotic lesions can alternate with aneurysmal dilatation giving rise to fusiform or saccular aneurysms. Characteristically, densely inflamed regions are alternating with normal vessel wall, creating the typical “inflamed” lesions. Besides the aorta and its primary branches, coronary and pulmonary arteries can be involved.

Microscopic examination shows inflammatory infiltrates composed of lymphocytes and plasma cells primarily around the vasa vasorum, causing vasa vasoritis with luminal stenosis. Lymphocytes, histiocytes, and occasional giant cells accumulate in the media, sometimes complicating the distinction between GCA and TA. Patches of medial necrosis can occur, and destruction of elastic membranes is typical. Growth of fibroblasts and smooth-muscle cells and deposition of acid mucopolysaccharides result in widening of the intimal layer, representing fibromuscular hyperplasia. Vascular insufficiency in the aortic branches is related to ostial stenosis or more extended involvement.

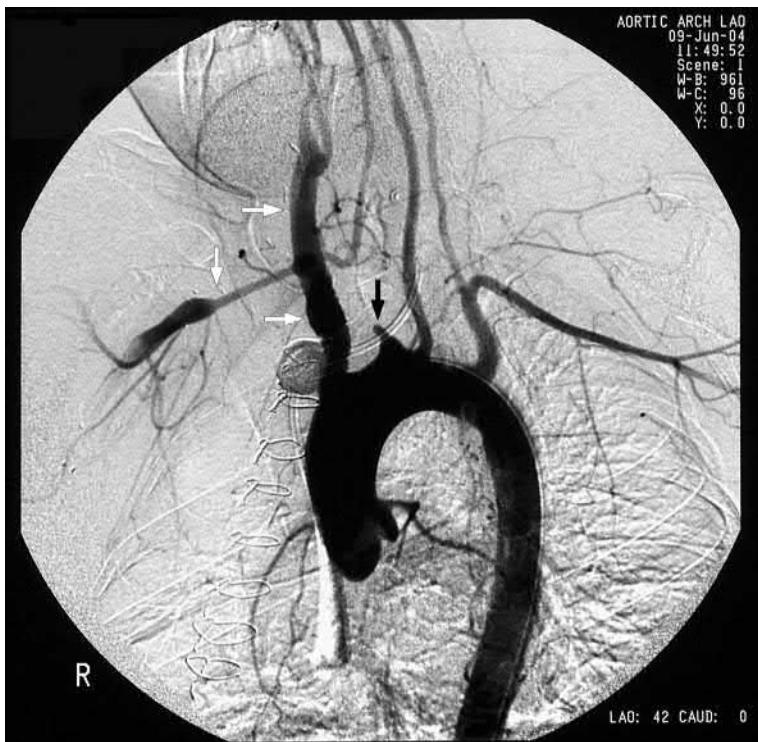

The clinical spectrum of TA may vary in distinct geographic areas (Numano, 1997) (Table 66.5). Japanese, Korean, and North American patients are more likely to present with impairment of cervical, cerebral, and upper extremity blood flow and aortic regurgitation, due to involvement of the ascending aorta and the primary aortic arch branches. In Indian patients, the abdominal aorta, including the renal arteries, appears to be the preferred target resulting in renovascular hypertension. Overall, blindness and severe retinal ischemia are less common now than they used to be (Numano, 2002).

Initial presentation may be dominated by a generalized inflammatory syndrome with fever, night sweats, weakness, arthralgias, and chest pain (Kerr et al., 1994) (Table 66.5). Direct complications of vessel wall inflammation include headaches, syncope, visual disturbances, and face and neck pain from insufficient blood flow in cervical vessels. Stenotic lesions in the brachiocephalic and subclavian arteries lead to arm claudication,

**TABLE 66.5** The Clinical Spectrum in Takayasu's Arteritis

Organ system	Sign/symptom	Frequency (%)
Vascular Takayasu's	Bruit	70
	Claudication	70
	Reduced/absent pulses	60
	Asymmetrical blood pressure	50
CNS	Dizziness	40
	Visual abnormalities	30
	Stroke/TIA	10
Cardiac	Aortic regurgitation	20
	Angina	10
	Congestive heart failure	<5
Extravascular Takayasu's	Malaise	70
	Fever	30
	Weight loss	20

TIA, transient ischemic attack.

**FIGURE 66.5** Takayasu's arteritis. Angiography of the aortic arch and the cervical vessels. The native brachiocephalic artery (black arrow) is occluded just distal to its origin. A graft has been placed (white arrows) from the ascending aorta to the right common carotid artery with a separate limb connecting to the right subclavian artery. The left carotid artery and both vertebral arteries are normal.

pulselessness, and discrepant blood pressure measurements (Fig. 66.5). Ischemic heart disease is a result of reduction in coronary blood flow. A feared complication of TA is aortic regurgitation caused by dilatation of the ascending aorta. Congestive heart failure is not unusual (Endo et al., 2003).

Marked progress has been made in imaging modalities, compensating at least partially for the difficulties in accessing tissue to establish the diagnosis of TA and follow its course for patients receiving therapy. Besides conventional angiography, which has been the standard imaging tool for diagnosing and evaluating patients with TA (see Fig. 66.5), a number of alternatives have emerged, including magnetic resonance (MR) imaging and MR angiography, computed tomography (CT), Doppler ultrasound, and metabolic imaging with PET (Cheng et al., 2013; Kissin and Merkel, 2004; Litmanovich et al., 2012; Tezuka et al., 2012). Ultrasound is particularly useful in evaluating the carotid arteries, with high sensitivity for submillimeter changes in wall thickness. The diffuse circumferential thickening (halo) of the carotid artery wall in TA has been named the "macaroni sign" (Keo et al., 2013). CT and MR imaging provide excellent visualization of vessels and their relationship to neighboring structures and demonstrate both luminal and mural abnormalities. Contrast enhancement is necessary for the CT to depict the vessel lumen, but it can provide fast information about the aorta and its wall; MR imaging has inherent multiplanar imaging capabilities, can be used with or without contrast enhancement, and lends itself for the evaluation of the aorta and its major branches (Matsunaga et al., 2003; Nastri et al., 2004). With the potential to assess mural edema and vascularity, it has been hoped that it would be an ideal instrument to monitor disease activity and progress in patients on immunosuppression. However, a recent study has cast doubt on the utility of edema-weighted MR as a sole means to estimate disease activity (Tso et al., 2002). A role for PET, which detects areas of active glucose metabolism in the vascular wall has been suggested (Webb et al., 2004), but no large-scale controlled studies are available. A recent study has reported only moderate sensitivity of 18FDG-PET in estimating disease activity in TA (Cheng et al., 2013), whereas a study of 39 Japanese patients with TA suggested superiority of FDG-PET/CT over ESR and CRP in detecting active disease (Tezuka et al., 2012).

## Genetic Features

In contrast to GCA, which is an HLA class II–associated disease, the strongest genetic risk factor for TA has been localized to the HLA class I region. Specifically, HLA-B\*52 is most enriched amongst TA patients, holding in several ethnicities (Terao, 2016). Through genome-wide associations studies, several non-HLA susceptibility

loci have been added to the list, including IL12B, IL-6, FCGR2A/3A, RPS9/LILRB3, supporting the concept of a complex genetic predisposition for this LVV (Renauer and Sawalha, 2017). Interestingly, TA patients share a significant proportion of their genetic background with patients diagnosed with ulcerative colitis, including enrichment of HLA-B\*52:01 and cooccurrence of ulcerative colitis with TA (Terao et al., 2015).

## Pathogenic Mechanisms

Despite considerable overlap in the histomorphology and clinical presentation of GCA and TA, evidence suggests that pathogenic mechanisms are distinct (Seko, 2002). Whereas CD4<sup>+</sup> T cells producing IFN- $\gamma$  have been identified as key regulators in the vascular lesions of GCA, they appear to be less important in TA. In the vascular infiltrates of TA,  $\gamma\delta$  T cells account for 31% of the cells, natural killer cells for 20%, and CD8<sup>+</sup> cytotoxic T cells for 15% (Seko, 2000). CD4<sup>+</sup> T cells, macrophages, and B cells were less frequent. In support for the concept that cytotoxic cells directly damage resident cells in the aorta, Seko et al. (1994) have shown cellular expression of perforin and deposition of perforin directly onto wall resident cells. Heat-shock proteins, in particular HSP65, have been proposed as the antigen stimulating cytotoxic lymphocytes (Seko et al., 2000). Restricted usage of T-cell receptor AV and BV genes in tissue infiltrating T cells also support the concept of selective expansion of antigen-reactive T cells in the vessel wall infiltrates (Seko et al., 1996). Dense expression of costimulatory molecules is in line with a role for adaptive immune responses driving the disease process. Data suggesting a possible role of metalloproteinases as biomarkers of disease activities refocus interest on macrophage-dependent disease mechanisms (Matsuyama et al., 2003). Destruction of elastic membranes points toward release of elastolytic enzymes, likely derived from tissue-infiltrating macrophages.

Much less is known about the pathomechanisms underlying extravascular TA. Cytokine levels of IL-6 and RANTES have been reported to be elevated and to correlate with clinical activity (Noris et al., 1999). Serum IL-18 levels have been correlated with disease activity (Park et al., 2006). IL-18 is a Th1 immunity promoting cytokine, suggesting a role for IFN- $\gamma$ -producing T cells in this vasculitis. Possible, not yet validated, biomarkers of disease activity include pentraxin-3 and MMP-9.

## Treatment and Outcome

Immunosuppressive therapy remains the mainstay of treatment for this arteritis, but, in contrast to GCA, surgical procedures are gaining in importance for managing patients with TA (Perrotta et al., 2012). While endovascular treatment of TA has been associated with poor outcomes with respect to patency, more recent experience with newer endovascular techniques appear to be associated with better results (Qureshi et al., 2011).

As with most rare diseases, randomized controlled treatment trials are explicitly difficult to perform, are missing, or are based on small patient numbers. The immunosuppressants of choice are corticosteroids, which are started at a dose of 40–60 mg/day prednisone. Clinicians in Japan have advocated doses of only 20–30 mg/day (Numano, 2002). Once acute disease activity is controlled, an effort needs to be made to reduce corticosteroids. Tapering by 5 mg/day every 2–3 weeks has been adopted as a useful guideline. However, there has been agreement that a target maintenance dose of 5–10 mg/day should be kept stable over a prolonged period to avoid exacerbation of vascular and generalized inflammation. Although not formally tested, most patients receive aspirin or an alternative agent to reduce platelet aggregation and thrombus formation.

About 50% of patients may be considered to be insufficiently treated with corticosteroid monotherapy (Kerr et al., 1994). Some of these patients may benefit from methotrexate as a steroid-sparing agent (Hoffman, et al., 1994). Mycophenolate mofetil has been reported to show clinical efficiency in a small patient cohort (Daina, et al., 1999). TNF- $\alpha$  blocking agents have been reported to induce sustained remission in a subset of patients, but about 50% of patients fail treatment with anti-TNF- $\alpha$  (Schmidt, et al., 2012). Given the role of IL-6 in driving inflammation in TA, rescue therapy with anti-IL-6 blocking antibodies has been reported for selected cases (Salvarani, et al., 2012). More recent reports of persistent aortic wall inflammation despite IL-6-blocking therapy have raised concerns that this therapeutic approach may be less effective than expected (Xenitidis et al., 2013). In a recent randomized, double-blind, placebo-controlled, phase 3 trial testing the efficacy and safety of tocilizumab in patients with refractory TA, the primary endpoint of the study was not met, questioning the usefulness of IL-6 blockade in this patient population (Nakaoka et al., 2018).

Monitoring for and managing hypertension is prudent in patients with TA. There is an ongoing discussion about whether vascular inflammation predisposes for the accelerated development and progression of

atherosclerosis, although it may be difficult to separate these disease processes (Numano et al., 2000). Accelerated atherosclerosis demands appropriate monitoring for risk factors and treatment of dyslipidemia.

Critical renal artery stenosis, limiting claudication of extremities, cerebrovascular ischemia, coronary ischemia, and aortic regurgitation may represent indications for surgical intervention. If clinically possible, vascular inflammation should be quiescent prior to surgery. Prevention of stroke may be possible if critical stenosis of cervical vessels is bypassed with grafts originating from the ascending aorta. Percutaneous transluminal angioplasty has emerged as an alternative to bypass surgery, specifically for renal artery stenosis (Weaver et al., 2004), and may be useful for preserving blood flow in other territories.

The best outcome data for TA are available from Japan where all patients with TA are registered by the government. Analysis of 897 patients through 1998 showed that more than 70% of patients had well-controlled disease, enjoying almost normal lives. Twenty-five percent of patients had severe complications. Cardiac manifestations have become the most common cause of death among TA patients (Numano, 2002). Modern imaging techniques are enabling close monitoring of vessel wall inflammation. The time between disease onset and diagnosis is shortening (Isobe, 2013), and the overall prognosis is improving. In a recent analysis of 251 TA patients in Southern India, upfront immunosuppressive combination therapy was associated with only 7% of refractory disease, and relapse-free survival was above 50% at 10 years (Goel et al., 2018).

## CONCLUDING REMARKS—FUTURE PERSPECTIVES

Vasculitides are infrequent yet clinically challenging diseases because they threaten blood supply to vital organs. Damage to large and medium-sized arteries immediately puts the host at risk for severe clinical consequences, as compensatory mechanisms for losing the function of the aorta and its major branches are very limited. Large-vessel arteritides are characterized by a combination of extravascular and vascular disease. Pathogenic mechanisms relevant for these two disease dimensions are distinct, require distinct diagnostic approaches, and respond differentially to therapy. Extravascular LVV is characterized by the induction of an abrupt and massive acute phase response. Hepatic acute phase proteins elevate ESR and CRP. Upstream inducers appear to be innate cytokines, for example, IL-6. Such cytokines are druggable, but whether their blockade has any impact on vessel wall inflammation is unknown. Possibly, the extravascular component lies downstream of the vasculitic events in the arteries, serving as a biomarker, but not a driver of arteritis.

The aorta and its large branches are immune-privileged tissues, in line with their life-sustaining function. Three mechanisms have been identified, which lead to breakdown of arterial wall immune protection and arteritis: unopposed expansion of CD4 T cells in the peripheral immune system (Wen et al., 2016); leakiness of microvascular networks that are supposed to keep T cells out of the vessel wall (Wen et al., 2017); and uncontrolled T-cell activation in the wall due to failure of the immunoinhibitory PD-1 checkpoint (Zhang et al., 2017).

Once T cells have made it into the wall structure, they become the key regulators of tissue injury. They either mediate direct cellular damage, as in the case of TA, or orchestrate the functional activity of tissue-injurious macrophages, as in GCA. Arterial wall injury causes hyperproliferation of myofibroblasts and results in thickening of the intima, the underlying mechanism of vessel stenosis/occlusion.

GCA and TA are unique among the chronic inflammatory diseases in that they respond explicitly well to corticosteroids. However, even prolonged therapy can usually not induce complete remission and the vessel wall inflammation enters a phase of chronic-smoldering persistence. Conventional immunosuppressive appear amazingly ineffective in depleting inflammatory cells from the vessel wall. Better understanding of mechanisms that foster tissue-residence of T cells and of the maladaptive repair mechanism that sustain wall remodeling is needed to target core elements of vasculitis and its consequences.

Despite advances in noninvasive imaging methods, monitoring patients for disease activity continues to be a challenge. Structural changes, such as neoangiogenesis and neointimal growth, may not be reversible. Biomarkers reflecting persistence of adaptive immunity in the wall and of maladaptive tissue remodeling need to be developed to capture these elements of vasculitis. It is relatively easy to follow the hepatic acute phase response linked to extravascular vasculitis, as it leads to laboratory abnormalities such as elevation of ESR and CRP, anemia, thrombocytosis, etc.

The ultimate challenge in understanding GCA and TA remains the identification of the initial triggers of the disease process. Predictably, infectious microorganisms are suspected to start vasculitis, but unequivocal evidence is missing. Local factors intrinsic to the artery itself, such as loss of protective mechanisms, acquisition of immune-stimulatory functions of nonimmune vascular cells, or misfiring of vascular dendritic cells, may be

instrumental in breaking tolerance and giving rise to misplaced immune responses (Watanabe et al., 2017b). Also, age is a major risk factor in GCA and TA, suggesting that age-related changes in T-cell function may be critical determinants of disease susceptibility (Goronzy and Weyand, 2017).

## INTRODUCTION

Interstitial lung disease is a broad category of heterogenous diseases which share the common feature of inflammatory and fibrotic changes that primarily affect the alveoli and small airways. The two most common manifestations are cryptogenic organizing pneumonia (COP) and idiopathic pulmonary fibrosis (IPF), both of which can occur as “idiopathic” conditions or in association with several autoimmune diseases. Although both are classified as “lung disorders of unknown etiology,” there are multiple clues suggesting that autoimmune mechanisms play a role in the pathogenesis of both disorders. The focus of this chapter is to explore the link between autoimmune mechanisms underlying COP and IPF as models for autoimmune disorders of the lung. To do so, we first discuss the history and the clinical features of COP and IPF, followed by a summary of the autoimmune, genetic, environmental features, current concepts of pathogenesis, and the therapies currently available and under investigation for both disorders.

## HISTORY

Although both COP and IPF are inflammatory/fibrotic disorders, they have different clinical, radiologic, and pathologic features and therefore are considered to be different disorders.

### Cryptogenic Organizing Pneumonia

The term “bronchiolitis obliterans” was first used by [Lange \(1901\)](#), when he described two patients in whom the bronchioles were blocked by the plugs of granulation tissue, though those patients likely had what is now known as “COP.” In [Baar and Galindo \(1966\)](#) used the term “bronchiolitis fibrosa obliterans” to describe concentric rings of fibrotic tissue in the wall of the airways. In [Gosink et al. \(1973\)](#) employed “bronchiolitis obliterans” to describe a group of patients that had submucosal and peribronchiolar infiltrate of granulation tissue resulting in extrinsic narrowing of the bronchiolar lumen. During the 1970s, several rheumatological conditions, particularly rheumatoid arthritis (RA), were recognized to be associated with bronchiolitis obliterans, as were adverse reactions to therapies used for RA such as gold and penicillamine ([Geddes et al., 1977](#)).

In [Davison et al. \(1983\)](#) first used the term “cryptogenic organizing pneumonitis” to describe eight patients that had pulmonary infiltrates and histology similar to bronchopneumonia, yet no organism was identified, and they responded to corticosteroids. In [Epler et al. \(1985\)](#) similarly described 50 patients not only with bronchiolitis obliterans but also with granulation tissue in airways, airway ducts, and alveoli and coined the term bronchiolitis obliterans organizing pneumonia (BOOP). COP and BOOP are now believed to represent the same disease, and COP is the preferred term. Current usage of the term “bronchiolitis obliterans” is reserved primarily for transplant-related lung injury that occurs almost exclusively at the bronchiole.

### Idiopathic Pulmonary Fibrosis

The first recognition of the broad category of idiopathic interstitial lung diseases, which includes IPF, is credited to [Osler \(1892\)](#), when he described a chronic fibrinoid change occurring between the alveolus and the blood vessels. Osler demonstrated great foresight by also noting that there were diverse patterns of the disease that made classification difficult.

IPF, also referred to as “cryptogenic fibrosing alveolitis,” “idiopathic interstitial pneumonitis,” “usual interstitial pneumonitis” (UIP), and “idiopathic interstitial pneumonia,” was first described by the Czech pathologist Sandoz (1907), but this went largely unnoticed. [Hamman and Rich \(1935\)](#) are frequently credited with the first description of IPF in 1935, despite the fact that their initial cases were more acute in presentation, unlike classic IPF, and may have been the descriptions of acute respiratory distress syndrome (ARDS). In [Scadding \(1964\)](#) coined the term “cryptogenic fibrosing alveolitis” to describe IPF as a diffuse inflammatory and fibrotic lung disease affecting primarily the alveoli. Scadding advanced the concept that IPF was a slow, progressive disease that was distinctly different from the relatively acute process described by Hamman and Rich.

IPF was further defined by Liebow and Carrington in the 1960s using histologic criteria. These investigators separated IPF into two morphologic patterns, which they referred to as “usual interstitial pneumonia” (now often referred to as “usual interstitial pneumonitis”) and desquamative interstitial pneumonia (DIP; [Liebow and Carrington, 1969](#)). The inflammatory component of IPF was characterized by our group using bronchoalveolar lavage (BAL) to distinguish IPF from other interstitial lung disorders ([Crystal et al., 1976](#); [Reynolds et al., 1977](#)). The pathological pattern of UIP was further refined over the next several decades, including the description of nonspecific interstitial pneumonia (NSIP) by [Katzenstein and Fiorelli \(1994\)](#) as a distinct entity. The classification system developed by the American Thoracic Society (ATS) and European Respiratory Society (ERS) in 2001 separates IPF from NSIP and DIP based primarily on pathologic findings (American Thoracic Society and European Respiratory Society, 2002). The most recent guidelines on idiopathic interstitial pneumonias were published by ATS/ERS/Japanese Respiratory Society in 2011 and highlight the importance of a multidisciplinary discussion to render a diagnosis ([Raghu et al., 2011](#)).

## CLINICAL, PATHOLOGICAL AND EPIDEMIOLOGICAL FEATURES

### Cryptogenic Organizing Pneumonia

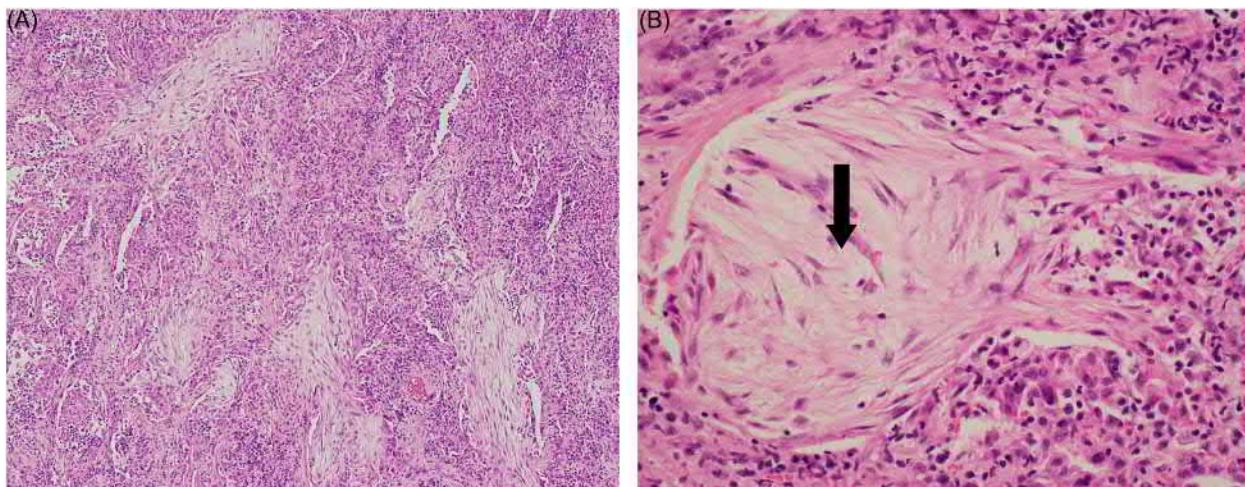

COP is identified pathologically by an accumulation of granulation tissue resulting in near obstruction of the small airways and that can extend into the alveoli with a surrounding interstitial lympho-plasmacytic infiltrate (Murray and Nadel, 2000). Overall, there is preservation of the underlying lung architecture and apparent temporal homogeneity, with very little fibrotic changes present (Fig. 67.1). These findings may also be present during the “organizing” phase of a bacterial or viral pneumonia, but when they occur in the absence of an infectious disease, it is termed “COP.” Thus the definition relies on both pathologic and clinical features.

Individuals with COP usually present with persistent cough and worsening dyspnea on exertion, which can mimic bronchopneumonia. The physical exam is notable for crackles in the affected lobe(s). Most patients will have a mild obstructive pattern on pulmonary function testing, although the disease can present with normal, restrictive, or mixed pattern (King and Mortenson, 1992). Routine chest radiographs may reveal bilateral air-space opacities, peripherally located, that can be migratory. High-resolution computed tomography (HRCT) reveals patchy air-space consolidations or ground glass opacities that can be indistinguishable from bacterial pneumonia or eosinophilic pneumonia. Fibrosis or honeycombing is rarely seen. The areas affected by COP are scattered and patchy in distribution. For this reason, transbronchial lung biopsy is insensitive as a diagnostic tool, as it often misses the involved area, and thus a surgical lung biopsy is often necessary to make the diagnosis.

There have been no formal epidemiological studies that quantify the overall prevalence of COP, although one study found a yearly cumulative incidence of six to seven cases per 100,000 hospital admissions (Alasaly et al., 1995). COP is generally considered a rare disease, though it is likely that it is underdiagnosed and may account for a small percentage of cases misdiagnosed as bacterial or viral pneumonia.

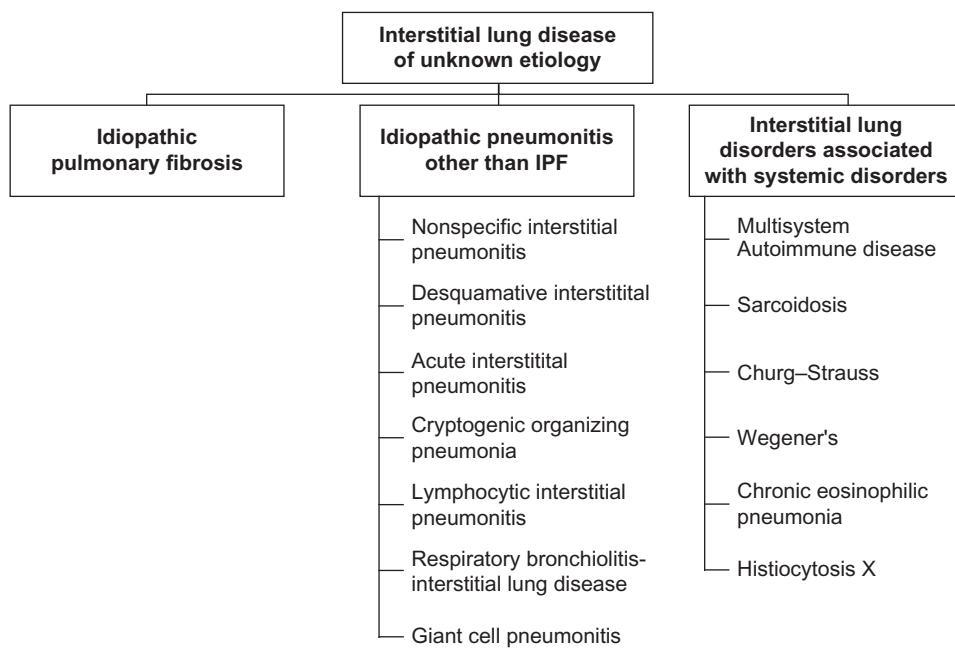

### Idiopathic Pulmonary Fibrosis

IPF (sometimes referred to as “cryptogenic fibrosing alveolitis” in Europe) refers to a distinctive type of chronic inflammatory/fibrotic interstitial lung disorder of unknown cause that is limited to the lungs and

**FIGURE 67.1** Histologic pattern of cryptogenic organizing pneumonia. (A) Low power view of lung tissue, showing that the normal lung architecture with intraalveolar fibroblastic plugs filling several airspaces, surrounded by lymphoplasmacytic infiltrates. (B) High power view demonstrating fibroblastic proliferation occurs amidst loose extracellular matrix filling the airspace (arrow).

**FIGURE 67.2** Relationship of idiopathic pulmonary fibrosis to other idiopathic interstitial disorders. Some of the rare disorders have been left off the lists [see (American Thoracic Society and European Respiratory Society, 2002; Cantin and Crystal, 1985; Schoenberger and Crystal, 1983) for further details].

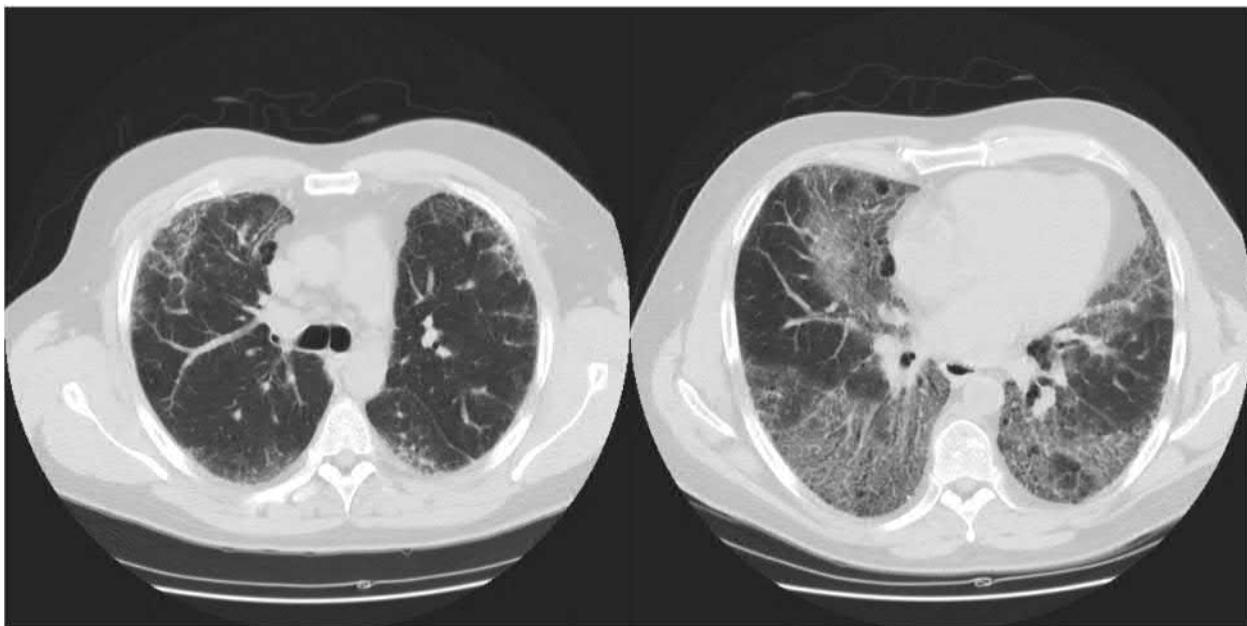

associated with a histologic pattern of UIP (Fig. 67.2; American Thoracic Society and European Respiratory Society, 2002). The pattern of UIP on surgical lung biopsy is also seen in patients with multisystem autoimmune disease who present with similar pulmonary-related clinical features as IPF (Harrison et al., 1991).

Individuals with IPF typically present with the gradual onset of symptoms, most commonly dyspnea on exertion and nonproductive cough. Most will have had at least 6 months of symptoms before presentation, with an average duration of 24 months (American Thoracic Society and European Respiratory Society, 2002). The clinical course typically involves gradual deterioration, occasionally punctuated by periods of rapid decline, although some of the diseases stabilize in some individuals. The best estimates for life expectancy from time of diagnosis to death are derived from case-control cohort studies that are not biased like prevalence studies which tend to be overrepresented by survivors. According to two such studies, the average survival from the time of diagnosis to death is 3–4 years (Hubbard et al., 1998; Mapel et al., 1998). This survival average likely represents the more aggressive phases of the disease. With the increased utilization of CT scans, more cases of IPF have been identified at the earlier stages of disease and have much slower progression.

On physical exam, patients with IPF may have digital clubbing (25%–50%) and fine, inspiratory, Velcro-like crackles confined to the bases of the lungs. As there is progressive loss of alveoli, and the diffusing capacity drops below 50% predicted, pulmonary hypertension develops, first with exercise, and later at rest (Crystal et al., 1976; McLees et al., 1979). Once established at rest, the pulmonary hypertension is associated with an increased pulmonary component of the S2 on cardiac exam, and eventual fixed split of the second sound. In the late stages of the disease, there can be signs of right heart failure, such as peripheral edema.

Pulmonary function testing usually shows a restrictive pattern of ventilatory defects and a decrease in diffusing capacity, although in the early stages of the disease, these tests can be normal (Cherniack et al., 1995; Fulmer et al., 1979; Keogh and Crystal, 1980). Individuals with IPF typically have mild-to-moderate hypoxemia with concomitant low resting oxygen saturation that falls with exercise (Keogh and Crystal, 1980).

Chest radiographs of individuals with IPF are routinely abnormal, with a reticular pattern seen at the periphery and in the bases. Later, in the disease, there is honeycombing and volume loss in the lower lobes (Staples et al., 1987). In the early stages of the disease, chest radiographs may be normal. HRCT is more sensitive and is the preferred imaging modality. The typical HRCT findings are reticular–nodular opacities (Fig. 67.3). Later, in the disease, traction bronchiectasis is commonly seen in the peripheral and basal segments of the lower lobes. Volume loss and ground glass opacities are frequently present. As the disease progresses, honeycomb cysts develop and enlarge overtime (Staples et al., 1987). The chest X-ray and HRCT appearance of IPF is nearly

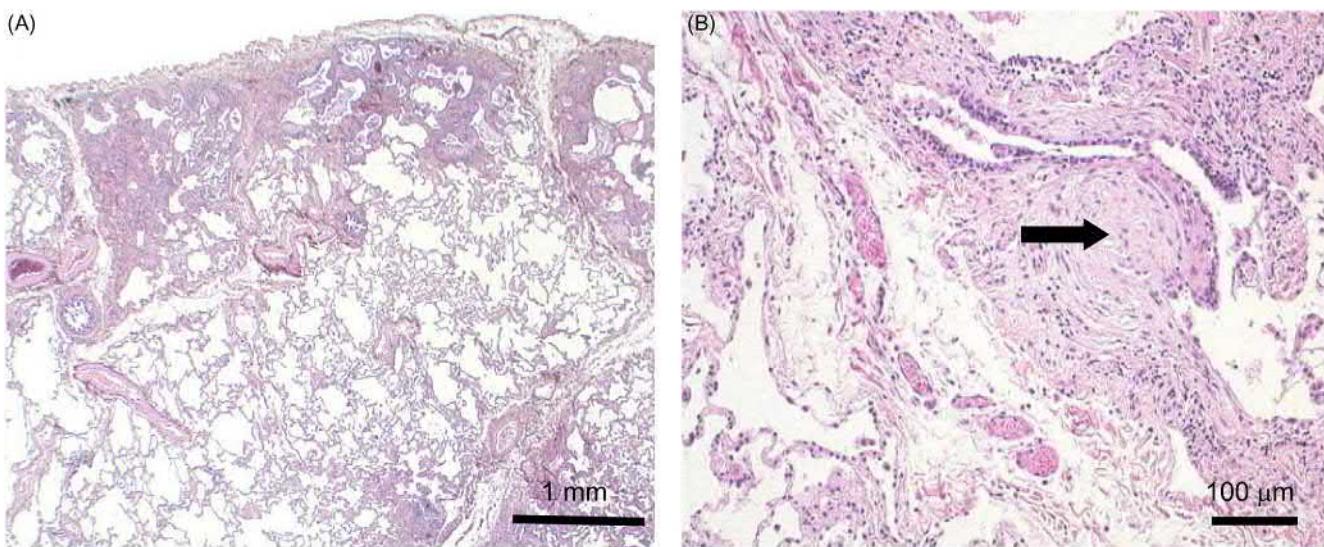

**FIGURE 67.3** Diffuse reticular–nodular pattern on high-resolution chest tomography commonly observed in idiopathic pulmonary fibrosis. Note areas of honeycombing.

identical to that seen in pulmonary fibrosis associated with the rheumatic disorders, with the lone exception of possibly more basal involvement seen on HRCT in IPF (Chan et al., 1997).

Transbronchial biopsies are insufficient to diagnose IPF because the biopsy specimen is too small and does not preserve the architecture of the lung. However, transbronchial biopsies may be useful to rule out other conditions, such as sarcoidosis, that can mimic IPF. Bronchoscopic lung cryobiopsy is a new technique that permits a larger sample of lung to be obtained through the flexible bronchoscope that provides diagnostic information with lower risk (Lentz et al., 2017). A surgical lung biopsy has been required in the past to firmly establish the diagnosis. However, the consensus statement by the ATS and ERS permits the diagnosis of IPF when there are typical clinical and HRCT findings of IPF (American Thoracic Society and European Respiratory Society, 2002; Hunninghake et al., 2001; Raghu et al., 2011). Surgical lung biopsies are still recommended whenever there are atypical clinical or HRCT features.

The histological pattern characteristic for IPF is referred to as UIP (Fig. 67.4). This pattern is distinct from the other forms of idiopathic interstitial lung disorders such as DIP, lymphocytic interstitial pneumonia, COP, nonspecific interstitial pneumonia, and acute interstitial pneumonia (American Thoracic Society and European Respiratory Society, 2002; Katzenstein and Fiorelli, 1994; Liebow and Carrington, 1969). There is typically a heterogeneous distribution of interstitial fibrosis interspersed within the areas of normal lung, suggesting different temporal stages of involvement. There is patchy inflammation, dominated by alveolar macrophages, and to a lesser extent, lymphocytes, neutrophils, and sometimes eosinophils. The alveolar epithelium undergoes marked changes, referred to as “cuboidalization,” with a loss of type I epithelial cells, and their replacement with cuboidal cells, both alveolar type II epithelial cells and bronchiolar epithelium. One hallmark finding in IPF is the subepithelial “fibroblastic focus,” which is a nodule of spindle shaped, mesenchymal cells that produce an abundant deposition of extracellular matrix. These “foci” are believed to be the “leading edge” of the fibrotic process. Occasionally, the interstitial fibrosis extends through breaks in the epithelium into the alveolar space to form intraalveolar fibrosis (Basset et al., 1986). Later, in the disease, there is architectural destruction and fibrosis with honeycombing. Frequently, the subpleural parenchyma is the most severely involved region. When a biopsy shows areas of both UIP and nonspecific interstitial pneumonitis, the default pathologic diagnosis becomes the clinical diagnosis IPF, as these patients have been shown to behave similarly to IPF with UIP-only pattern (Raghu et al., 2011; Flaherty et al., 2001).

The histological features of pulmonary fibrosis associated with multisystem autoimmune disease can be classified into the same pathological descriptions of idiopathic interstitial pneumonias put forth by the ATS and ERS, including UIP, NSIP, DIP, and COP (Fig. 67.2). The UIP pattern that is seen with multisystem autoimmune

**FIGURE 67.4** Histologic pattern of idiopathic pulmonary fibrosis. The patterns are often referred to as “usual interstitial pneumonitis.” (A) Subpleural, paraseptal, and interstitial collagen deposition together with the areas of mildly abnormal alveolar parenchyma (hematoxylin and eosin, bar = 1 mm). (B) Thickened interstitium with collagen deposition, mild-to-moderate alveolar septal mononuclear cell infiltrates, mainly lymphocytes, cuboidalization of the epithelium and large fibroblastic foci (thick arrow). The fibroblastic foci are composed of spindled mesenchymal cells and are thought to represent the “leading edge” of the progressive fibroinflammatory process (hematoxylin and eosin; bar = 100 m).

diseases is essentially identical to the pattern seen in the IPF. In polymyositis, dermatomyositis, and scleroderma, NSIP is the most frequently seen histologic pattern followed by UIP (Bouros et al., 2002; Douglas et al., 2001). The prevalence of the different histologic subtypes of idiopathic interstitial pneumonias has not been well characterized in the other multisystem autoimmune diseases.

The estimated annual incidence of IPF is 7 per 100,000 for women and 10 per 100,000 for men. Most patients present between 50 and 70 years of age; however, the incidence, prevalence, and death rate rise with age (Coults et al., 1994).

Several studies have tried to establish the prevalence of pulmonary fibrosis in patients with the multisystem autoimmune diseases, but the results have varied depending on the method by which patients are screened for pulmonary involvement. Studies that utilize autopsy or lung biopsy data are subject to overdiagnosis, since they have been shown to detect subclinical disease that fail to progress (Cervantes-Perez et al., 1980). Likewise, HRCT screening studies may also overestimate the prevalence of disease by detecting parenchymal changes that may not be clinically significant. In RA, cross-sectional studies using chest radiographs estimate the prevalence to be less than 5% of patients (Hyland et al., 1983). When HRCT is used to screen patients, the prevalence appears to be between 20% and 50%, although these studies are limited by selection bias (Remy-Jardin et al., 1994; Gabbay et al., 1997). Pulmonary fibrosis is most prevalent in scleroderma, where autopsy series have shown it to be present in 70% of the cases and chest radiograph series estimate the prevalence between 25% and 65% (Wiedemann and Matthay, 1989; Minai et al., 1998). The prevalence of clinically overt pulmonary fibrosis is 30% in polymyositis and dermatomyositis, 5% in systemic lupus erythematosus, and 10% in Sjogren’s syndrome (Schwarz, 1998; Gardiner, 1993; Eisenberg et al., 1973).

## AUTOIMMUNE FEATURES

### Cryptogenic Organizing Pneumonia

COP has been reported in association with many different types of autoimmune disorders, including RA, lupus erythematosus, ankylosing spondylitis, Sjogren’s syndrome, and scleroderma (Ryu et al., 2003; Colby, 1998). COP is most frequently seen with RA. In one case series of 40 RA patients undergoing open lung biopsy, COP was the second most common diagnosis behind rheumatoid nodules of the lung (Yousem et al., 1985). In RA, bronchiolar involvement typically presents in the fifth and sixth decades of life and is more frequently seen

in women (Epler et al., 1979; Geddes et al., 1977; Herzog et al., 1981). Most patients with COP in association with RA have long-standing symptoms of arthritis, though occasionally the pulmonary involvement predates the rheumatologic disease. Occasionally, COP will appear at the same time as a flare in arthritic symptoms, and there is a case report of it occurring simultaneously with the onset of pernicious anemia, an autoimmune disease. Further support for the autoimmune basis is the fact that most cases of COP in RA will have a positive rheumatoid factor (85%) and usually have very high titers (Mori et al., 2008). Immunofluorescence stains in the affected regions of the lung of patients with RA have IgM and IgG depositions in the alveolar septum (Yousem et al., 1985; Begin et al., 1982), and many cells are positive for S-100 protein (Yoshinouchi et al., 1999).

The BAL fluid from patients with COP is notable for a marked activation of macrophages and lymphocytes, and an overall Th1 helper response (Cordier, 2006). BAL obtained from patients with COP has elevated levels of tryptase, mast cells, and interleukins-10, -12, and -18 (Forlani et al., 2002; Pesci et al., 1996). Platelet-derived growth factor and interleukin-8 also appear to play a role in the pathogenesis of COP (Carre et al., 1994; Aubert et al., 1997).

Indirect evidence for autoimmune mechanisms in COP comes from the bronchiolitis obliterans syndrome associated with both lung and allogeneic stem cell transplants. These cases, which can be viewed as *in vivo* human models of bronchiolar disease, have been more extensively studied than COP or rheumatic disease-associated COP. The bronchiolitis obliterans syndrome is the main cause of morbidity and mortality in association with lung transplantation (Arcasoy and Kotloff, 1999). It is a form of chronic lung rejection that is mediated by B-cell and T-cell activation against mismatched HLA class I and II antigens (Kelly and Hertz, 1997). Bronchiolitis obliterans associated with allogeneic bone marrow transplants is also thought to represent graft versus host disease. The disease progresses from inflammatory changes around the bronchioles to fibrosis and scarring (Ratanatharathorn et al., 2001). In bronchiolitis obliterans syndrome associated with lung transplant or with bone marrow transplant, the bronchioles are the more frequent site for chronic rejection, not the lung parenchyma.

## Idiopathic Pulmonary Fibrosis

Although the etiology of IPF remains unknown, it has been hypothesized for 30 years that autoimmune mechanisms to external stimuli are the driving force for repeated injury and inflammation that ultimately lead to fibrosis (Crystal et al., 1976, 1981, 1984). Although no clear infectious or environmental agent has been found as the etiology of IPF (Gross and Hunninghake, 2001), there are extensive data regarding autoimmune cellular and humoral processes ongoing in this disorder.

Initial studies in IPF relevant to autoimmunity focused on identifying autoantibodies that target the pulmonary parenchyma. Turner-Warwick demonstrated that 40% patients with IPF had circulating, nonspecific autoantibodies such as antinuclear antibodies (ANA) and rheumatoid factor (Turner-Warwick and Doniach, 1965). Increases in circulating ANA and rheumatoid factor were observed in 30% of our patients (Crystal et al., 1976). Similar studies which evaluated the presence of autoantibodies to nuclear antigens, DNA topoisomerase, and cytokeratin detected the antibodies in some patients (Table 67.1). More recent studies have focused on antibodies that are specific to lung proteins, although these studies have also shown variable expression of autoantibodies (Robinson et al., 2001; Wallace et al., 1994). These results raise the possibility that autoantibodies are a secondary consequence of the ongoing immune activation in the setting of inflammation and tissue damage, rather than the causative mechanism.

Similarly, investigations have evaluated the role that immune complex deposition plays in the pathogenesis of inflammation and fibrosis in IPF. Early studies observed the elevated levels of circulating immune complexes in certain subsets of patients with IPF; however, these were performed prior to the current classification system and included patients with other forms of interstitial lung disease (Haslam et al., 1979; Dreisin et al., 1978). Hunninghake et al. (1981) demonstrated a correlation between the level of immune complexes in BAL fluid and the levels of neutrophil chemotactic factor released by alveolar macrophages in patients with IPF. Other studies have also seen the elevated levels of immune complex in lavage fluid, but the levels are variable and do not correlate with disease activity.

More recently, attention has turned to immune-based microvascular injury as the ongoing trigger for pulmonary fibrosis. In scleroderma-associated pulmonary fibrosis, studies have shown complement and immunoglobulin deposition in the microvasculature. Some have hypothesized that perhaps antiendothelial cell antibodies, which are present in circulation in several autoimmune conditions, may be responsible for the injury.

**TABLE 67.1** Autoantibodies Associated with Idiopathic Pulmonary Fibrosis<sup>a</sup>

Antigens	Number of patients	Result	Reference
Fresh unfixed lung tissue, rheumatoid factor, nuclear, thyroglobulin, gastric parietal cells	48 IPF	Sensitivity: positive titers for: RF 49%, ANA 28%, rat liver homogenate 19%, gastric cells 0%; no autoantibodies specific to lung were detected by immunofluorescence	Turner-Warwick and Doniach (1965)
Nuclear ANA, ds-DNA, ss-DNA, RF <sup>b</sup>	53 IPF 33 SLE <sup>c</sup> 50 controls	Sensitivity: IPF patients had 42% ANA (titer > 1/10), 25% anti-dsDNA, and 100% anti-ssDNA titers that were two standard deviations above the normal range, levels did not correlate with disease activity	Holgate et al. (1983)
Nuclear <sup>d</sup> ANA, nRNP, dsDNA, Sm, SS-A and SS-B	68 IPF 54 PF-AID 47 controls	Sensitivity: ANA present in 21% of IPF and 46% of PF-AID. Anti-nRNP present in 15% of IPF and PF-AID. Other antibodies were not significantly different from control group  Specificity: ANA 94%, anti-nRNP 98%	Chapman et al. (1984)
Histidyl-tRNA synthetase (Jo-1 antigen)	62 IPF 19 PF-AID (myositis) 53 myositis alone	Sensitivity: Antibody present in 68% of PF-AID (myositis) patients compared to 3% IPF alone and 7.5% myositis alone  Specificity: >99% normal and 98% autoimmune controls	Bernstein et al. (1984)
Topoisomerase II	41 IPF	Sensitivity: 44% positive. Remained elevated in 17 of 19 follow up patients. Did not correlate with disease activity	Meliconi et al. (1993)
Collagen type I, II, III, IV	16 IPF 29 controls	Sensitivity: 75% of IPF patients had antibody titers to at least one type of collagen >1:16  Specificity: 83% using cutoff titer 1:16  Negative correlation between antibody level and duration of disease	Nakos et al. (1993)
Lung proteins derived from IPF, sarcoid, and normal lung	17 IPF 17 controls	Sensitivity: 71% of IPF patients had IgG that reacted to lung proteins in the 70–90 kDa range by western blot; IgG reacted to alveolar lining cells  Specificity: 82%	Wallace et al. (1994)
Cytokeratin 19	26 IPF 11 PF-AID 52 controls	Significantly higher mean serum levels in IPF compared to control. No cutoff value determined by ELISA because of overlap between groups	Fujita et al. (1999)
Expressed cDNA library from lung cancer cell line	11 IPF	Serum from index patient used to probe expressed cDNA library. Antigens recognized were unique to index patient (including anti-alanyl tRNA synthetase), but not shared with sera from other 10 patients	Robinson et al. (2001)
Endothelial cell protein extract	45 PF-AID (scleroderma) 16 controls	Sensitivity: 93% PF-AID had positive staining using an indirect immunofluorescent assay against rodent lung tissue  Specificity: 88%	Wusirika et al. (2003)
RNA helicase melanoma differentiation-associated gene 5 (MDA5)	61 amyotrophic dermatomyositis 61 dermatomyositis controls	Anti-MDA-5-positivity was significantly associated with ILD, since 50% of MDA-5-positive subjects (8 of 16) had ILD versus 25.5% of MDA-5-negative subjects (27 of 106; $P = .04$ )	Sato et al. (2009)

<sup>a</sup>Summary of autoantibody studies in patients with idiopathic pulmonary fibrosis (IPF). PF-AID—pulmonary fibrosis associated with autoimmune disease.<sup>b</sup>RF—rheumatoid factor.<sup>c</sup>SLE—systemic lupus erythematosus.<sup>d</sup>Nuclear antigens: ANA—anticellular antibodies; nRNP—nuclear ribonucleoprotein, Sm—Smith antigen, SS-A and SS-B—Sjogren's syndrome A and B antigens.

Several studies have correlated the presence of antiendothelial cell antibodies with the development and severity of IPF (Magro et al., 2007).

The lack of clear evidence for a humoral mechanism as the primary cause for IPF shifted the focus toward cellular immunity. One popular theory is that an unknown stimulus triggers a dysregulated activation of cell-mediated immune response that results in the fibrotic process analogous to that observed in abnormal wound healing. This theory rests on the belief that a normal cell-mediated defense to a pulmonary insult would be a Th1 response, as seen in most infections and in hypersensitivity pneumonitis (Kunkel, 2004; Lukacs et al., 2001; Wallace et al., 1995). The Th1 response is characterized by the release of interferon- $\gamma$  and the activation of neutrophils and macrophages for the efficient clearing of the antigen, as well as the suppression of fibroblast activation and collagen deposition. Cytokine profiles in IPF are closer to Th2 response which are typified by elevated IL-4, IL-5, and IL-13 levels and result in fibroblast activation (Hancock et al., 1998; Wallace and Howie, 1999). Early evidence for this T-cell-mediated mechanism in IPF was demonstrated by Kravis et al. (1976), who demonstrated that circulating lymphocytes from patients with IPF released migration inhibitor factor after exposure to collagen and lysed collagen-coated sheep red blood cells.

One experimental model used to demonstrate a cell-mediated autoimmune mechanism is the adoptive transfer, hapten-immune pulmonary interstitial fibrosis model (Stein-Streilein et al., 1987). In this model, donor mice are sensitized by a hapten, and then lymph nodes and spleen are transferred to recipient mice. When the recipient mice are then challenged with intratracheal administration of the hapten, they develop pulmonary fibrosis in 7–14 days. Interestingly, when the adoptive transfer with Th1 cells was used, an alveolitis developed, but not fibrosis, thus supporting the Th2 theory regarding the pathogenesis of the fibrotic component of IPF (Irifune et al., 2003).

In pulmonary fibrosis associated with the multisystem autoimmune disease, several serological and genetic markers are linked to the development of lung disease. For instance, patients with RA that have high levels of rheumatoid factor and prominent rheumatoid nodules are at increased risk for developing pulmonary fibrosis (Hyland et al., 1983). In systemic sclerosis the presence of antitopoisomerase antibodies and diffuse cutaneous involvement is associated with pulmonary fibrosis (Fanning et al., 1998).

Perhaps the best evidence for associating autoantibodies to pulmonary fibrosis is in patients with polymyositis and dermatomyositis, in which antibodies against aminoacyl-tRNA synthetases are highly correlated with pulmonary fibrosis (Targoff, 1993; Bernstein et al., 1984). At least five known forms of the autoantibodies have been identified, which include anti-alanyl-tRNA synthetase (PL), anti-histidyl-tRNA synthetase (Jo-1), anti-isoleucyl-tRNA synthetase (OJ), anti-glycyl tRNA synthetase, and anti-threonyl tRNA synthetase. The strongest correlation appears to be with anti-Jo-1 antibodies, which have been reported to have a frequency of interstitial lung disease between 50% (Hochberg et al., 1984) and 100% (Yoshida et al., 1983). Patients with polymyositis or dermatomyositis can frequently present with the “antisynthetase syndrome” characterized by pulmonary fibrosis in 50%–75% of the patients of arthritis, Raynaud’s phenomenon, and fevers. Occasionally, the antisynthetase syndrome can occur in the absence of clinical myositis (Marguerie et al., 1990). There are also several case series of patients with isolated pulmonary fibrosis occurring in association with aminoacyl-tRNA synthetase antibodies (Sauty et al., 1997; Friedman et al., 1996). These patients have been shown to have a CD8 lymphocyte predominant BAL and nonspecific interstitial pneumonitis pattern on lung biopsy. Most of the patients described in these case series have been more responsive to therapy with cyclosporine and azathioprine than patients with IPF.

Prior studies have suggested that the prognosis may be favorable for patients with pulmonary fibrosis associated with systemic sclerosis (Wells et al., 1994). However, Hubbard and Venn (2002) demonstrated with actuarial data that the mortality rates for patients with pulmonary fibrosis associated with all rheumatic disorders, predominantly RA in their study, are remarkably similar to those that are idiopathic in origin.

## GENETIC FEATURES

### Cryptogenic Organizing Pneumonia

There are no studies that demonstrate a genetic predisposition to this condition. The same is true for the autoimmune associated forms of COP.

## Idiopathic Pulmonary Fibrosis

Up to 3% of the cases of IPF occur in clusters of families, suggesting that a genetic predisposition may be responsible for the susceptibility to disease (Hodgson et al., 2002). A simple pattern of Mendelian inheritance has not been observed. Familial cases appear to be inherited in an autosomal dominant pattern, although the penetrance is variable. In familial cases of IPF, children of individuals with fibrotic lung disease can have the evidence of inflammatory alveolitis in bronchial lavage fluid, without having any clinical evidence of the disease (Bitterman et al., 1986). There have been several reports of pulmonary fibrosis occurring in separately raised monozygotic twins, underscoring the role of genetic factors (Jawaheri et al., 1980; Peabody et al., 1950). Using a candidate gene approach in one large family kindred with IPF, Thomas et al. (2002) identified a mutation in the highly conserved coding region of surfactant protein C, resulting in aberrant cellular distribution of SP-C in the lung tissue of affected individuals. From the Vanderbilt Familial Pulmonary Fibrosis Registry a telomerase gene mutation was found to be associated with the familiar form of IPF (Armanios et al., 2007).

In addition to the familial form of the disease, there is evidence for a genetic basis for the more common, sporadic form of the disease. A study from Finland demonstrated a clustering of sporadic cases of IPF in areas where familial cases were found, suggesting a founder's effect (Hodgson et al., 2002). One prevailing hypothesis is that susceptibility does not lie in one gene locus, but rather within multiple genes that interact through inflammatory and fibrotic mechanisms, creating a background genotype of fibrotic potential, yet still requiring an insult to create the profibrotic phenotype. This theory would explain why the familial form of the disease has an earlier age of onset (55 vs 67), yet still presents relatively later in life, implying that a reduced threshold for the development of fibrosis exists in familial types (Marshall et al., 2000). This theory is also supported by the fact that only a small proportion of individuals who receive drugs known to cause pulmonary fibrosis (such as bleomycin or amiodarone) actually develop the disease (Tisdale et al., 1995).

One major limitation in the search for genetic sources for susceptibility is that the sizes of the association studies are limited because of the rarity of the disease. Polymorphisms in several genes have been explored as potential causes for the inherited susceptibility to IPF; however, these studies utilized a traditional candidate gene approach which is limited by the current understanding of the disease and may lead to false positive associations. The best evidence for a genetic linkage to IPF susceptibility has been found with polymorphisms in the gene for MUC5B, which has been shown to convey increased risk in the general population (Seibold et al., 2011). The biologic role of MUC5B is related to mucin secretion in bronchial epithelial cells. Its role in pathogenesis is not clear, but MUC5B was found to be present in the epithelial cells of IPF but not in the fibrotic regions of scleroderma-associated NSIP (Borie et al., 2013).

Most of the genetic linkage studies are focused on genes involved in the inflammatory pathways, such as interleukin-1 $\alpha$  and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and have shown conflicting results (Pantelidis et al., 2001; Whyte et al., 2000). Xaubet et al. (2003) demonstrated that transforming growth factor- $\beta$  (TGF- $\beta$ ) polymorphisms were related to disease progression, but they found no association to susceptibility to IPF.

Given recent advances in genomics, microarray analysis, and proteomics, there is an excellent opportunity to perform genome-wide searches for linkage in patients with IPF to identify novel genes that are involved in pathogenesis and may represent therapeutic targets. Many of these genetic approaches are simply hypothesis generators; however, this may be a necessary first step to decipher the complex interactions of multiple loci. In addition, microarray technology can be used for "molecular fingerprinting" to identify subclassifications within the general category of IPF.

## IN VIVO AND IN VITRO MODELS

Animal models of the classical human Mendelian genetic diseases are relatively easy to produce because the genotype typically involves one affected gene, and knockout models of that gene, in mice for instance, can usually approximate the phenotype. Generating an animal model of a complex polygenic disease poses far more challenges because it involves multiple genes, each exerting a relatively small effect.

## Cryptogenic Organizing Pneumonia

The best animal model for COP involves inoculating CBA/J mice with reovirus serotype 1 via intranasal route (Bellum et al., 1997). These CBA/J mice develop intraluminal fibrosis and lymphocytic, peribronchial infiltrates

that are identical to the pathologic findings of COP in human disease. Interestingly, the COP pathological changes appear when titers of  $10^6$  are used; however, when  $10^7$  titers of the same virus are used, the CBA/J mice develop diffuse alveolar damage, the pathological finding of ARDS. This suggests that the tendency toward COP versus ARDS may be due to severity of the initial insult (London et al., 2002a, 2002b).

Other animal models for COP are designed to mimic bronchiolitis obliterans, the transplant-associated form of the disease. One model frequently used is the heterotopic murine tracheal transplant, whereby grafts of trachea and main bronchi are placed subcutaneously into allogeneic mismatched recipients (Hertz et al., 1993). By 21 days, grafts demonstrate fibroproliferation in the airway lumen, a characteristic for the human chronic rejection process. Subsequent studies on this model have shown that this is mediated by cellular and humoral immunity (Kelly and Hertz, 1997). Although this model can successfully mimic the phenotypic changes of bronchiolitis obliterans, it has limited applicability to understand COP because the entire tracheo-bronchial graft is an immunogenic stimulus, which is not likely the case in the idiopathic or autoimmune-associated forms of the disease.

## Idiopathic Pulmonary Fibrosis

There is no animal model for IPF that clearly represents human IPF. However, there are several animal models for susceptibility to developing experimental pulmonary fibrosis. The susceptibility to bleomycin-induced interstitial lung disease has been correlated with both immune-related (TH2 type) and nonimmune-related genes in different strains of mice (Rossi et al., 1987). Transforming growth factor- $\beta$  has been shown to induce pulmonary fibrotic changes when overexpressed via intratracheal administration of an adenoviral vector (Liu et al., 2001). Likewise, when mice are treated with an adenoviral vector expressing SMAD-7, an inhibitory regulator of TGF- $\beta$  production, they appear to be protected against bleomycin-induced lung injury (Nakao et al., 1999).

Many different transgenic and knockout mice have also been developed to investigate the molecular pathways that lead to pulmonary fibrosis. One example is mice that overexpress TNF- $\alpha$  that develops pulmonary fibrosis and have some of the features of human IPF (Miyazaki et al., 1995). Knockout mice with targeted deletions of genes necessary for fibrosis (e.g., adhesion molecules, ICAM-1 and L-selectin, which facilitate the accumulation of leukocytes) show significantly decreased fibrosis in response to bleomycin (Hamaguchi et al., 2002).

Many of these models are focused on only a select number of candidate genes, which may or may not have relevance to human disease. While these studies have been useful to identify genes that may play a role in susceptibility, the actual human form of the disease is likely far more complex and polygenic, which may prohibit creating a comprehensive animal model that reflects the underlying pathogenesis.

## PATHOLOGIC EFFECTOR MECHANISMS

### Cryptogenic Organizing Pneumonia

The sequence of events that ultimately leads to organizing pneumonia has been established in multiple studies. The common initial event is airway epithelial injury, with necrosis and denudation of the pneumocytes, but preservation of basal laminae and endothelial cells. This is distinct from ARDS, where there is a breakdown in the basal membrane leading to hyaline membrane formation. The first alveolar changes in COP involve the formation of inflammatory cell clusters (macrophages, lymphocytes, and neutrophils) bound together by fibrin. The next stage involves the migration of fibroblasts through the basal lamina and proliferation of fibrotic and inflammatory "buds" in the airway. The final stage is when these buds progress to a mature stage, and there is less inflammatory component, and the alveolar space begins to clear of fibrin (Kuhn and McDonald, 1991; Myers and Colby, 1993; Peyrol et al., 1990). Vascular endothelial growth factor and basic fibroblast growth factor are highly expressed in COP, and this results in a proliferation of capillary tissue as is normally seen in response to wound healing (Lappi-Blanco et al., 2002).

Environmental factors are clearly linked to the development of COP in general, although specific causative environmental factors for COP are difficult to identify. Perhaps the best documented environmental cases of COP occurred after exposure to aerosolized textile dye Acramin (Sole et al., 1996; Romero et al., 1998; Moya et al., 1994; Camus and Nemery, 1998). In this outbreak, 14 textile workers in Valencia Spain developed a severe respiratory illness following exposure to this dye.

Inhalational injuries can progress into bronchiolitis obliterans, which is similar pathologically to COP, except the injury is predominantly bronchiolar in location, without necessarily an inflammatory alveolar infiltrate.

The mechanism is believed to be due to inflammation caused by the irritant in the bronchioles that progresses into irreversible fibrosis and airway obstruction. Frequently, this occurs after exposure to water-insoluble gases (such as oxides of nitrogen in the case of silo-filler's lung) and organic dusts or fumes, which are not rapidly absorbed in the mucus membranes of the upper airways (Fleming et al., 1979; Ramirez and Dowell, 1971). Nitrous fumes are a significant industrial hazard and can be found in the agriculture, firefighting, and chemical industries. The timing of the injury can be delayed from the exposure because the gases are slowly hydrolyzed into acids that act as powerful oxidants which eventually penetrate the small airways and cause severe tissue injury. Clinical symptoms may present as acute, subacute, or chronic. The chronic form usually presents as a new clinical illness, weeks to months after recovery from the initial acute illness (King, 2003).

There have been many case reports of industrial exposures followed by the development of bronchiolitis obliterans in unrelated industries such as battery workers, food flavoring workers, and nylon flock workers (Eschenbacher et al., 1999; Konichezky et al., 1993; Kreiss et al., 2002). It is difficult to prove causation when only a few workers are affected. Kreiss et al. (2002) reported a high incidence of bronchiolitis obliterans in 7% (8 out of 117) of workers at a microwave popcorn plant, which was attributed to inhalation of the volatile agent, diacetyl in the butter flavoring. This observation was supported by toxicity studies of diacetyl inhalation in rats (Hubbs et al., 2002). Bronchiolitis obliterans has also been described in a truck driver who inhaled fly ash, as well as in a young man with smoke inhalation from a fire (Tasaka et al., 1995; Boswell and McCunney, 1995). Both cases recovered from the acute illness only to have their symptoms recur and progress weeks to months later.

Organizing pneumonia can also occur as a sequela from prior pulmonary infections, most commonly seen with adenovirus, but also associated with other viruses (Respiratory syncytial virus (RSV), influenza) and mycoplasma (Wright et al., 1992; Penn and Liu, 1993; Chan et al., 1997). When an organizing pneumonia pattern is observed after an infection, it is referred to as "secondary organizing pneumonia." COP has been reported to occur in the contralateral lung in women undergoing breast radiation for breast cancer (Stover et al., 2001). Some medications have been implicated as etiological agents in the development of COP, including amiodarone, amphotericin, bleomycin, mesalazine, methotrexate, phenytoin, and sirolimus (Cordier, 2006). Both gold and penicillamine have been suspected; however, it is difficult to determine if the COP results from the medication or the underlying disease (Geddes et al., 1977).

## Idiopathic Pulmonary Fibrosis

The original theory for the pathogenesis of IPF rested on the premise that inflammation of the alveoli was followed by fibrosis (Crystal et al., 1976, 1981, 1984; Hunninghake et al., 1979). There are many observations that support this hypothesis. Early studies that used bronchial lavage demonstrated increased numbers of alveolar macrophages, neutrophils, eosinophils, and lymphocytes (Weinberger et al., 1978; Reynolds et al., 1977; Crystal et al., 1976). Gallium scans, which are nonspecific markers of inflammation with macrophages and neutrophils, are positive in about 70% of all patients with IPF (Crystal et al., 1976; Line et al., 1978). Biopsies that are performed in the early stages of the disease reveal large amounts of inflammation and alveolar wall derangement compared to biopsies taken in the later stages of disease when fibrosis predominates (Carrington et al., 1978). Alveolar macrophages are believed to play a central role in the inflammatory process through the release of cytokines that affect other cells. Alveolar macrophages from patients with IPF have been shown to secrete neutrophil chemotactic factor which does not occur in normal nonactivated alveolar macrophages (Hunninghake et al., 1980, 1981). Animal models have shown the presence of inflammation preceding fibrosis, and the suppression of the inflammatory response attenuates the progression to fibrosis (Snider, 1986).

More recently, there has been a focus on the fibrotic aspect of the disease as also playing an important role. These theories about the pathogenesis of IPF involve the idea of recurrent, ongoing stimulus and injury to the lung, with abnormal wound healing. The abnormal wound healing is believed to result from a complex interplay of the genetic background of the individual, the predominant inflammatory phenotype (Th1 or Th2), and the environmental triggers. The stimulus that acts as the driving force remains a mystery, as does the mechanism that promotes a pathological fibrotic response instead of the normal reparative response.

The lung parenchyma regulates its immune and fibrotic processes through cytokine signaling between the cells of the interstitium, including epithelial cells, endothelial cells, fibroblasts, and macrophages, and it is likely that these cells contribute to the pathogenesis of IPF (Standiford et al., 1991; Selman et al., 2001; Martinet et al., 1987). Although the exact sequence of chemokine signaling that leads to the progression of fibrosis is not understood, it

has been shown that cytokines are responsible for the cell-to-cell communication and fibroblast activation, proliferation and collagen production.

One theory is that an imbalance in inflammatory phenotype, shifted toward a Th2 response, is responsible for the fibrotic phenotype. Support for this theory comes from the observation that IL-4 and IL13, major Th2-type cytokines, have been shown to be major stimuli for fibroblast-derived extracellular matrix deposition (Hancock et al., 1998; Furue et al., 1997). Interferon- $\gamma$ , one of the major Th1-type cytokines, has been shown to suppress the production of collagen and fibronectin by fibroblasts (Goldring et al., 1986). The increased presence of eosinophils, which have been associated with Th2 cytokine expression in asthma and parasitic infections, in association with fibrotic changes in IPF is consistent with the concepts of the Th2 paradigm of abnormal healing. Davis et al. (1984) demonstrated that eosinophils represented greater than 5% of the cells in the lavage fluid of 20% of patients with IPF compared to less than 1% of the normal controls. These eosinophils were shown to have collagenase activity and have the capacity to injure lung parenchymal cells.

The pathogenetic mechanisms that lead to the development of pulmonary fibrosis associated with rheumatic diseases have been most extensively studied in scleroderma. The most common theory, which may or may not be applicable to the idiopathic form, is that an initial environmental injury triggers an ongoing, amplified immune response in the lung. Both TNF- $\alpha$  and TGF- $\beta$  have been shown to be upregulated early in the course of the disease (Corrin et al., 1994; Bolster et al., 1997), and there is a cytokine shift from Th1 to Th2 in helper T cells (Bolster et al., 1997). BAL fluid from patients with scleroderma has increased levels of several inflammatory cytokines such as IL-8, TNF- $\alpha$ , and macrophage inflammatory protein (Southcott et al., 1995). Lavage is also believed to have prognostic value in patients with systemic sclerosis. Scleroderma patients with a neutrophil and eosinophil predominant BAL have been associated with more extensive pulmonary fibrosis seen on CT and more rapid clinical deterioration (Witt et al., 1999; Silver et al., 1990; Rossi et al., 1987; Friedman et al., 1996; Behr et al., 1996).

The stimulus that leads to the inflammatory response in the lungs of patients with scleroderma is also unknown, but one hypothesis suggests that aspiration of refluxed esophageal and gastric contents may be the cause. The premise behind this theory arises from the fact that many patients with systemic sclerosis have both esophageal dysmotility and pulmonary fibrosis. This association was initially observed in a relatively small cohort of 12 patients (Johnson et al., 1989a). Subsequent studies have found conflicting results when trying to correlate pulmonary function parameters meant to be a surrogate marker of pulmonary fibrosis (such as total lung capacity and diffusion capacity) with esophageal manometry (Troshinsky et al., 1994; Lock et al., 1998). These studies are limited by confounding because both esophageal dysmotility and pulmonary fibrosis may be the independent markers of scleroderma disease severity, without having a causal link.

Several environmental factors have been investigated for an etiological role in IPF. The premise of an environmental stimulus that leads to repeated lung injury followed by abnormal wound healing fits nicely into one theory of the pathogenesis of IPF (see below). The search for these stimuli is challenging because the offending agent may be different between individuals based on individual differences in genetic susceptibility. Nevertheless, epidemiological studies have identified links between IPF and occupational exposures, medications, and infectious agents.

Four separate case-controlled studies have looked at the association between occupational exposure and IPF. Although these studies are limited because of recall bias, there were some consistent observations. Metal dust exposure was significantly associated with IPF in every study and in a dose-response relationship (Baumgartner et al., 1997, 2000; Hubbard et al., 1996; Iwai et al., 1994). Two studies showed a significant association with livestock exposure, farming, and agricultural exposure (Baumgartner et al., 2000; Iwai et al., 1994). Paraquat, an herbicide used in agriculture, has been found to cause fatal pulmonary fibrosis in humans and experimental animals after oral, inhalational, or cutaneous exposure (Schoenberger et al., 1984). Anecdotal case reports have linked the cases of IPF with occupations that result in toxic dust or fume exposure such as diamond polishing, dairy work, welding, gold extraction, and dental work (Baumgartner et al., 1997).

Pulmonary fibrosis is a well-known side effect of several medications, most notably bleomycin, amiodarone, methotrexate, and nitrofurantoin (Holmberg and Boman, 1981; Israel-Biet et al., 1991; Martin and Rosenow, 1988; Schoenberger and Crystal, 1983; Sleijfer, 2001). It has also been found as a rare complication of more commonly used medications such as beta blockers, antidepressants, anticonvulsants, and nonsteroidal antiinflammatory drugs. However, these associations have been difficult to prove given the ubiquity of these medications and the relative rarity of IPF (Coulas et al., 1994).

The effect of smoking on the natural history of IPF is controversial, but of four case-control studies examining the association of smoking with pulmonary fibrosis, three showed a significant link between smoking and the development of IPF (Iwai et al., 1994; Hubbard et al., 1996; Baumgartner et al., 1997, 2000). Some studies have

shown improved survival in smokers with IPF compared to nonsmokers (King et al., 2001; Cherniack et al., 1995). However, this observation may be due to lead time bias in the smoking group and simply reflect a greater severity of disease in the nonsmoking groups.

## TREATMENT AND OUTCOME

### Cryptogenic Organizing Pneumonia

One of the defining features of COP is that it usually has an excellent response to corticosteroids. Although there have not been any randomized clinical trials to prove their efficacy, there is widespread consensus based on individual experience that corticosteroids are highly efficacious. When patients respond, there is typically complete radiographic and clinical resolution of the organizing pneumonia. There is no consensus on duration of treatment, with some authorities suggesting 6–8 weeks, while others advocate for 1 year. Spontaneous remissions are unusual, except when a precipitating factor is identified and withdrawn, for example, new medication. Second-line agents, for example cytotoxic agents, or macrolide antibiotics, can be used when steroids are contraindicated, but high-quality data for these are lacking.

### Idiopathic Pulmonary Fibrosis

IPF usually portends a poor prognosis and is typically poorly responsive to therapy. Early diagnosis and treatment have traditionally been advocated so that therapy can be initiated and, hopefully, prevent irreversible fibrosis. Therefore, the typical medications used to treat IPF work through antiinflammatory and immunosuppressant mechanisms. However, these traditional approaches have failed to show that the inflammatory or fibrotic process can be altered or reversed. As the understanding of the pathogenesis of the disease improves, newer agents are being developed based on cellular mechanisms to inhibit fibrogenesis. There are currently two FDA-approved antifibrotic therapies for IPF, pirfenidone and nintedanib. Both medications have been shown to slow progression; however, no therapy for IPF has been shown to improve survival.

Pirfenidone is an oral antifibrotic agent that was the first drug approved for the treatment of IPF in 2014. Pirfenidone initially performed two parallel phase 3 trials, called CAPACITY (studies 004 and 006) which evaluated the safety and efficacy of pirfenidone after 72 weeks in about 350 IPF patients, with the primary end point being change in forced vital capacity (FVC% predicted). CAPACITY 004 showed a significant reduction in the rate of decline in FVC% predicted, while CAPACITY 006 showed no significant decline. This prompted a third phase 3 trial called ASCEND, which enrolled 555 IPF patients and demonstrated a reduction in decline of FVC% predicted at 52 weeks and an improved progression free survival (Noble et al., 2016).

Nintedanib is an intracellular inhibitor of multiple tyrosine kinases that block many of the growth factors thought to be involved in the pathogenesis of IPF. Two replicate double-blinded phase 3 trials with 1066 patients total, demonstrated that nintedanib reduced the decline in FVC over a 52-week period. Both nintedanib and pirfenidone are currently approved for IPF, their efficacy in patients with pulmonary fibrosis associated with autoimmune diseases has not been studied to date (Richeldi et al., 2014).

### Corticosteroids

Prior to the approval of nintedanib and pirfenidone, the most common medication used to treat IPF was corticosteroids, despite the fact that they have not been properly evaluated in a large clinical trial. Early studies showed that 10%–30% of patients with IPF appear to improve or survive longer when treated with corticosteroids (Stack et al., 1972; Turner-Warwick et al., 1980). However, these studies likely included other forms of idiopathic interstitial pneumonia, such as nonspecific interstitial pneumonia or COP, which tend to have a more favorable prognosis than IPF. When histopathological criteria are used for the diagnosis of IPF, the clinical response (0%–16%) and survival rates are much worse than for the other pathological patterns (Ziesche et al., 1999; Nicholson et al., 2000; Daniil et al., 1999). Despite the lack of evidence for a beneficial role of corticosteroids, some pulmonologists use a 3–6-months trial of corticosteroids with close monitoring for radiographic or physiologic improvement. Patients who improve with corticosteroids or who remain stable are then kept on a maintenance dose of 10–20 mg of prednisone per day (American Thoracic Society and European Respiratory Society, 2002). Intravenous pulse corticosteroids for 3–5 days are generally recommended for an acute exacerbation of IPF, as Keogh et al. (1983) demonstrated that the higher doses of corticosteroids can significantly reduce the neutrophil accumulation during an active alveolitis of IPF.

### Cytotoxic Agents

Other antiinflammatory and cytotoxic agents have been investigated for a beneficial role in IPF. Cyclophosphamide, when used in combination with corticosteroids, had promising results toward a survival advantage compared to corticosteroids alone in an early randomized control trial (Johnson et al., 1989b; Baughman and Lower, 1992). Cyclophosphamide has been shown to reduce the neutrophil component of the active alveolitis after 3 and 6 months of therapy (O'Donnell et al., 1987). However, subsequent studies have shown cyclophosphamide to have limited efficacy and a high frequency of side effects when used to treat patients with IPF who failed to respond to corticosteroid therapy (Zisman et al., 2000). Cyclophosphamide may be effective in patients with scleroderma-associated pulmonary fibrosis, as it was shown to improve pulmonary function testing in this population. Scleroderma patients with a neutrophil predominant BAL seemed to have the best outcomes, although these studies were limited by either small sample size, lack of a control group or selection bias from retrospective review (Schnabel et al., 1998; Silver et al., 1990; White et al., 2000). Cyclophosphamide is currently considered a second-line drug for patients with progressive IPF. Side effects include leukopenia, thrombocytopenia, and hemorrhagic cystitis.

### Antifibrotic Agents

Many other novel strategies have been investigated in the treatment of IPF, including colchicine, interferon  $\beta$ , cyclosporine A, sildenafil, bosentan, and etanercept (Raghu et al., 2011). These therapies focus on different aspects of the pathogenesis of the disease, such as antioxidants; inhibitors of cytokines, proteases, and fibroblast growth factors. However, all of these agents have failed to demonstrate clinically meaningful responses; and therefore, the joint statement by the ATS and ERS recommended against using corticosteroids, colchicine, interferon  $\beta$ , cyclosporine, bosentan, or etanercept for the treatment of IPF (Raghu et al., 2011).

Lung transplantation should be considered for individuals with IPF who progress despite optimized medical management. Patients should be referred to a transplant center relatively early in their course, since wait times on the list can exceed 2 years due to limited donor availability. Those who receive a successful transplant can experience significant improvement in arterial oxygenation, pulmonary hypertension, and right ventricular dysfunction. Unfortunately, the 5-year survival rates for lung transplant are only about 60%, with death frequently due to graft failure, infection, or bronchiolitis obliterans (Lu and Bhorade, 2004).

## CONCLUSIONS

The autoimmune disorders of the lung, notably COP and IPF, have long been recognized as inflammatory and fibrotic processes that are associated with variable prognosis, whether idiopathic in nature or in association with the multisystem autoimmune diseases. Both diseases appear to be mediated through repetitive cell-mediated injury directed at the bronchioles and alveoli/interstitium, followed by wound healing. Recent advances in the classification and diagnostic testing for these diseases have improved our ability to study their incidence, prognosis, and response to therapy. While much progress has been made, the search for antigenic stimuli and genetic polymorphisms that are responsible for disease pathogenesis continues. Only through a better understanding of the disease pathogenesis we will be able to offer new therapies for these diseases.

### OUTLINE

Introduction	1355	Pathological Features	1359
History	1355	Autoimmune Responses (Allograft Rejection) in Kidney Transplantation	1360
Epidemiology	1356	Clinical Features and Disease Associations	1361
Genetics	1357	Summary	1363
Autoimmune Features	1357	References	1363
Animal Models	1358		

### INTRODUCTION

The kidney, like most other organs, is a target of autoimmunity. This can happen as a consequence of systemic autoimmunity, such as systemic lupus erythematosus (SLE) which causes nephritis in 35%–55% of patients due to an abnormal inflammation in the glomerulus (Bombard, 2017). In other instances, kidney disorders are caused by deposits of nonspecific autoantibodies in the glomerulus as in cases of antineutrophil cytoplasmic antibody (ANCA), complement 3 (C3), and immunoglobulin (Ig)A glomerulopathies (Sethi et al., 2016). The kidney is also the target of autoantibodies that attack specific cell types in the glomerulus (McAdoo and Pusey, 2017). These include membranous nephropathy (MN) and glomerular basement membrane (GBM) nephropathy. Besides these established autoimmune diseases, acute kidney injury (AKI) and chronic kidney disease (CKD) have autoimmune features and are increasingly being considered to have important autoimmune components (Jang and Rabb, 2015). This chapter briefly summarizes the main autoimmune diseases of the kidney, treatments, and connections to the general concept of autoimmunity.

### HISTORY

The original idea that nephrotoxic substances, later identified as autoantibodies, mediated nephritis was suggested by early studies. A study in Japan in 1933 showed that injecting rat kidney adjuvants into rabbits caused disease signs that resembled human glomerulonephritis (GN), implicating nephrotoxic substances in disease

pathogenesis (Redakcja naukowa et al., 2009). Smadel et al. (Farr and Smadel, 1939) followed up by a study in 1939 where they induced acute nephritis in rats injected with anti-rat kidney serum obtained from immunized rabbits. Another study by Schwentker and Comployer (1939) showed that the injection of rabbits with homologous kidney emulsions mixed with *Staphylococcus* toxins generated complement-fixing antibodies that were reactive with rabbit kidney. Given the presence of antibody in patients with scarlet fever, the authors speculated that the toxin combined with kidney tissues formed a complete antigen that induced kidney-specific antibodies (Mackay, 2010).

A major breakthrough came in 1959 when Marianne and Bielschowsky developed the first lupus model by crossbreeding of New Zealand black (NZB) and New Zealand white (NZW) mice (Bielschowsky and Bielschowsky, 1964). The F1 generation developed spontaneous autoimmune hemolytic anemia with renal lesions comparable to those found in SLE patients. Subsequent studies showed the presence of the same antibodies in the NZB/NZW mice and SLE patients as reviewed by Mackay (2010). In the same year, Stanton et al. showed that the Goodpasture's disease or antiglomerular basement disease has autoimmune features (Hellmark and Segelmark, 2014). Using direct immunofluorescence (IF), the authors were able to visualize Ig deposits along the GBM in multiple patients. The pathogenic roles of these antibodies were demonstrated by inducing Goodpasture-like symptoms and lesions in primates injected with antibodies isolated from patients (Hellmark and Segelmark, 2014). Subsequent studies brought in a new era of renal histological methods and the use of transmission electron microscopy. In 1959 two children with scarlet fever and nephritis were found to have low hemolytic activity and low C3 serum content (Cunningham, 2000). Using electron microscopy and IF techniques, Mueller-Eberhard and Nilsson identified a C3 nephritic factor which when mixed with normal human serum caused GN (Nilsson and Mueller-Eberhard, 1965).

Besides antibodies, T cells have been gradually implicated in the pathogenesis of autoimmune disorders of the kidney. CD4 T cells can directly help B cells to produce antibodies. In addition, they have been shown to cause kidney pathology (Tsokos, 2011). CD4<sup>+</sup> T cells mediate renal ischemia-reperfusion injury, making AKI another likely autoimmune disease (Rabb et al., 2016). Autoreactive T cells in patients with Goodpasture's disease are specific for peptides in the autoantigen that has a high affinity for the disease-associated human leukocyte antigen (HLA) Class II molecule, DR15 (Phelps et al., 1996). Furthermore, while B-cell hyperactivity in SLE is T-cell dependent, CD4<sup>+</sup> T-cell activation is essential to SLE pathogenesis. Most recently, T-cell Ig and immunoreceptor tyrosine-based inhibition motif (ITIM) domain (TIGIT), an inhibitory receptor, was identified as a powerful negative regulator of CD4<sup>+</sup> T cells in SLE (Mao et al., 2017).

## EPIDEMIOLOGY

*Environmental factors.* Environmental factors play important roles in the development of renal autoimmune diseases. These factors range from infectious agents (Krawczak et al., 2017), chemicals/metals and toxins (Stevenson et al., 1995), stress (Richter et al., 2018), diet (Johnson et al., 2015), smoking (Donaghy and Rees, 1983), exposure to prolonged sunlight exposure (Ngo et al., 2014), and xenobiotics.

*Infectious agents.* Bacteria, viruses, and parasites have been associated with autoimmune glomerular diseases. There is a strong correlation between IgA nephropathy and infections, especially upper respiratory tract infections (Roberts, 2014). *Escherichia coli* is the most common bacterial cause of hemolytic uremic syndrome (HUS) (Jokiranta, 2017). Hepatitis B and C viruses can cause membranous GN (Gupta and Quigg, 2015), while HIV is associated with a glomerular immune complex disease (Nebuloni et al., 2009). Furthermore, molecular mimicry between self-antigens and microbial determinants has been associated with the anti-GBM disease and acute dengue infection (Lizarraga et al., 2015). On the other hand, infectious agents can be protective, as it has been reported that infecting BWF1 mice with malaria parasite protects from lupus by reducing B-cell autoreactivity (Badr et al., 2015).

*Chemicals/metals.* Penicillamine, an antirheumatic drug and exogenous chemical, is associated with MN (Dische et al., 1984). Exposure to gold and mercury, in the environment or for therapeutic reasons, causes autoimmune responses in kidneys and other tissues in some individuals (Bigazzi, 1999). Lithotripsy-associated kidney trauma is associated with the development of anti-GBM disease (Xenocostas et al., 1999). On the other hand, intermittent exposure to ultraviolet radiation with sun-simulation has been reported to protect and even treat vitamin D deficiency in chronic and end-stage kidney disease patients (Krause, 2013). However, under the experimental conditions, exposure to ultraviolet radiation has been shown to have detrimental effects on rat kidney tissue cells (Türker and Yel, 2014).

*Ethnic/gender.* As with most other autoimmune diseases, there are significant gender differences in the prevalence of kidney autoimmune diseases with females generally more susceptible than males (Ngo et al., 2014).

The only notable exception is IgA nephropathy where the disease incidence in men is double than in women (O'Shaughnessy et al., 2017). There are also major differences in prevalence depending on ancestry. For example, lupus nephritis (LN) affects 68.9% of African-Americans, 60.6% of Hispanics patients compared to only 29.1% of Caucasians (Bastian et al., 2002). On the other hand, IgA nephropathy is less common in African-Americans and Caucasians but is the most common form of glomerular disease in Asian, accounting for 30%–40% of all cases (Falk PHNJCJRJ, 2008). Age is also another important factor; whereas IgA nephropathy declines with age, LN peaks in early adulthood, and ANCA GN dramatically surges after the age of 50 years (Jennette and Nachman, 2017).

## GENETICS

Genetic background contributes to autoimmune diseases of the kidney. For example, two variants of the APOL1 gene have been linked to the development of multiple glomerular disorders in African-Americans (Genovese et al., 2010). The low-affinity Fc gamma receptors II and III (FcγR2a, FcγR2b, and FcγR3a) are important regulators of immune responses that are encoded for in the FCRG locus. Polymorphisms and variations in copy numbers of genes in this locus are associated with LN and to impair IgA binding and clearance, resulting in increasing amounts of circulating IgGs (Relle et al., 2015). Studies in SLE mouse models showed that deletion of CAMK4 decreased IL-2 production by T cells and reduced the severity of GN, making it a potential genetic link with LN (Otomo et al., 2015).

There are multiple different pathways that can cause IgA nephropathy: abnormal antigen presentation, the complement system, regulation of global mucosal Ig production, and innate immunity (Magistroni et al., 2015). Each of these pathways is controlled by certain genetic loci. For examples, *ITGAM-ITGAX*, *VAV3*, *CARD9*, *HLA-DQB1*, and *DEFA* are tightly linked to IgA nephropathy (Magistroni et al., 2015). *CFHR1/3* and *ITGAM-ITGAX* loci are linked with the complement system, whereas *TNFSF13* and *LIF/OSM* loci regulate the IgA production in mucosal membranes (Magistroni et al., 2015).

Occurrence of MN varies among individuals depending on their ethnic backgrounds (Sim et al., 2016). Polymorphisms in *HLA-DQA* and phospholipase A2 receptor (*PLA2R1*) have been correlated with the MN. European Caucasians have been documented with the most cases of circulating anti-PLA2R antibodies and incidences of MN compared to other racial ethnicities (Ronco and Debiec, 2015). Furthermore, a truncating mutation in the neutral endopeptidase (NEP) results in complete absence of the NEP protein in homozygous mothers who can become alloimmunized during pregnancy/miscarriage and generate high titers of anti-NEP antibodies upon reexposure to antigens from fetal or placenta tissues to cause antenatal MN due to fetomaternal alloimmunization (Beck, 2015).

There are also positive correlations between the expression of HLA-DRB1<sup>\*</sup>1501 and DRB1<sup>\*</sup>1502 and the over-production of anti-GBM antibodies in 80% of the patients studied (Cui and Zhao, 2011). On the other hand, HLA-DR7 and DR1 have protective effects and negative genetic linkage with the anti-GBM disease (Hellmark and Segelmark, 2014). Recent studies in congenic rats have shown that the Fcgr3 gene and the expression of the activator protein (AP)-1 transcription factor, JunD, could also affect the severity of the anti-GBM disease by modulating macrophage activity (McAdoo and Pusey, 2017).

Immunoglobulin G4-related disease (IgG4-RD) is a systemic fibro-inflammatory disorder that affects most organs, including the kidney (Pradhan et al., 2015). Tubulointerstitial nephritis (IgG4-TIN) is the most common form of IgG4-RD with the majority of patients having autoantibodies free in serum and bound to podocytes (Cortazar and Stone, 2015).

Genome-wide association studies that aimed at identifying genetic loci influencing susceptibility to SLE (Harley et al., 2008) have identified >50 genes associated with SLE (Chen et al., 2017). Inclusion of patients with LN in these studies has provided additional important insights into the potential pathogenic pathways that lead to both SLE and LN (Gualtierotti et al., 2010).

## AUTOIMMUNE FEATURES

Adaptive immune cells, B and T cells, are responsible for the major pathogenic features of kidney autoimmunity. A pivotal role for B cells is the production of pathogenic autoantibodies. Anti-DNA antibodies produced by autoreactive antibodies deposit in the GBM through interactions with DNA, nucleosomes trapped in the GBM,

and/or binding to intrinsic non-DNA glomerular antigens (Yung and Chan, 2008). Anti-dsDNA antibodies also play pathogenic roles in LN (Misra and Gupta, 2015). Natural autoantibodies against myeloperoxidase (MPO) and proteinase 3 are detected in patients with ANCA-associated disease (Cui and Zhao, 2011). B cells also serve as potent antigen-capturing cells, particularly to stimulate activated/memory T cells and perpetuate injurious autoimmune processes (Silveira et al., 2004).

Despite their perceived importance and growing evidence, the pathogenic role of T cells in mediating renal diseases is yet to be thoroughly characterized. Follicular helper T CD4 T cells, reside in the germinal center and are specialized in helping B cells, produce antibodies, participate in renal autoimmune injury (Crotty, 2014), and play a central role in the pathogenesis of SLE (Blanco et al., 2016). On the other hand, regulatory T cells (Tregs), which usually play a protective role against autoimmune responses (Schaerli et al., 2000), have been described to be deficient in SLE patients and Tregs bearing exon 2-deficient FoxP3 splice variant are reported to predominate in ANCA-associated vasculitis (AAV) (Free et al., 2013).

## ANIMAL MODELS

*LN model.* There are several spontaneous mouse models that develop the lupus-like nephritis (LN). These include the F1 hybrid between the NZB and NZW strains (NZB/W) F1, New Zealand Mixed (NZM)/Aeg2410 (NZM2410), MRL/lpr, and BXSB/Yaa strains (Peng, 2012). NZB/W F1 mice develop high titers of antinuclear antibody (ANA), hemolytic anemia, splenomegaly, and early onset immune complex-mediated GN (Peng, 2012). The NZM2410 and NZM2328 strains have lupus-like disease, and their phenotypes are similar to those of (NZB/W) F1 mice, with anti-DNA autoantibodies and nephritis (Waters et al., 2001). Lupus-like disease in the NZM2328 strain shows a strong gender bias toward females similar to the NZB/W F1 mice, whereas NZM2410 mice exhibit nephritis with similar severity in males and females (Waters et al., 2001). The BXSB/Yaa mouse represents a recombinant inbred strain derived from backcrossing of (B6 × SB/Le) F1 and SB/Le (Li et al., 2017). These mice develop high levels of ANA and severe GN (Li et al., 2017). MRL/lpr mice and MRL/Mp mice are also used for the study of LN (Beck et al., 2000). MRL/lpr mice produce autoantibodies against dsDNA and Sm, leading to large amounts of immune complexes that induce renal disorder (Andrews et al., 1978). The SNF1 model is produced by crossing the Swiss Webster (SW) strain with the NZB strain. The autoantibodies derived from SNF1 mice are cationic IgG2b anti-dsDNA and are nephritogenic with restricted idiotypes, and they cluster along the GBM to initiate renal injury (Gavalchin et al., 1985).

*ANCA-induced GN model.* The anti-MPO model is based on the use of MPO-deficient (MPO – / –) mice to produce high-titer, high-affinity, and anti-MPO IgG that are pathogenic when transferred into wild-type or immune-deficient mice (Xiao et al., 2002). They cause necrotizing crescentic GN (NCGN), demonstrating a pathogenic role for MPO-ANCA and that anti-MPO IgG alone is sufficient to induce focal NCGN in naive subjects (Xiao et al., 2002). Jennette et al. demonstrated that an oral small-molecule antagonist of human C5aR blocks induction of anti-MPO NCGN in 129S6/B6 mice bearing a transgenic human C5aR (Xiao et al., 2014).

*IgA nephropathy—the ddY mouse model.* The ddY mouse was first reported in 1985 (Imai et al., 1985). It is a model of spontaneous IgA nephropathy, which develops GN with a striking deposition of IgA in the mesangium, as well as codeposits of IgG, IgM, and C3 after the age of 40 weeks. Recently, Tomino et al. used a novel strain of ddY mice termed “grouped ddY mice” by selective mating to establish the early-onset IgA nephropathy (Okazaki et al., 2012).

*Anti-GBM nephritis model.* Human anti-GBM nephritis presents a clinical course of rapidly progressive GN with diffuse crescent formation (Ohashi et al., 2003). A number of animal models of anti-GBM nephritis have been developed. One model is developed by immunization of mice with homologous or heterologous GBM in complete Freund’s adjuvant (Reynolds et al., 1998). A second model, which was originally developed in sheep (the T.D. Hewitson Steblay nephritis model), is also easily inducible in rabbits but less reliably in rats (Steblay, 1962). Another model, first described in the 1930s, is induced by passive administration of heterologous anti-GBM antibodies in rats (El Nahas, 1993). Furthermore, anti-GBM nephritis can be induced in mice and rats, but with great variations in susceptibility between strains (Yang et al., 2010).

*AKI model.* AKI is a cause of renal damage in diverse clinical circumstances (Basile et al., 2012). Three different models of ischemic AKI are commonly used for research. Bilateral clamping of the renal pedicle has been used by many groups to simulate AKI induced by acute severe hypotension (Wang et al., 2017). Clamping of a single renal artery, which induces a unilateral disease, derives its value from allowing the use of contralateral kidney as control, and overall survival is higher than with bilateral clamping (Wei and Dong, 2012). Finally, the removal of

one kidney prior to occlusion of the contralateral renal artery avoids the confusion caused by functioning and nonfunctioning kidneys and also more closely mimics the situation often occurring in renal transplantation (Burne-Taney et al., 2003).

The degree of AKI in these models is proportional to the period of ischemia and has to be determined for the individual animal strain used and age. As a guide, 30–50 minutes of the occlusion is generally used in uninephrectomized rats and mice. However, the functional effects remain highly variable, with small differences in ischemia time significantly changing the characteristics of the model. These differences can make comparative studies problematic (Wei and Dong, 2012).

*MN-Heymann nephritis (HN) rat model.* The study of rat HN identified fundamental disease mechanisms that revolutionized our understanding of human MN (Foster, 2016). Human membranous nephritis is a significant cause of end-stage kidney disease (Ronco and Debiec, 2015). Active HN is an autoimmune model of membranous nephritis induced in Lewis rats by immunization with a crude renal tubular antigen (Fx1A) or megalin (gp330). The pathogenesis involves binding of anti-Fx1A autoantibodies to the autoantigen expressed on glomerular epithelial cells, causing severe glomerular injury and proteinuria. The pathological features of HN include immune deposits in glomeruli and infiltration of glomeruli and the tubulointerstitium by macrophages and T cells (Wang et al., 2015).

*Nephrotoxic models.* Drugs affect renal function in a variety of ways. Adriamycin results in nephrotic syndrome and cisplatin as well as mercuric chloride and gentamicin are associated with tubular toxicity (Servais et al., 2008). In most cases, outcomes are directly related to the duration of exposure. With the injection of cisplatin, AKI induced in rats or mice generates renal pathology and tubular dysfunction comparable to those seen in humans (Deng et al., 2001). Repeated injection of cisplatin in rats results in inflammatory and fibrotic processes that are being regulated by IL-10 (Deng et al., 2001). Exposure to mercury is an environmental cause of heavy metal–induced renal toxicity in humans that results in acute proximal tubule injury within 2–3 days, followed by a regenerative process (Anders and Schlondorff, 2000). Intraperitoneal injection of gentamicin in mice is used as a highly clinically relevant model that leads to myeloid bodies in proximal tubule cells, a morphologic feature of gentamicin exposure in humans (Zager et al., 2007).

## PATHOLOGICAL FEATURES

*LN.* The histopathological features specific to LN include immune complex deposits in the mesangial, subendothelial and subepithelial glomerulus, extraglomerular deposits within tubular basement membranes (TBMs), and tubuloreticular inclusions in the glomerular endothelial cells. Tissues were stained for the “full house” of three IgGs (IgG, IgA, and IgM) and two complement factors (C3 and C1q), which when all detected together are strong indicators of SLE (Barisoni, 2015). There are multiple stages of LN, depending on the presence, placement, and severity of endocapillary proliferation, glomerular leukocyte infiltration, wire loop deposits, fibrinoid necrosis, karyorrhexis, cellular crescents, and interstitial inflammation (Gerald et al., 2008). There are six classes of LN: Class I, minimal mesangial LN; Class II, mesangial proliferative LN; Class III, focal LN; Class IV, diffuse LN; Class V, membranous LN; and Class VI, advanced sclerosing LN. Class I and II LN point to mesangial proliferation which could progress to membranous LN in the epithelium. Class III LN is characterized by more damage in the glomerular area, including necrotizing or sclerosing lesions. Class IV LN lesions have more necrosis and crescents, with severe interstitial lesions and fibrosis. The various forms of LN may overlap with cases of Class V membranous nephritis, which is characterized by subepithelial deposits on the loops of glomeruli (Anders and Fogo, 2014).

*Crescentic GN.* Although light microscopy lesions may be similar in all the three types of crescentic GN, IF is useful to distinguish diseases (Barisoni, 2015). Linear deposits of IgG along the GBM are typical of Goodpasture syndrome (Cui and Zhao, 2011). Diabetic nephropathy and fibrillary GN are often confused with anti-GBM disease because of the IgG staining; however, they do not show evidence of crescents under light microscope. In later stages, it can be characterized by breaks in the Bowman’s capsule and fibrinous necrosis and adjacent segments of glomeruli (Hellmark and Segelmark, 2014).

Among type 2 crescentic GN, the diagnosis of IgA nephropathy essentially depends on microscopic examination. Light microscopy shows proliferation of mesangial cells, whereas IF reveals “dominant” (greater than any other Ig) mesangial granular IgA staining, whereas mesangial deposits are seen on electron microscope (EM). Postinfectious GN (PIGN) is also an immune-mediated GN associated with extrarenal bacterial infections. Its pathologic features include glomerular endocapillary hypercellularity by light-microscopy (LM), granular IgG

and C3 staining in capillary walls by IF, and subepithelial “hump”-like deposits by EM (Roberts, 2014). The characteristic lesion in pauci-immune GN is glomerular capillary necrosis (often segmental) with the cellular crescent formation and few to no immune deposits by IF and EM.

*Autoimmune MN.* It is characterized by glomerular capillary wall thickening on LM, prominent granular (“lumpy-bumpy”) capillary wall staining for IgG and C3 on IF, and subepithelial deposits on EM (Barisoni, 2015). Cases of early MN may show no overt changes by LM and quite a subtle staining by IF, whereas EM readily establishes the diagnosis in such early cases by revealing small subepithelial deposits. Detection of enhanced PLA2R expression in glomeruli by IF can serve as a footprint of PLA2R-associated MN. MN has been reported in association with IgG4-RD. In IgG4-related MN, unlike primary MN, IF staining for PLA2R is negative while IgG4 is primary (Barisoni, 2015).

*C3 glomerulopathy (C3G).* The pathology of C3G includes glomerular disorders with a membranoproliferative LM pattern and IF characterized by C3 deposition and little to no Igs. C3G includes both C3GN and the rare dense deposit disease (DDD, previously known as Membranoproliferative glomerulonephritis (MPGN) type II). These two disorders are best distinguished on EM: mesangial and capillary wall (usually subendothelial) deposits in C3GN and dense osmiophilic intramembranous deposits in DDD (Barbour et al., 2013).

*TIN.* The pathology of acute interstitial nephritis (AIN) is characterized by the interstitial infiltration of inflammatory cells and edema, which may be sparse, focal, or intense. The most numerous cell types are lymphocytes, monocytes, and macrophages, but they can also be associated with plasma cells, eosinophils, and neutrophils. EM may show that the TBM is discontinuous, partially thickened, or even disrupted (Muriithi et al., 2014).

Chronic TIN is characterized by renal interstitial fibrosis with mononuclear cell infiltration, tubular atrophy, luminal dilation, flattened epithelial cells, and thickening of TBM. The cellular infiltrate in chronic interstitial disease is composed of lymphocytes, macrophages, and B cells, with occasional neutrophils, plasma cells, and eosinophils. Infiltrate is chronic TIN typically less marked than in AIN (Barisoni, 2015).

## AUTOIMMUNE RESPONSES (ALLOGRAFT REJECTION) IN KIDNEY TRANSPLANTATION

*Hyperacute rejection.* Microscopy shows diffuse glomerular and peritubular capillary (PTC) thrombosis with interstitial hemorrhages, ischemic acute tubular necrosis, and infarction. Capillary neutrophils and platelets are abundant. IF shows focal IgG, IgM, and C3 in the PTC. C4d may be detectable in PTC. Diffuse capillary endothelial swelling and detachment from the basement membrane, platelet-fibrin thrombi, neutrophils, macrophages, and capillary rupture may be seen by EM (Han et al., 2015).

*Acute rejection.* Acute rejection can be divided into 30%–60% cell-mediated rejection, 10% humoral-mediated rejection, and about 30% mixed rejection. Light microscopy of cell-mediated rejection manifested mainly as interstitial mononuclear inflammation, edema, tubulitis, intimal arteritis (acute endarteritis), ± acute transplant glomerulitis. Antibody-mediated rejection is mainly manifested as acute capillaritis, glomerular + PTC, acute tubular necrosis (ATN), Thrombotic Microangiopathy (TMA) (rare), and necrotizing arteritis. Indirect IF reveals diffuse PTC C4d in humoral acute rejection (AR). Direct IF reveals little Ig or other complement components in vasculature. EM is useful to assess basement membranes of interstitial capillaries, multilayered in chronic antibody-mediated rejection (AMR) (Han et al., 2015).

*Chronic rejection.* Chronic transplant glomerulopathy is characterized by diffuse, often segmental, GBM duplication on PAS-stained sections and variable mesangial sclerosis with segmental adhesion of the glomerular tufts to Bowman capsule. Global and segmental glomerular sclerosis and hyalinosis may be prominent. PTCs have basement membrane thickening and multilayering. Arteries have intimal fibrous thickening with small amounts of infiltrating T cells and foamy macrophages, which are features diagnostic of chronic endarteritis. Interstitial inflammation and fibrosis with tubular atrophy are variable. IF reveals little IgG, IgM, and C3 in glomeruli. PTC, glomerular capillary, and mesangial C4d deposition are frequent in biopsies with chronic transplant glomerulopathy. Diffuse PTC C4d correlates with the presence of circulating donor-specific antibodies in chronic rejection. EM shows glomerular capillaries with swollen endothelium, fenestral loss, detachment from the basement membrane, and formation of new subendothelial strands of the basement membrane. Cellular interposition could also be evident, whereas electron-dense deposits of immune complexes absent. On the other hand, mesangial sclerosis will be prominent, podocyte foot processes effaced, PTCs will have swollen endothelium and multiple periendothelial layers of new basement membrane (Han et al., 2015).

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

Pathogeneses of these autoimmune diseases often involve loss of self-tolerance and induction and mobilization of immune effector cells that cause cell injury and organ dysfunction.

**LN.** SLE is the classic autoimmune disease of the kidney. Although SLE has diverse organ involvement, the kidney is among the most commonly affected organs. Nearly 50% of the Afro-Caribbean women with SLE develop LN that results in significant morbidity and mortality (Saxena et al., 2011). Abnormal proteinuria, abnormal urinary sediment, or decreased glomerular filtration rate (GFR) are present at the time of diagnosis in at least one-half of the SLE patients. According to the American College of Rheumatology's guideline, the use of renal biopsy is important for a demonstration of immune complex-mediated GN indicative of LN (Petri et al., 2012). Indicators such as anti-dsDNA, C3, C4, C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR) provide the most useful clinical information. Raised serum levels of antibody to dsDNA and serum complement component levels are generally reduced in LN.

**Treatment.** Patients with SLE are treated with nonsteroidal antiinflammatory drugs, antimalarial agents, glucocorticoids, and immunosuppressive drugs, including cyclophosphamide, azathioprine, methotrexate, and mycophenolate mofetil (Yildirim-Toruner and Diamond, 2011). Inhibitors of cyclooxygenase-2, which have antiinflammatory effects, have been claimed to promote the death of autoreactive T cells (Esmaeili et al., 2017). The choice of drug depends largely on the severity of the disease and functions of the organs involved. Blockade of BLyS with an anti-BLyS antibody, which has been approved by the Food and Drug Administration for the treatment of lupus (Navarra et al., 2011), results in a small but significant beneficial clinical effect within the first year of treatment in patients with mild or moderate disease. The role of B-cell depletion therapy using anti-CD20 antibody (rituximab) in the treatment of SLE is unclear. However, the use of BLyS after B-cell depletion still sounds reasonable. Restorations of T-cell tolerance with peptide components of putative autoantigens and anti-CD40L antibodies are undergoing clinical trials (Tsokos, 2011).

**Crescentic GN.** Crescentic GN often presents as a rapid progressive GN (RPGN) with the histological manifestation of severe glomerular damage rather than the specific disease. It is characterized by the accumulation of proliferating and dedifferentiated visceral and parietal cells in the Bowman's space, which surround and compress the glomerular tuft. Crescentic GN is usually associated with macroscopic or microscopic hematuria, erythrocyte casts, variable degrees of proteinuria that result in loss of renal function within 3 months after the clinical onset (Falk PHNJCRJ, 2008). There are three categories of crescentic GN based on the presence and the distribution of immune deposits at IF. Type 1 accounts for about 10% of crescentic GN. Goodpasture syndrome is a typical example of this category. Type 2 accounts for 15%–20% of crescentic GN. It is a heterogeneous group of RPGN characterized by granular deposits of IgG (Singh et al., 2008). Different immune complex diseases could lead to type 2 crescentic GN. These include PI acute GN, LN, Henoch–Schonlein purpura, mixed cryoglobulinemia, IgA nephritis, immune complex-mediated membranoproliferative GN, diabetic glomerulosclerosis, and primitive or secondary amyloidosis. Type 3 is the most common form of crescentic GN as it accounts for 60%–80% of all cases which is now reclassified as AAV.

Almost half of crescentic GN patients have AKI as their clinical presentation (Chen et al., 2016). Nephritic syndrome and RPGN are common features in all types of crescentic GN. Circulating anti-GBM antibodies are typical of Goodpasture syndrome. Low C3 levels are frequent in PIGN. ANCA test is the immunologic marker of AAV, present in 90% of the cases.

**Treatment.** Early treatment is paramount for crescentic GN patients (Moroni and Ponticelli, 2014). The current approach utilizes a combination of corticosteroids and cytotoxic drugs to suppress active inflammation and reduce cellular response and the antibody production. Plasmapheresis can be used to remove circulating antibodies and immune complexes (Syed et al., 2015). Prognosis depends largely on the level of serum creatinine at presentation (Perez-Valdivieso et al., 2007). In one European survey, an estimated GFR of <15 mL/min, advancing age, lower hemoglobin, higher Birmingham Vasculitis Activity Score, and higher white cell count were identified as significant negative prognostic factors for a patient's long-term survival. While the natural course of crescentic GN often leads to the end-stage renal disease (ESRD), an appropriate treatment could halt progression and even lead to complete remission. Prompt diagnosis and treatment are thus essential for favorable prognosis (Moroni and Ponticelli, 2014).

**Autoimmune MN.** MN is a rare disease that is considered a model of organ-specific autoimmune disorder that targets the glomerulus (Sinico et al., 2016). It is the most common cause of the nephrotic syndrome (defined by massive urinary protein loss) in White patients (Hull and Goldsmith, 2008), accounting for about 30% of the cases (annual incidence, 1.7 per 100,000; approximately 1300 and 10,000 new cases in France and European Union each

year, respectively). Autoimmune idiopathic MN involves *in situ* formation of subepithelial deposits, resulting from binding of circulating anti-PLA2R autoantibodies to podocyte's PLA2R. Approximately 70%–80% of the patients with idiopathic (primary) MN have circulating anti-PLA2R autoantibodies while secondary forms of MN (e.g., membranous LN) generally lack these autoantibodies, hence an excellent biomarker of the disease (Beck and Salant, 2014). Furthermore, MN is one of the most frequent etiologies of nephrotic syndrome after renal transplantation which affects 10%–40% of the patients and can cause graft loss (Golgert et al., 2008).

**Treatment.** Clinical outcome is extremely variable and unpredictable with more than one-third of the patients with idiopathic MN experience spontaneous remission of the nephrotic syndrome. However, a significant number of patients will have a poor response to immunosuppressive therapy and progress to ESRD.

**C3G.** C3Gs are a group of severe renal diseases with distinct patterns of glomerular inflammation and C3 deposition caused by complement dysregulation (Medjeral-Thomas et al., 2014). The clinical features of C3 GN are heterogeneous with up to 50% of the patients retain normal renal function while as many as 15% progress to ESRD. Forms of C3G include DDD, C3 GN, familial MPGN3, CFhr5 nephropathy, and immune complex-mediated MPGN. Recent advances in the assessment of CFHR proteins have revealed roles in atypical HUS (aHUS) and C3Gs (Tortajada et al., 2013). aHUS is an acute and severe disease belonging to thrombotic microangiopathies, whereas C3Gs are chronic diseases characterized by glomerular C3 deposition with no or limited Ig deposition.

**Treatment.** Before 2012, the treatment has invariably included antacellular immune suppression targeting T and/or B cells (e.g., cyclophosphamide, mycophenolate, or rituximab) with or without plasma therapy. More recently, the treatment plans have sometimes included anticomplement C5 therapy (Wong and Kavanagh, 2015). Plasma therapy is used on a case-by-case basis in C3Gs.

**TIN.** AIN is caused by multiple factors. Drugs such as antibiotics and non-steroidal anti-inflammatory drugs (NSAIDs) are the most common cause of acute TIN; however, other causes include autoimmune and systemic disorders, infections, and metabolic etiologies (Perazella and Markowitz, 2010). Cellular and humoral immunity are involved in the pathogenesis of the disease with renal biopsy showing significant renal interstitial infiltration by T cells (Hooke et al., 1987). The typical clinical manifestations of AIN include fever, rash, joint pain, and other systemic inflammatory manifestations. Kidney manifests as abnormal urinalysis, renal impairment, and tubular injury. In addition to drugs, infection is another common cause of AIN. Viruses such as hantavirus and polyomavirus manifest as AKI at an early stage, with persistent tubular necrosis leading to interstitial fibrosis, and tubule atrophy ultimately to renal failure (Gnemmi et al., 2015). AIN can also be caused by a variety of autoimmune diseases such as SLE, Sjogren's syndrome, sarcoidosis, Wegener granulomatosis, primary biliary cirrhosis, and cryoglobulinemia while chronic interstitial nephritis (CIN) may develop chronically following acute TIN or may be the initial manifestation of an autoimmune or systemic process (Guillevin and Dorner, 2007). Besides renal tubular dysfunction, clinical manifestations of CIN include kidney endocrine dysfunction, such as reduced production of erythropoietin, vitamin D metabolic disorders, and chronic renal failure (Kokot et al., 1990).

Diagnosis includes clinical assessment and serum tests, and urine examination includes dipstick urinalysis, urine eosinophils, and urine microscopy. Imaging tests, such as kidney ultrasonography/computed tomography (CT) scan, gallium-scintigraphy, and fluorodeoxyglucose-positron emission tomography (FDG-PET) scan, offer limited benefits (Perazella, 2017). Unfortunately, none of these allows a definitive diagnosis, making kidney biopsy a real necessity to accurately diagnose and manage AIN and CIN.

**Treatment.** AIN and CIN treatment include immediate halting of using suspicious drugs, control of infection, and the primary disease (Perazella, 2017; González et al., 2008). Hemodialysis or plasmapheresis can be used as supportive care. Tubulointerstitial diseases are a relatively common cause of both acute and CKDs. The extent of tubulointerstitial fibrosis is closely linked to kidney function and is an important predictor of kidney functional recovery.

**Autoimmune responses (allograft rejection) in kidney transplantation.** Allograft rejection is classified into three major categories: hyperacute, acute, and chronic (Haas, 2014).

**Hyperacute rejection.** Begins immediately after perfusion, the diagnosis is confirmed by an intraoperative biopsy of the kidney that shows polymorphonuclear leukocytes in the glomeruli and PTCs with widespread vascular thrombosis (Boehmig et al., 1971). This type of rejection results from preformed cytotoxic antibodies reactive to endothelial cells of the graft.

**Treatment.** The treatment of hyperacute rejection is disappointing and is generally associated with graft loss.

**Acute rejection.** It occurs in 10%–40% of allografts within the first year after transplantation (Boehmig et al., 1971). With the current immunosuppression, the only presenting sign is a rise in the serum creatinine level. Allograft biopsy is an effective method of diagnosis. Approximately 90% of acute rejections are cell-mediated

and are characterized by lymphocytic invasion of the interstitial and tubular epithelium. Ten percent of acute rejections show evidence of antibody-mediated rejection, characterized by complement deposition (C4d) in the PTCs. Vascular rejection signifies arterial inflammation and can result from either cell-mediated or antibody-mediated rejection (Haas, 2014). Acute rejection within the first year after transplantation can be successfully reversed approximately 80% of the time.

*Treatment.* Acute cellular rejection is treated by high-dose methylprednisolone, antilymphocytic antibodies, or increasing the dosage of calcineurin inhibitor medications. For antibody-mediated acute rejection, most clinicians favor the rapid removal of the circulating antibodies by plasmapheresis and the neutralization of the remaining antibodies with intravenous Ig.

*Chronic rejection.* This is identified in most renal transplants after a few years. Renal allograft biopsies show the evidence of accelerated atherosclerosis, interstitial fibrosis, and tubular atrophy (Orandi et al., 2016). Both antigen-dependent and antigen-independent mechanisms of vascular injury are implicated. The serum creatinine concentration slowly "creeps" up until the allograft fails. Although immune factors including acute rejection play a role in the development of chronic rejection, chronic allograft nephropathy more accurately describes the multi-factorial nature of this disease. Hypercholesterolemia, hypertension, immunosuppression nephrotoxicity, ischemia-reperfusion injury, and infection have all been associated with the same pathologic findings.

*Treatment.* Many clinical trials are now being designed to determine whether this process can be stopped or prevented. Increasing immunosuppressive treatment is usually not advised.

## SUMMARY

Autoimmune and alloimmune diseases of the kidney are common, serious, and increasingly treatable because of advances in basic and translational research. Further benefits will come from the application of novel technologies and approaches such as precision medicine, population-based genetics, and better experimental models.

Spectrum of Autoantibodies	1373	Standardization and Quality Assurance	1381
Approaches to and Standardizing Autoantibody Testing	1374	Summary	1383
Clinical Interpretation and Application of Autoantibody Testing	1377	References	1383
Clinical Practice Guidelines	1378		

## INTRODUCTION

The history of autoantibodies (aab) dates back more than a century to Ehrlich's description of "horror autotoxicus" (Ehrlich, 1900) and the development of the Wassermann test for syphilis (Wassermann et al., 1906). Progress in the identification and detection of aab lagged from about 1900 to 1950, with the notable exception of organ-specific autoimmune diseases (reviewed in Conrad et al., 2017). In stark contrast, over the following 65 years, aab discoveries and novel testing platforms flourished and achieved prominence in both laboratory and clinical settings. The more recent advances in aab testing date to the seminal discovery of the lupus erythematosus (LE) cell in 1948 (Hargraves et al., 1948) and the introduction of the LE cell test (Conn, 1994). In the ensuing 20 years, a number of techniques such as indirect immunofluorescence (IIF), immunodiffusion (ID), hemagglutination, and complement fixation were developed and then refined in the following 20 years (reviewed in Olsen et al., 2017). IIF was described by Coons, Kaplan, and Weller in the early 1950s (Warde, 2011) and this immunoassay stands out as one of the few aab technologies that is still in wide use today, particularly as a screening test in the diagnosis of systemic autoimmune rheumatic diseases (SARD) (Agmon-Levin et al., 2014; Mahler et al., 2014a; Pisetsky, 2017).

In the years following the introduction of IIF, a variety of assay substrates were utilized, but cryopreserved sections of rodent organs became the mainstay for the first 25 years (Holborow et al., 1957; Kunkel and Tan, 1964; Beck, 1961). In the mid-1970s, human tissue culture cells such as HeLa and HEp-2 became the substrate of choice because they were superior to organ sections in the identification of many aab, primarily because these cells had larger nuclei, target antigens were expressed in various stages of the cell cycle, and the assay kits using these substrates were relatively economical to manufacture.

Despite the advantages of HEp-2 cells, the increased sensitivity of the IIF techniques using these cells became an issue of concern that lead to a study by the Serology Subcommittee of the International Union of Immunology Societies/World Health Organization/Arthritis Foundation (IUIS/WHO/AF) who recommended that adult sera should be screened at dilutions of 1/40 and 1/160 but that a cutoff of 1/160 was the most appropriate to achieve a balance of sensitivity and specificity for the diagnosis of SARD (Tan et al., 1997). This recommendation achieved limited acceptance because many laboratories preferred to screen at serum dilutions that provided the appropriate balance of sensitivity and specificity in their own clinical environment. In addition, many manufacturers “fine-tuned” their kits and components (i.e., secondary antibodies) so that a “one-size-fits-all” recommendation seemed inappropriate. Eventually, there was a move away from HEp-2 IIF screening techniques to higher throughput, enzyme-linked immunoassays (ELISA) and addressable laser bead immunoassays (ALBIA). Some clinicians expressed concerns that this trend was troubled by an unacceptable loss of diagnostic sensitivity and subsequent clinical errors. After deliberation, a study committee commissioned by the American College of Rheumatology declared that the antinuclear antibody (ANA) IIF test on HEp-2 cell substrates should continue to be regarded the “gold standard” for the detection of ANA (Meroni and Schur, 2010; American College of Rheumatology, 2011; Fritzler, 2016). Nevertheless, following this “declaration,” there was little evidence that the majority of high-throughput laboratories reverted to the IIF test. Furthermore, with continuous improvement of ELISA and ALBIA, there is mounting evidence that these high-throughput screening assays now outperform the ANA IIF test (Pisetsky, 2017; Pérez et al., 2018). In this context, it is important to emphasize that there is no evidence-based consensus on approaches to or interpretation of aab testing by IIF (or any diagnostic technology) in children, although key observations are emerging (Mahler and Fritzler, 2014).

The use of HEp-2 cell substrates to detect aab in SARD ushered in the “golden age” of aab discovery (Fritzler, 2012) leading to the identification of novel intracellular autoantigen targets but, equally important, provided cell and molecular biologists with valuable probes for studies of novel cell structures and macromolecules (Tan, 1989; Backes et al., 2011) such as anti-proliferating cell nuclear antigen (PCNA) and other cell cycle targets (Mahler et al., 2010) and centromere (Fritzler et al., 2010), as well as targets in the nucleoli (Reimer et al., 1987; Welting et al., 2003), nuclear envelope (Enarson et al., 2004), and cytoplasm (Stinton et al., 2004; Fritzler et al., 2007). The identification of these novel targets and their disease relevance occurred in parallel with emerging technologies, such as immunoblotting (IB), expression cloning, and rapid and economical DNA sequencing.

The remarkable advances in identifying and cataloguing the molecular targets of aab lead to a new generation of technology platforms such as ELISA (Halbert et al., 1981; Reichlin and Harley, 1986; Tonutti et al., 2004), dot blots (Stott, 1989; Nezlin and Mozes, 1995), line immunoassays (LIA) (Pottel et al., 2004; Damoiseaux et al., 2005), multiplexed immunoassays such as ALBIA (Fritzler and Fritzler, 2009) and chemiluminescence (CLA) (Mahler et al., 2011b) (Table 69.1). Some of these newer technologies are gaining favor by modern diagnostic laboratories because they are automated, amenable to high throughput and shortened turnaround times, can be linked to elaborate and secure laboratory information systems and the patient’s electronic medical record (EMR), all resulting in reduced reporting errors and considerable laboratory cost-savings. Other emerging but as yet not widely adopted technologies include lateral flow (Renger et al., 2010), antigen arrays on planar surfaces (Baker et al., 2004; Balboni et al., 2008; Chandra et al., 2011), nanobarcodes (Freeman et al., 2005), and electrochemical sensors (Rubin et al., 2014; Konstantinov and Rubin, 2017). These technology platforms seem to be more suited to point of care diagnostics (Fritzler, 2015; Rubin and Konstantinov, 2016; Dincer et al., 2017; Joh et al., 2017), a field that has been slow to be adopted in autoimmune diseases.

The continued use of IIF has advantages, but the limitations of this technology in the context of ever changing clinical algorithms should not be overlooked (Pisetsky, 2017; Fritzler, 2012, 2016). It has become clear that the results from any immunoassay can be at considerable variance with the other. This has prompted concerns about the relative value of old and new diagnostic platforms where the implications of false-negative and false-positive test results are debated (Fritzler, 2011c, 2016). Many clinicians prefer to adhere to assay results that are easily understood, fit within existing diagnostic paradigms, and are clinically relevant. Hence, some prefer test results derived from IIF on specified substrates (i.e., HEp-2) and regard them as the “gold standard” for aab testing (Meroni and Schur, 2010; Satoh et al., 2009).

One of the arguments supporting continued use of IIF on HEp-2 substrates is that this substrate is essentially a mini-array containing more than 100 different target antigens whereas newer screening technologies such as ELISA, LIA, ALBIA, or CLA typically are configured to detect less than 20 different aab targets (Meroni and Schur, 2010; American College of Rheumatology, 2011). While the claim that numerous target autoantigens are expressed in HEp-2 cells is true from a molecular biology perspective, it should not be taken to mean that they are necessarily detectable by IIF on cells that are stabilized with a variety of fixatives, especially if certain

conformational epitopes are required for aab binding. Indeed, there is substantial evidence that IIF does not detect all aab in a given human sera even when they are directed to an autoantigen that is expressed in HEp-2 cells (Fritzler, 2016). For example, a significant proportion of sera that have aab directed to Jo-1 (histidyl tRNA synthetase) (Suzuki et al., 2014), ribosomal P proteins (Mahler et al., 2004; Somani et al., 2008), PCNA (Mahler et al., 2010), GW Bodies (Stinton et al., 2010), SSA/Ro60 (Op De Beeck et al., 2011), Ro52/TRIM21 (Peene et al., 2002; Schulte-Pelkum et al., 2009), and PM/Scl (Mahler and Fritzler, 2009) (to name a few) detected by ELISA, ALBIA, LIA, and CLA are often not detected by IIF on conventional HEp-2 substrates. It has been suggested that these “false-negative” IIF results are attributable to low aab titers, hidden or cryptic epitopes, technical features of antihuman secondary antibodies, and/or characteristics of the substrate (i.e., cell density, growth media, and fixation protocols). However, evidence to support any of these contentions has not been thoroughly studied or proven.

Further limitations of IIF testing are highlighted by the evidence that when five different manufacturer substrates and a characterized set of SARD sera were used and then read and interpreted by the same cadre of technologists, the agreement of test results was only 78% (Copple et al., 2012). And within the specific groups of serum samples, agreement ranged from only 44% for systemic sclerosis (SSc) samples to 72% agreement for the systemic LE (SLE) sera but, reassuringly, 93% for healthy control sera. In this particular study, variations in slide and substrate quality (i.e., clarity, consistency of fluorescence, cell size, number, and quality of mitotic cells) from different manufacturers were also noted. Therefore, along with problems of subjective interpretation, IIF on

HEp-2 substrates is subject to problematic issues of intermanufacturer and interlaboratory assay standardization ([Copple et al., 2007](#)).

Some of the issues plaguing IIF assays, particularly subjective reader bias, are partially addressed through the development of technology platforms that provide automated, digital reading of IIF ([Mahler et al., 2014a](#); [Hiemann et al., 2009](#); [Egerer et al., 2010](#)). These technologies have advantages of machine-learning algorithms and archival of digital images of the IIF result for subsequent review. In addition, some of these platforms require only a single serum dilution to derive a digital end point titer, resulting in significant cost savings ([Copple et al., 2014](#)). However, a current limitation of this technology is an inability to correctly classify complex IIF patterns in sera where multiple or less common aab are present.

At this juncture, it is important to refer to the emergence of cell-based IIF assays (CBA) that have taken a significant place in the repertoire of aab techniques ([Table 69.1](#)). In the CBA, a cell host is chosen and transfected with the cDNA of the desired antigen target and after the cDNA is overexpressed, the cells are stabilized and then used in a conventional IIF protocol to detect antibodies to the desired target. Untransfected cells or cells transfected with an irrelevant cDNA serve as controls. This approach has been particularly useful to produce a substrate to detect antibodies directed to targets in low abundance (i.e., SS-A/Ro60) ([Keech et al., 1996](#)) and/or highly conformational (i.e., PLA2R, NMDAR1 AQP4) targets ([Table 69.2](#)) ([Beck et al., 2009](#); [Gerstein et al., 2014](#); [Dalmau, 2016](#)).

In summary, the rapid proliferation of aab specificities along with the emergence and adoption of novel technologies has created a dilemma for standardization of aab testing protocols and the results that are communicated to clinicians ([Fritzler et al., 2003a](#); [Wiik et al., 2004](#)). Rapid advances in diagnostic technologies have made it difficult for even the most modern laboratory to keep abreast of the changes, not to mention clinicians who are hard pressed to keep abreast of new diagnostic paradigms that follow the adoption of the newer technologies.

## SPECTRUM OF AUTOANTIBODIES

In a single chapter, it is a challenge to cover the spectrum of aab that are now regarded disease-specific or disease-related diagnostic and prognostic biomarkers. Selected aab and their primary disease associations are shown in [Table 69.2](#) to illustrate the spectrum of diagnostic technologies used to detect them ([Table 69.2](#)). The task of a more comprehensive discussion of disease-related aab has been left to authors of other chapters in this book and is also detailed in other publications ([Conrad et al., 2017](#); [Conrad et al., 2015](#)). Given the variation of observations with the same technology or between different technologies, the spectrum of aab and their associated sensitivity or specificity is typically wide and needs to be interpreted in the context of the clinician's own clinical and laboratory setting. As an example of the complexity of data sets, there are now well over 10 different

diagnostics platforms (Table 69.1) and in autoimmune conditions such as SLE there are now over 200 aab catalogued (Sherer et al., 2004; Sherer and Shoenfeld, 2007), over 30 in SSc (Mehra et al., 2013; Kayser and Fritzler, 2015), and a growing number in autoimmune inflammatory myopathies (Tansley et al., 2013; Casciola-Rosen and Mammen, 2012; Mahler et al., 2014b; Lundberg et al., 2016). In contrast to SARD, in most organ-localized autoimmune diseases, the aab are typically directed to only one or a few antigens that tend to be harbored in the affected organ (Conrad et al., 2017).

A challenge in performing and interpreting aab test results is related to the complexity of the B-cell repertoire and the limited ability of assays to capture a complete profile of different aab subclasses, isotypes, and posttranslational modifications of both antibodies and antigens. Detection of this aab spectrum is highly dependent on the secondary antibodies and the target antigens used in various immunoassays. Hence, the relative clinical value of IgG, IgM, and IgA aab is not always clearly defined. In addition, there is evidence that IgG1, IgG3, and various immunoglobulin glycosylation patterns (galactosylation, sialylation) have greater pathogenic significance in some clinical settings (Feehally, 2017). One of the relatively new arrivals on the aab scene is a class of autoimmune diseases referred to as IgG4-related diseases (IgG4-RD) that encompasses a variety of clinical entities once regarded as being separate diseases (Mahajan et al., 2014; Wolfson and Hamilos, 2017; Bozzalla and Stone, 2017). Clinical manifestations of IgG4-RD have been reported in virtually all organ systems where they display consistent histopathological similarities: diffuse lymphoplasmacytic infiltrates, abundant IgG4-positive plasma cells, modest tissue eosinophilia, and extensive fibrosis (Khosroshahi et al., 2011). Polyclonal elevations of serum IgG4 are found in approximately 70% of patients and in some cases IgG4 aab directed to specific targets are found. In general, the strength of aab associations with autoimmune disease subgroups can vary according to the diagnostic techniques being used but also varies in accord with demographic, environmental, and genetic factors (Fritzler, 2006; Whelan and Isenberg, 2009).

## APPROACHES TO AND STANDARDIZING AUTOANTIBODY TESTING

As mentioned above, the IIF technique using HEp-2 or other cellular substrates is currently regarded by some as the preferred screening immunoassay to detect aab, especially in SARD. However, it is also important to appreciate that a negative IIF screening test does not necessarily exclude the presence of a wide spectrum of aab in SARD (Fritzler, 2012, 2016; Mahler et al., 2007; Salazar et al., 2014). Therefore, in the setting of high clinical suspicion of a SARD or another autoimmune disease (i.e., autoimmune hepatitis, juvenile arthritis with uveitis) and a negative IIF test, the identification of aab should include a more specific and sensitive assay that includes an array of relevant autoantigens. These newer technologies (Olsen et al., 2017; Fritzler and Fritzler, 2009; Mahler et al., 2011a) are described in more detail below. In general, the approach to requesting and screening for clinically relevant aab should be highly dependent on the differential diagnosis (Table 69.3) and a selected few IIF patterns are highly associated with specific autoantigens and diseases (Table 69.4). For example, the IIF test is a reliable screening test if the diagnosis of SLE, SSc, mixed connective disease, autoimmune hepatitis, and uveitis in juvenile arthritis is being considered. In this clinical context, if the ANA IIF screening test is negative and the clinical suspicion is high (i.e., high pretest probability), multiplexed disease-related aab testing is recommended (Table 69.3). By comparison, IIF is not a reliable screening test for Sjögren's syndrome, autoimmune inflammatory myopathies, antiphospholipid syndrome, vasculopathies, autoimmune encephalopathies, or autoimmune kidney diseases, to name a few. In these conditions, disease-specific and disease-related multiplexed assays should be considered the initial screening test of choice.

Because the evolution of clinically recognizable SARD and other autoimmune conditions can span decades before a diagnosis is firmly established, long-term longitudinal studies are ideally required to reach definitive conclusions about aab specificities. In the setting of very early SARD (i.e., SSc, SLE), screening for disease-specific aab may be more clinically relevant than ANA IIF screening (Choi et al., 2016; Choi and Fritzler, 2016).

With the emergence of the more sensitive immunoassays, care must be taken to ensure that cutoffs are based on age- and gender-matched healthy and comparative disease controls (Fritzler et al., 2003a; Bossuyt et al., 2008; Shoenfeld et al., 2007). Also, the source and characteristics (i.e., recombinant vs native, peptide vs full length) of the autoantigen used in different immunoassays can affect the results. Despite years of substantial effort, standardization of aab assays continues to be a major challenge (Satoh et al., 2009; Mahler et al., 2011a; Kessenbrock et al., 2007; Mahler and Fritzler, 2010).

For routine aab detection, many laboratories rely on commercial aab assay kits that employ a variety of technologies such as IIF, ID, IP, IB, LIA, ELISA, ALBIA, and CLA (Olsen et al., 2017; Mahler et al., 2011b). In the

**TABLE 69.3** Screening Autoantibody Tests for Systemic Autoimmune Rheumatic and Related Diseases

Disease: differential diagnosis	Screening test	Comments
Systemic lupus erythematosus	IIF HEp-2	Sensitivity >80%. If serum has single specificity antiribosomal P, SSA/Ro60 or anti-Ro52/TRIM21 IIF often negative; some anti-dsDNA positive sera can have negative ANA
Systemic sclerosis	IIF HEp-2	Sensitivity >85%. Newer autoantibodies (i.e., BICD2) not detected by IIF
Mixed connective tissue disease	IIF-HEp-2	Sensitivity >90%
Rheumatoid arthritis	RA-specific testing	In juvenile RA/inflammatory arthritis, ANA IIF is an important biomarker for development of uveitis
Autoimmune inflammatory myopathies	AIM-related array(s)	Approximately 50% of anti-Jo-1 (histidyl tRNA synthetase) can have cytoplasmic staining by IIF
Sjögren's syndrome	SjS-related array	HEp-2000 (ImmunoConcepts) engineered to detect anti-Ro60 by IIF in transfected HEp-2 cells (sensitivity ~85%)
Vasculopathies	Vasculitis-related testing: ANCA, PR3, MPO	In special cases, testing for "atypical" ANCA may be considered (i.e., antielastase for levamisole/cocaine-related vasculopathy)
Antiphospholipid syndrome	Anticardiolipin, anti-β2 glycoprotein I (domain 1), anti-PS/PT	
Autoimmune liver diseases	Disease-related arrays	IIF screen of antimitochondrial antibodies sensitivity of 80% for PBC; IIF ANA IIF may be helpful in diagnosis of autoimmune hepatitis; antibodies to "rods and rings" seen in patients with ribavirin-treated viral hepatitis

ANA, Antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; BICD2, bicaudal D2; IIF, indirect immunofluorescence; PS/PT, phosphatidyl serine/prothrombin complex; MPO, myeloperoxidase; PBC, primary biliary cholangitis; PR3, proteinase 3; TRIM21, tripartite motif 21.

**TABLE 69.4** Autoantibodies Determined by IIF Patterns That May Be Useful in Clinical Diagnostics

Cellular structure/IIF staining pattern/ICAP pattern designation <sup>a</sup>	Molecular targets	Disease associations
CENP-B/AC-3	Centromere B protein	lcSSc, PBC
Coiled bodies/AC-7	p80 coilin	Localized SSc, Raynaud's syndrome, also seen in association with DFS pattern (see below)
Dense fine speckled/AC-2	DFS70/LEDGF	Rare in SARD; in isolation, may rule out diagnosis of SARD
Golgi complex/AC-22	Golgins, giantin	SLE, SjS, RA overlap syndromes, malignancy, viral infection
GW bodies/AC-18	GW182, hAgo2, Ge-1/Hedls, RAP55	SjS, sensory/motor neuropathy, SLE, PBC
Mitotic spindle apparatus	Enolase, pericentrin, ninein	SSc, SjS, postviral syndromes
Centrioles/AC-24	NuMa 235	<i>Mycoplasma</i> infection
NuMa pattern/AC-26	HsEg5	SLE, SjS
Spindle microtubules/AC-25		SjS, SLE
Multiple nuclear dots/AC-6	SP-100	Primary biliary cirrhosis
Nuclear envelope/AC-11	Lamins A/C, B1, B2, LAP1/2	SLE, SjS, CAH, APS, SNP
Nuclear pore complex/AC-12	p62, gp210, Tpr	PBC, SjS

APS, Antiphospholipid antibody syndrome; CAH, chronic active hepatitis; dcSSc, diffuse cutaneous systemic sclerosis; DFS, dense fine speckles; ICAP, International Consensus on Autoantibody Patterns (see Fig. 69.1); lcSSc, limited cutaneous systemic sclerosis; LEDGF, lens epithelium-derived growth factor; NuMA, nuclear mitotic apparatus; PBC, primary biliary cirrhosis; RA, rheumatoid arthritis; SARD, systemic autoimmune rheumatic diseases; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; SNP, seronegative polyarthritis; SSc, systemic sclerosis; Tpr, translocated promoter region; IIF, indirect immunofluorescence.

quest to understand relationships between multiple aab, higher density antigen arrays are being used (Olsen et al., 2017; Sokolove et al., 2012; Dorner and Lipsky, 2016; Cohen, 2016). The use and application of these diagnostic platforms has been attended by certain considerations that are not always apparent to the clinician (Box 69.1). One of the more popular assay platforms is the ELISA because it offers high sensitivity, efficient throughput, only modest equipment required to perform the assay, all resulting in a relatively economical assay. Unfortunately, little has been done to standardize these kits (Feltkamp, 1996; Tan et al., 1999; Fritzler et al., 2003b) and postmarketing surveillance and quality assurance are largely left to the manufacturers (Fritzler et al., 2003a). Although the ELISA and other array technology kits are constantly being improved, high titer aab to a variety of autoantigens, especially those bearing discontinuous conformation epitopes, are often not detected. Hence, a report that indicates a “negative ELISA” screen should not be interpreted as “negative” for all relevant aab, because they might otherwise be detected by IIF, CBA, CLA, and/or other immunoassays.

Like ELISA, the performance of ALBIA also continues to improve and many studies show good agreement with other platforms (Fritzler and Fritzler, 2009; Shovman et al., 2005a; Hanly et al., 2010; Ronnelid, 2015). However, some ALBIA have limitations especially when comparing the results for specific analytes such as anti-dsDNA (Shovman et al., 2005b; Caramaschi et al., 2007; Avaniss-Aghajani et al., 2007; Bardin et al., 2009). In general, the same limitations and observations regarding progressive improvement of diagnostic accuracy apply to LIA (Almeida et al., 2010; Lee et al., 2012; Van Praet et al., 2011; Chandratilleke et al., 2016), although the use of LIA as a screening assay in individuals who have at least one criterion for SARD was found to be cost-effective (Wallace, 2006). An advantage of ALBIA and CLA over LIA and ELISA is that the target antigen is bound to a bead and the assay is then performed so that the aab can bind its target in the fluid phase rather than on a solid surface bearing the adsorbed antigen.

It has been suggested that because there is considerable variation in the sensitivity of the various commercial diagnostic kits, the identity of the particular assay used to generate the test result should be made available to the clinician (Meroni and Schur, 2010; American College of Rheumatology, 2011; Yazdany et al., 2013). In addition, because of the growing trend to use automated immunoassay systems that provide quantitative results, laboratories should follow standards of chemistry instrumentation including a requirement to demonstrate commutability, traceability, analytical measured ranges, and periodic calibrations (Meroni et al., 2014). Clinical laboratories that adopt multiplexed assays (i.e., ALBIA, CLA, and LIA) must establish reference ranges and cutoff values for each analyte, and the sensitivity and specificity must be established with care as the laboratory findings may present a difficult problem for the clinician who has to interpret the results.

#### **BOX 69.1**

#### **CONSIDERATIONS REGARDING THE CLINICAL INTERPRETATION OF AUTOANTIBODY TESTING**

- The definition of a positive autoantibody test is based on an empirically defined threshold.
- Autoantibodies are found in the sera of first degree relatives of patients, infectious diseases, malignancies, and normal individuals.
- Disease-specific autoantibodies can antedate diagnosis and in the context of early signs and symptoms of autoimmune diseases can be used as biomarkers to develop strategies for disease prevention and precision medicine.
- The approach to and interpretation of autoantibody testing in pediatric populations requires more thorough evaluation and evidence-based consensus.
- Autoantibody tests, once regarded as a tool for confirmation of a specific disease (i.e., IIF on HEp-2 cells for SLE), are used by a wide spectrum of health-care providers and for an ever-widening spectrum of autoimmune conditions.
- Limitations of assays based on subjective interpretation, such as indirect immunofluorescence, are being mitigated by the introduction of automated digital technologies.
- New high-throughput immunoassays and diagnostic assay platforms continue to emerge but new assays should only be adopted after validation of local performance.
- The advent of electronic medical records is enhancing the autoantibody reporting system.
- Short-term cost and budget restraints have an impact on autoantibody testing, while the long-term impact of autoantibody testing on total health-care expenditures and quality of life is mostly unreported.

## CLINICAL INTERPRETATION AND APPLICATION OF AUTOANTIBODY TESTING

As referred to earlier, it is important to appreciate some issues and limitations that impact on the interpretation and clinical application of aab tests (Box 69.1). Many of the perceived shortcomings of aab testing are due to a lack of thorough knowledge of autoimmunity, such as the perpetuation and perturbation of aab production, and the continuum of B-cell responses that span innate to acquired immunity (Fritzler, 2012). It is firmly established that any given human serum contains varying concentrations of a wide range of aab (Rose, 1996). As mentioned earlier, it is also important to understand that the measurement and assignment of an abnormal or elevated aab test are based on an empirically defined threshold, which, in turn, is dependent on numerous variables such as the equipment used to perform the assays, antihuman secondary antibodies, and adherence to manufacturer's protocols (Fritzler et al., 2003a; Wiik et al., 2004).

One of the most misused and misunderstood terms in aab testing is that the result is a "false positive." First, it needs to be recognized that there is substantial evidence that a number of aab can antedate the diagnosis of SARD and organ-specific autoimmune diseases by as much as 20 years (Arbuckle et al., 2003; Rose, 2007; Bizzaro et al., 2007; Senecal et al., 2008; Fritzler, 2008, 2011a; Meroni and Shoenfeld, 2008; Kallenberg, 2011; Villalta et al., 2012; Frech et al., 2016; Graf et al., 2012; Watad et al., 2014; Elnady et al., 2016; Nihtyanova and Denton, 2017). For example, antibodies to centromere proteins may antedate the clinical diagnosis of SSc (Choi and Fritzler, 2016; Wigley et al., 1992; Kallenberg et al., 1988) and antibodies to SS-A/Ro6 and dsDNA antedate the clinical diagnosis of SLE (Choi et al., 2016; Arbuckle et al., 2001, 2003) by many years. Second, even ANA-positive, apparently "healthy" individuals have been shown to exhibit dysregulation in multiple immune pathways (Slight-Webb et al., 2016). Therefore, unless there is a systematic laboratory error in performance of the test, the evidence indicates that the use of the term "false-positive aab test" should be used with caution and the dismissal of a person that may have an evolving autoinflammatory condition carefully considered. The performance characteristics of each test must be known to avoid misinterpretation, incorrect diagnosis, and potentially harmful treatment, outcomes that are commonly attributed to so-called false-positive tests. As diagnostic paradigms move more and more to precision medicine and disease prevention (Choi et al., 2016; Choi and Fritzler, 2016), an evidence-based understanding of aab and other biomarkers as predictors of disease needs to be more clearly defined. It is equally important to consider the impact of "false-negative" tests that can lead to delayed diagnoses and unnecessary morbidity (Fritzler, 2011c). Therefore, to achieve significant clinical utility, it is important to perform aab tests that discriminate between disease and the absence of disease, between emerging or subclinical disease, or between disease and confounding clinical conditions (Conrad et al., 2012).

Decades of clinical experience and research have led to the development of classification and diagnostic criteria to support the diagnosis of SARD and other autoimmune diseases, many of which include aab biomarkers (Kasukawa, 1987; Nishimaki et al., 1991; Hochberg, 1997; Petri et al., 2012; Jennette et al., 2013; Aletaha et al., 2010; Ferreira et al., 2015; Bossuyt et al., 2017). Since SARD frequently involve multiple organ systems, multiple criteria are required to support accurate classification. As a consequence, it is rare that a single criterion can be translated into certainty that a given diagnosis is correct or that a certain disease is emerging. To ensure that results from the immunology laboratory gain maximum utility for clinicians, it is important to study the performance of each aab assay as an aid to diagnostics in early disease because that is the time at which a serologic result would impact prognostic considerations the most (Fritzler, 2016; Conrad et al., 2012; Fenger et al., 2004). Since the clinical diagnosis may be established only after months or years of clinical follow-up, the more knowledgeable the clinician is with regards to the early clinical and laboratory characteristics of diseases, the greater the chance that a correct diagnosis will be made. Studies based on literature review and metanalysis have been published as "evidence-based guidelines" (Kavanaugh and Solomon, 2002; Solomon et al., 2002; Reveille and Solomon, 2003) but the translation of this information is limited because of the newer assays and assay parameters that have come into use since these studies and recommendations were published. The ongoing need for prospective, unbiased, and multicenter studies is needed to ensure that the clinical accuracy of contemporary aab testing is much clearer.

Many of the diseases listed in Table 69.2 have clinical subgroups with somewhat dissimilar manifestations and, hence, prognosis. These subgroups are often associated with different aab profiles and specificities (Cervera et al., 1993, 2002; Kuwana et al., 1994; Permin et al., 1978; Mustila et al., 2000; Wiik, 2001; Scussell-Lonzetti et al., 2002; Targoff, 2002). Therefore, certain aab are valuable biomarkers of a disease subgroup with markedly different clinical features, end organ involvement, and prognosis. Indeed, SARD subtypes and phenotypes based on aab profiles have been suggested to be more clinically relevant than other distinguishing features

or parameters (Mahler et al., 2014b; Walker et al., 2007; Agmon-Levin et al., 2012; Biesen et al., 2016; Allenbach et al., 2017). Accordingly, the information imparted by aab profiles, in combination with other biomarkers, is likely to be valuable in the future as an approach to tailoring therapeutic strategies (i.e., personalized or precision medicine) (Biesen et al., 2016; Fritzler, 2011b; Andrade, 2009; Plenge and Bridges, 2011; Tak, 2012).

With the introduction and adoption of newer diagnostic technology platforms, aab that were thought to be specific for one disease based on older or even outdated technologies may subsequently turn out to be associated with a variety of autoimmune diseases or other conditions (van Eenennaam et al., 2002; Vermeersch et al., 2009). The appreciation that multiple disease-related aab occur in a single serum and that aab expression may change over time in individual patients (von Muhlen and Tan, 1995; Blass et al., 1999; Vasiliauskienė et al., 2001; Visser et al., 2002) suggests that aab serology in combination with other biomarkers (i.e., genomics, cytokines, metabolomics, transcriptomics) may lead to an earlier and more accurate diagnosis, and by extension, more effective therapeutic interventions (Fritzler, 2016; Choi et al., 2016; Choi and Fritzler, 2016; Plenge and Bridges, 2011). While some evidence indicates that certain aab are stable over the disease course (Ippolito et al., 2011), other evidence indicates that aab profiles as determined by array technologies will likely change over time (reviewed in Fritzler, 2012). Evidence supporting this notion includes observations that aab to RNA helicase occur only early in the course of SLE (Yamasaki et al., 2007) and only clinically distinct neuropsychiatric events attributed to SLE that occurred around the time of diagnosis were found to be associated with anti-P antibodies and the lupus anticoagulant (antiphospholipid, anticardiolipin) (Hanly et al., 2008). Hence, multiplexed and autoantigen array technologies that are now emerging provide more extensive aab profiles in a given patient (Kessenbrock et al., 2007; Mahler and Fritzler, 2010) and are altering approaches to diagnostics and therapeutics (Schachna et al., 2002; Robinson et al., 2002; Fritzler, 2002).

## CLINICAL PRACTICE GUIDELINES

Because of the complexity of modern autoimmune serology, there is a pressing need for clinical practice guidelines (CPG) that outline the appropriate and economic use of serologic testing. If a limited number and spectrum of clinicians are involved in ordering diagnostic testing, it is easier to achieve a consensus on testing strategies. However, there is a growing trend toward amalgamation of local laboratories into regional and even national laboratories that provide high-throughput service to a widening spectrum of health-care providers. Clearly articulated CPG that establish criteria for aab screening and an evidence-based testing algorithm that reduces unnecessary laboratory testing and health-care expenditures (HCE) have been thought to be a productive approach (Wiik et al., 2004), including a proposal to reduce testing as part of the “Choosing Wisely” campaign (Yazdany et al., 2013; Chow et al., 2015). It has been suggested that a related strategy is to develop aab order forms in such a way that the doctor chooses between tentative diagnoses, after which only evidence-based tests are done. It is important to realize that the pretest probability to detect useful diagnostic laboratory results increases dramatically when each clinical feature or diagnostic criterion has been incorporated into the tentative diagnosis (Keren and Nakamura, 1997). However, if CPGs indicate that testing should only be done on patients that already have a high pretest probability of an autoimmune disease based on other clinical findings, it can be argued that the test is not likely to add much clinical value and probably shouldn’t be done at all (Fritzler, 2016). In addition, if significant inroads are going to be made into tempering HCE, it is clear that there needs to be a more concerted approach to prevention of SARD, which means that screening tests such as ANA, extractable nuclear antigen (ENA), and other disease-related biomarkers will likely be needed to identify patients with pre-clinical disease when inroads to prevention of morbidity due to end organ failure can be made (Fritzler, 2016).

A common misperception among clinicians and some health administrators is that in vitro diagnostics, such as ANA, ENA, and other biomarkers, account for a high proportion of HCE, when in actual practice the entire spectrum of in vitro diagnostics is in the range of 2%–5% HCE per year (Rohr et al., 2016). It should be no surprise that aab testing accounts for a rather small proportion of expenditures on in vitro diagnostics (Fritzler, 2016). Taken together, a balance needs to be achieved in aab testing where it can be used to help confirm a diagnosis where the clinician is pressed with the “intent to treat” the disease but also needs to include early disease identification with an “intent to prevent” disease (Fritzler, 2016). There is a serious deficiency in our knowledge of the actual costs incurred through inappropriate laboratory testing, although the actual costs of laboratory diagnostic testing can readily be calculated (Fritzler, 2016; Rohr et al., 2016).

The implications of HCE are intimately linked to the three overarching tenets of clinical medicine: first, disease prevention is of utmost importance; second, an early and accurate diagnosis is the next most important; and third

appropriate, effective treatment follows the first two. Many health-care providers and payers give close attention to the first and third tenets without due consideration of the second. An estimation of long-term HCE related to an early and accurate diagnosis, attended by evidence-based interventions (Choi et al., 2016; Choi and Fritzler, 2016) as compared to a missed or a wrong diagnosis, with or without treatment, needs to be performed to highlight the value of high-quality laboratory diagnostics (Fritzler, 2016).

## **LABORATORY REPORTS, ELECTRONIC MEDICAL RECORDS, AND COST ANALYSIS**

Many laboratories use an aab testing algorithm that includes a rapid and inexpensive screening test (i.e., IIF) followed by more specific tests (i.e., LIA, ALBIA, and ELISA) as an approach to evidence-based screening for serum aab. For example, the IIF test or whole cell lysate ELISAs are often used to detect aab in SARD and other diseases (reviewed in Fritzler, 2011c, 2012; Stinton and Fritzler, 2007). This serves two purposes: first, as an approach to triage samples for further reflex testing; second, if the IIF or screening ELISA test is negative, unless there is a compelling clinical evidence to do so, no further testing is required and the result is reported as such. However, as discussed earlier, there is a caveat insomuch as the sensitivity of IIF testing is not as high as some presume and is attended by significant “false-negative” results (Pisetsky, 2017; Fritzler, 2011c). Although a few aab can be quite accurately identified solely by IIF screening (Table 69.4), as more and more aab are identified in SARD and other autoimmune conditions with overlapping clinical features, the usefulness of IIF as a screening test is diminishing. Hence, some laboratories have inverted the testing algorithm and screen with technologies that include a wide spectrum of target autoantigens and if that test is negative, then the test might be reflexed to an IIF test (Meroni and Schur, 2010; Fritzler, 2011a,c). More recent analysis, ahs indicated that combining IIF with solid phase immunoassays as a screen for SARD may be the most effective approach (Bizzaro et al., 2018)

It is very important to validate aab test results through regular quality assurance and quality control programs. In this context, borderline (low positive) test results can be especially troublesome. It is recommended that borderline-positive results must be confirmed or refuted to ensure that only certified positive results are reported. If uncertainty about the result persists, the laboratory should add a note of caution to the test report that the result may have limited significance in supporting a diagnosis and/or may recommend retesting a new serum sample in 2–6 months, or sooner if clinical features continue to progress or accumulate. Some regulatory agencies mandate that borderline-positive tests should be reported as positive until proven otherwise after repeat or follow-up testing at appropriate intervals. High and intermediate positive results of a single credible technique can be reported without independent confirmation by a second technique. To aid in the interpretation of laboratory results, the chosen limit for positivity should be stated in the report along with ranges of low, intermediate, and strong positivity.

A persistent problem is that easy to perform and high-throughput techniques are often adopted by clinical laboratories without proper clinical validation. As discussed above, screening for aab by ELISA that have adsorbed complex mixtures of native and/or recombinant autoantigens or nuclear extracts is now used by many laboratories instead of IIF ANA screening. This practice continues despite data showing that many patients with Sjögren's syndrome, SSc, autoimmune myopathies, and juvenile rheumatoid arthritis score negative for ANA using such composite ELISA screening techniques (Keren and Nakamura, 1997; Fawcett et al., 1999). While these alternative screening assays have improved remarkably over the last few years, HEp-2-IIF screening of these *false-negative* sera reveals that many of these sera contain aab to a variety of targets including nucleoli, nuclear matrix, nuclear envelope, nuclear pores, coiled bodies, promyelocyte leukemia domains, cell cycle-specific antigens such as PCNA and mitotic spindle apparatus components, or other cytoplasmic organelles and structures such as mitochondria, Golgi apparatus, signal recognition particle, or ribosomal proteins (Stinton et al., 2004; Bayer et al., 1999; Wiik, 2003a,b) (Tables 69.2 and 69.4).

Studies using older screening ELISAs have shown that some of these aab are readily recognized by experienced technicians (Wiik and Lam, 2001) but are missed by ELISAs for ANA screening (Bayer et al., 1999). Some of these aab have defined clinical associations and should be identified as such (Table 69.4). It needs to be emphasized that newer technologies and wider testing have not supported clinical associations of some aab. For example, anti-PCNA aab once thought to be highly specific for SLE have recently been shown to lack specific disease associations (Vermeersch et al., 2009; Merkel et al., 2012). Aab that lack proven clinical value should be reported but it must be clearly stated that their diagnostic specificity or value has not been clearly established.

At this point, it is important to point out that not all aab are diagnostic of or associated with clinically apparent autoimmune diseases. This includes established evidence that disease-specific aab can be detected in first degree relatives of autoimmune diseases patients, in individuals harboring a variety of bacterial and viral infections, or in apparently unrelated conditions and healthy individuals. Several lines of evidence indicate that approximately 20% of serum samples from apparently healthy individuals have a positive ANA test, a significant proportion of which produce an IIF pattern known as dense fine speckles (DFS) (Mahler et al., 2016; Ochs et al., 2016). Of note, the DFS staining pattern has been reported in 33% of ANA-positive healthy individuals, but not in ANA-positive SARD sera (Mariz et al., 2011). Since their first description, anti-DFS70 antibodies have been found in the sera of patients with a variety of chronic inflammatory conditions, such as interstitial cystitis, atopic dermatitis, as well as cancer and healthy individuals (reviewed in Mahler et al., 2016; Ochs et al., 2016). The typical IIF DFS staining pattern is observed as small speckles that are somewhat uniformly distributed throughout the nucleus and, notably, on metaphase chromatin. The target autoantigen is a 70-kDa protein and the target antigen was initially termed DFS70, but the primary target autoantigen was eventually identified as the lens epithelium-derived growth factor (LEDGF) (reviewed in Ochs et al., 2016). Since the intended use of the ANA HEp-2 test is to primarily serve as a screening test to aid in the diagnosis of SARD, the reporting of anti-DFS70 antibodies as a positive test significantly reduces the specificity and the positive likelihood of the ANA IIF test. This has important implications for ANA test algorithms because if these results are widely validated, it suggests that aab associated with DFS70/LEDGF can be used to rule out the diagnosis of SARD (Fitch-Rogalsky et al., 2014; Mahler et al., 2012; Mahler et al., 2019).

When aab are detected, the positive result is usually communicated in a printed or digital report that is sent directly to the requesting physician or the referring laboratory. Unfortunately, in some jurisdictions, regulatory constraints (i.e., Health Protection Act and Freedom of Information Acts) prohibit the transmission of a digital report directly to the referring physician's computer or other digital devices. Nevertheless, there is a trend in many jurisdictions to rapidly adopt EMRs that will accommodate uploading encrypted or otherwise secure data files directly to online or "cloud" storage of patient medical records. For many laboratories, this has added another layer of protocols and standard operating procedures that are intended to protect patient confidentiality. Efforts to develop consensus on the format and structure of the EMR, along with consensus terminology and content of aab results, would be an important step forward in standardizing the aab testing system (Pincus et al., 2009; Malaviya and Gogia, 2010; Wiik et al., 2010; Vogt et al., 2004). A number of advantages and disadvantages of the EMR have been identified (van der Vaart et al., 2013; Liao et al., 2010 Aug) (Box 69.2). The questions and concerns regarding unlimited access of patients to their EMR is unsettled (van der Vaart et al., 2013). While information on diagnosis, treatment plan, and consultations might be released for patient access, more complex data, such as physical examinations, laboratory results, and radiographic images, is more controversial. There is some thought that providing patients random access to their EMR might be an important step to empowering and enhancing patient service, provided that clinical and personal data and information security is optimal, and content and presentation of data are constructed so that they are clearly understood by patient and physician alike.

#### BOX 69.2

#### ADVANTAGES AND DISADVANTAGES OF THE EMR

##### Advantages

- Improved turnaround time and accessibility to laboratory results
- Eliminating part of "paper trail" improves accuracy of reporting
- Increased knowledge of the patient's disease status
- Improved interaction of patient with health-care providers
- Increased patient safety
- More knowledgeable patients involved in self-management

- Enhanced communication with health-care team
- Elimination of lower security multiple paper records and mailed/faxed paper reports
- Higher security of health information

##### Disadvantages

- Challenges interpreting reports and data
- Additional security protocols and standard operating procedures adds extra workload
- Consultation content changed
- Altered face-to-face patient-provider interactions

A description of the most common diagnostic associations related to an aab found in diagnostic testing should be included with the result. Also, the level (titer) of the aab or the strength of expression should be mentioned together with how these relate to cutoff values and how they were established (i.e., disease controls, normal controls, and the range of credible measurements).

## STANDARDIZATION AND QUALITY ASSURANCE

There is little debate that the most important issue that impacts on aab testing is standardization of test performance, and test result nomenclature and interpretation. Thankfully, there are substantial coordinated and cooperative efforts in various jurisdictions that are addressing these and related issues (Box 69.3). An example of this activity is ongoing concerted efforts of a subcommittee of the Autoantibody Standardization Committee, the International Consensus on Autoantibody Patterns (<https://anapatterns.org/index.php>) to achieve a standardized nomenclature of the different ANA IIF patterns observed on HEp-2 substrates (Damoiseaux and von Muhlen, 2016; Chan et al., 2016). This important activity allows laboratory personnel, diagnosticians, and clinicians alike to use a common nomenclature in research as well as diagnostic laboratory reports. The goal, now at least partially attained, was to assign both common nomenclature and a code to each of the most common aab IIF patterns observed in diagnostic laboratories (Fig. 69.1). On the surface, this may seem

### BOX 69.3

#### INTERNATIONAL EFFORTS TO STANDARDIZE AUTOANTIBODY TESTING

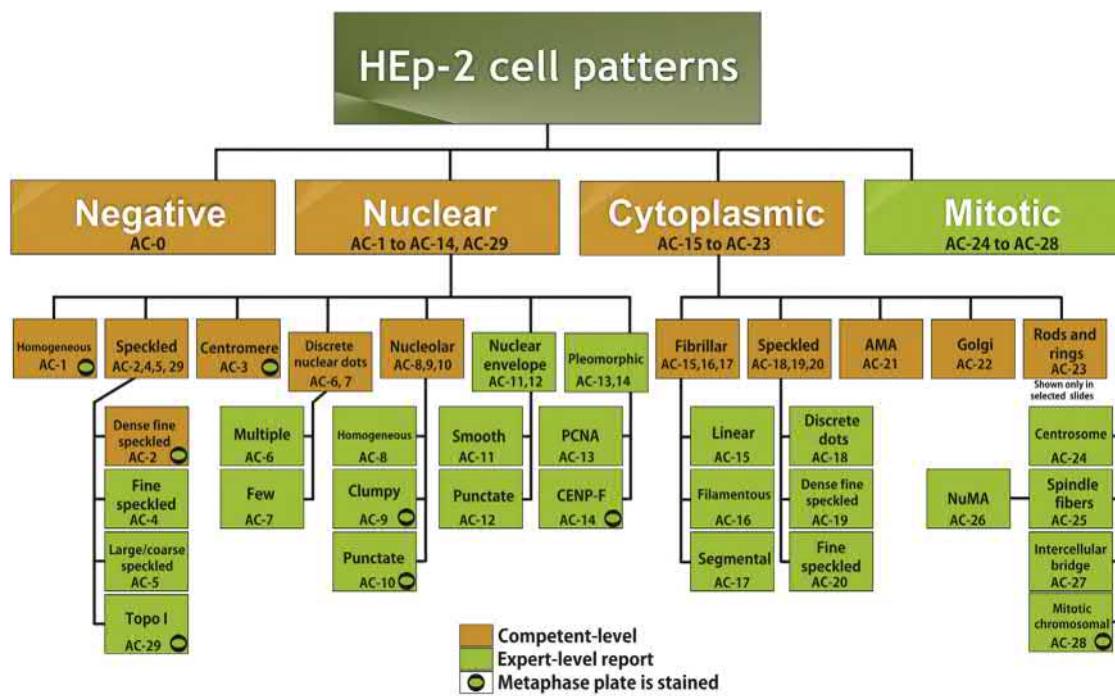

##### Committees and Leadership

- Royal College of Pathologists of Australasia—Quality Assurance Program (RCPAQAP): Louise Wienholt, Sydney, Australia
- Autoantibody Standardization Committee/International Union of Immunology Societies (ASSC/IUIS): Edward K.L. Chan, Gainesville, Florida, USA
- European Autoantibody Standardization Initiative (EASI): Jan Damoiseaux, Maastricht University Medical Centre, Maastricht, Netherlands.
- European Consensus Finding Study Group on Autoantibodies (ECFSGA): Johan Rönnelid, Uppsala, Sweden
- International Federation of Clinical Chemistry Committee on Harmonization of Autoimmune Tests (IFCC C-HAT): Joanna Sheldon, London, UK
- National Institute for Biological Standards and Control/World Health Organization (NIBSC/WHO): Bernard Fox and Lucy Studholme, Potters Bar, Herts, United Kingdom

##### Issues Under Consideration

- There is a need to coordinate the efforts of all the Committees.

- Training and ongoing competency of technologists and clinicians who read ANA slides I accord with expectations of ISO 15189.
- As various jurisdictions move to electronic medical records, standardized nomenclature and reporting of test results are needed.
- Since reference materials have different performance characteristics, their performance in different diagnostic platforms and protocols should be specified.
- New reference samples should be identified and made available.
- Address logistics (i.e., preparation, storage, quality assurance/quality control, distribution, financial support to assure sustainability) of making reliable reference materials available.
- Given continuously changing platforms for autoantibody detection, a strategy for ongoing validation is needed.
- Industry and other parties need samples from well-defined disease and control cohorts.
- Diagnostic manufacturers should be encouraged and incented to calibrate their kits according to the reference standards and the units of activity assigned to them.
- Effective communication and education of the medical, scientific, and industry communities.

[www.anapatterns.org](http://www.anapatterns.org)

**FIGURE 69.1** Consensus nomenclature of IIF staining patterns on HEp-2 substrate established by the ICAP (<https://www.anapatterns.org/>), a subcommittee of the Autoantibody Standardization Committee ([www.AutoAb.org](http://www.AutoAb.org)) (Damoiseaux and von Muhlen, 2016; Chan et al., 2015, 2016). ICAP, International Consensus on Autoantibody Patterns; IIF, indirect immunofluorescence.

like a straight forward exercise, but it has taken more than 5 years and four meetings to arrive at the current level of consensus, and even then some challenges remain. Most notably, the focus has shifted to the goal of standardizing reports and also the appropriate recognition of complex (multiple) IIF patterns that are often found in single sera (Damoiseaux and von Muhlen, 2016).

A number of jurisdictions have also recognized the importance of standardizing the technical aspects of aab testing (Shoenfeld et al., 2007; Wiik et al., 2006) and a set of standardized sera provided by the IUIS/AF/WHO/CDC Serology Committee ([www.autoab.org](http://www.autoab.org)) are currently available. Over the past two decades, these samples were available through the Centers for Disease Control (CDC) in Atlanta (Chan et al., 2007) but are now made available through the auspices of Plasma Services Group in Huntingdon Valley, Pennsylvania, USA (<https://www.plasmaservicesgroup.com/>). These reference sera have been continuously monitored and more recent additions to the reference sera available include those with defined aab directed to a number of aab targets (Box 69.3). Sera used as standards for a particular methodology or technology platform need to be reviewed from time to time as exemplified by the reevaluation of AF/CDC reference sera by a variety of contemporary techniques (Copple et al., 2012; Smolen et al., 1997). Although it would likely decrease interlaboratory variation in performance, standardized secondary antibodies are not widely utilized.

All clinical laboratories should participate in quality assurance and quality improvement programs such as the one administered by the College of American Pathologists ([www.cap.org](http://www.cap.org)) and the Royal College of Pathologists of Australasia, to name only two. The Clinical Laboratory Improvement Amendments of 1988 set standards for all laboratories engaged in clinical testing. These standards include requirements for trained and competent supervisory and testing personnel, record keeping and instrument maintenance, daily quality control practices, result reporting, and laboratory inspection and maintenance. It is not clear that these standards are being met in routine practice. In Europe and some other jurisdictions, the most widely used quality assurance and management program (DS/EN ISO/IEC 17025:2000) additionally sets laboratory standards aimed to prove that an assay actually gives results that are useful for clinical diagnostics.

## SUMMARY

Aab can serve as valuable biomarkers for early disease detection and case finding as well as confirmation of a diagnosis when it is the clinician's intention to treat the disease. Aab testing also drives the clinician's attention to involved tissues or organs using classical diagnostic tools such as histopathology, imaging techniques, and organ function testing. CPG to facilitate the communication between clinicians and laboratories need to be formulated, along with mutually accepted algorithms for test ordering and interpretation. The emergence of the EMR is a significant step forward but is attended by some logistic and ethical challenges.

In contemporary medical practice, changes in laboratory diagnostics and new technologies to detect aab are being introduced at a rapid pace. This is attended by concerns that certain key matters, such as clinical utility, are not thoroughly addressed. In many cases, the manufacturer has often been assumed to be the root cause for shortcomings in aab testing; however, the cost-effective use of commercial kits and their appropriate application in a clinical setting involves a rather complex set of contingencies and considerations (Fritzler, 2012, 2016; Fritzler et al., 2003a). It has been suggested that a higher level of commitment and partnership between all of the participants is required to achieve the goal of improving the quality of patient care through the use of aab testing and accurate interpretation of the results (Fritzler et al., 2003a; Wiik et al., 2004).

Virus Vaccination	1402		
Antigen-Specific Immunotherapy	1402	Further Reading	1413
Secondary Prevention	1402		

## OVERVIEW OF TYPE 1 DIABETES

### Autoimmune Pathology

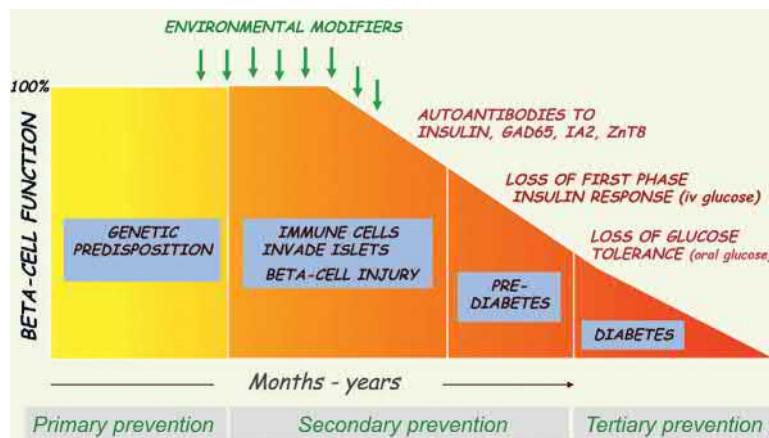

From the 1970s, it has gradually become clearer that type 1 diabetes (T1D) is an autoimmune disease (Eisenbarth, 1986). The evidence includes infiltration of the islets by immune cells (Gepts, 1965; Foulis et al., 1986), strong genetic risk associated with specific classes I and II human leukocyte antigen (HLA) genes coding for molecules that present peptide antigens to T cells, as well as with the insulin gene and a range of immune genes (Concannon et al., 2009), circulating autoantibodies to beta-cell antigens (Verge et al., 1996; Colman et al., 2000; Bingley et al., 1999; Ziegler et al., 2013), T cells in the blood (Harrison et al., 1993; Mannerling et al., 2005) and pancreas (Pathiraja et al., 2015) that recognize insulin and other beta-cell antigens, a report of recurrent immune beta-cell destruction after pancreatic isograft transplantation without immunosuppression between identical twins discordant for T1D (Sutherland et al., 1989), occasional reports of T1D after bone marrow transplantation from a T1D donor (Lampeter et al., 1998a,b) and induction of T1D by immune checkpoint inhibitor antibodies (Kapke et al., 2017). Beta-cell destruction in T1D is mediated by autoreactive T cells, the ultimate effectors being CD8 cytotoxic T cells. The evidence for this is unequivocal in the inbred nonobese mouse (NOD) model of T1D, which shares a number of key features with T1D in outbred humans (Leiter et al., 1987; Adorini et al., 2002).

The molecular mechanisms of beta-cell death, gleaned mostly from the NOD mouse, encompass a combination of apoptosis induced by activation of extrinsic (e.g., TNF receptor or Fas ligation) or intrinsic (e.g., endoplasmic reticulum stress) death pathways and necroptosis induced by cytotoxic CD8 T-cell granule components

(granzymes and perforin), reactive oxygen species, or ischemia. The NOD mouse has also served to demonstrate proof-of-principle for preventative therapies that could translate to humans.

Two major distinctions between T1D and other autoimmune diseases, that allow those at risk to be identified and, therefore, are requisite for prevention, are the major contribution of HLA genes to risk and the ability to identify children many months to years before eventual loss of most beta-cell function leads to clinical presentation (Fig. 70.1). Birth cohort studies of children with a T1D relative have shown that the development of diabetes by the age of 18 years is almost always associated with the appearance of islet autoantibodies in the first years of life. Of children with two or more islet autoantibodies before the age of 3 years, 57% (95% CI: 51.7%–62.3%) and 74.8% (95% CI: 69.7%–79.9%) progressed to diabetes by 6 and 10 years, respectively; with a single islet autoantibody, 14.5% progressed to diabetes by 10 years (Ziegler et al., 2013). In order to prevent T1D, a paradigm shift is necessary to redefine the disease as an autoimmune beta-cell disorder from the beginning of the asymptomatic phase of islet autoimmunity (Stage 1), rather than as a metabolic disorder of end-stage pathology (Stage 3) (Couper and Harrison, in press).

In children, the diagnosis of T1D at clinical presentation is usually based on symptoms and signs, but can be confirmed, and in older individuals established, by detecting circulating islet autoantibodies to beta-cell antigens, to insulin (IAA), glutamic acid decarboxylase 65,000 mol. wt. isoform (GADA), insulinoma-like antigen-2 (IA-2A), and zinc transporter-8. One or more autoantibody specificities is present in at least 90% of Caucasian children with T1D compared to ~1% of the general population, but in only ~50% of the Hispanic-American and African-American children diagnosed with T1D. IAA are more often the first sign of islet autoimmunity in children followed from birth and is the most predictive autoantibody. A family history of T1D in close relatives is present in only 10%–15% of newly diagnosed cases. However, affected families have provided major insights into the genetics and natural history of T1D. In T1D relatives the rate of progression to clinical diabetes is positively associated with the number and titer of islet autoantibodies (Verge et al., 1996; Bingley et al., 1999; Colman et al., 2000; Ziegler et al., 2013), the number and type of HLA classes I and II risk alleles (Honeyman et al., 1995; Tait et al., 1995) and the degree of insulin resistance (Fourlanos et al., 2004) and is negatively associated with age (Table 70.1).

**FIGURE 70.1** Stages in the natural history of type 1 diabetes.

**TABLE 70.1** Markers of Risk for Diabetes in Islet Autoantibody-Positive Relatives

- Number of antigen specificities of islet autoantibodies
- Antigen specificity of islet autoantibody
- Level of islet autoantibody
- Age at detection of islet autoantibody
- FPIR to i.v. glucose
- Insulin resistance, for example, estimated as HOMA-R
- HLA alleles for risk or protection
- HLA haplotype sharing with proband
- Kinship with proband
- Body mass index

FPIR, First phase insulin response; HOMA-R, Homeostatic model assessment-insulin resistance.

## Nature and Nurture

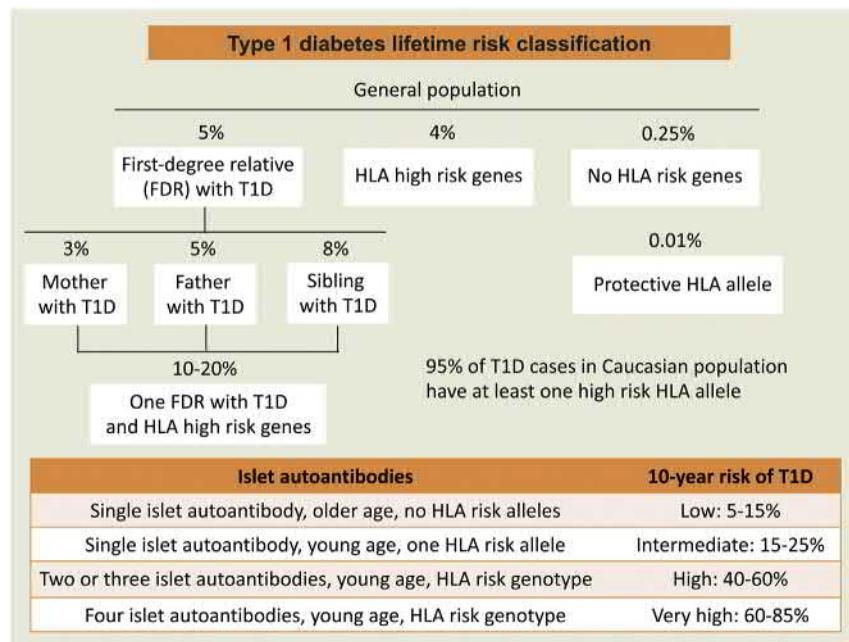

The incidence of T1D is highest in Caucasian northwest Europeans. This reflects the distribution of specific risk HLA genes, which account for up to 50% of the lifetime risk for T1D (Table 70.2).

However, the incidence of T1D has been rising on a background of lower risk HLA alleles. In Western European societies, the incidence in childhood has more than doubled since the 1980s and has been rising at ~3% annually, particularly in younger children (Gale, 2002). The same trend is beginning to be seen in countries such as Kuwait and Saudi Arabia, and areas of India and China that have adopted Western lifestyles, but where the prevalence of high-risk HLA genotypes for T1D is much lower. Environmental factors may increase the penetrance of risk genes for T1D. In the case of HLA genes, the increasing incidence of T1D is accounted for by children with intermediate (DR 4, 4 or DR 3, 3) or low (DR 4, X or DR 3, X) risk phenotypes, not the highest risk HLA phenotypes (DR 3, 4; DQ 2, 8) (Fourlanos et al., 2008). Interestingly, these lower risk HLA phenotypes are the ones seen in non-Caucasians and in adults presenting with T1D.

The environment in Western societies has changed dramatically during the last century including in ways that have been associated either epidemiologically or in animal studies with a rising incidence of T1D (Wentworth et al., 2009). A marker of the modern “exposome” is obesity, associated with insulin resistance and type 2 diabetes, and with alterations in the gut microbiome. When children at increased genetic risk for T1D (with an affected first-degree relative) were monitored from birth, weight gain in the first 2–3 years of life was a risk factor for islet autoimmunity (Couper et al., 2009). In at-risk children who developed islet autoantibodies, insulin resistance was an independent marker of those who progressed most rapidly to clinical diabetes (Fourlanos et al., 2004). Whether insulin resistance promotes the development of islet autoimmunity is an important question that can be answered by an ongoing pregnancy–birth cohort study (Penn et al., 2013). Thus, insulin resistance associated with obesity could synergize with impaired beta-cell function to accelerate the development of T1D, justifying attention to environment–lifestyle factors to forestall or prevent T1D.

Obesity is the outcome of increased energy consumption and changed diet composition, both readily provided by the modern “Western” diet. This diet lacks diversity of components, lacks plant-derived prebiotics and complex carbohydrates (starches and fiber), is high in saturated fats, sucrose, and fructose, and contains artificial preservatives, emulsifiers, and sweeteners. All of these alter the composition of the gut microbiome and reduce its diversity, which are features of the gut microbiome in children at risk (Dunne et al., 2014;

**TABLE 70.2** Lifetime Risks for Type 1 Diabetes

**Knip and Siljander, 2016).** Diets containing a diverse range of plant products (cereals, fresh fruits vegetables, nuts, seeds) provide complex carbohydrates for fermentation by colonic bacteria to short-chain fatty acids such as butyrate, propionate, and acetate, and other antiinflammatory products (Thorburn et al., 2014).

Microbial colonization of the gut is required for development of a normal immune system and the maintenance of gut epithelial homeostasis and “barrier function” mediated by products such as butyrate and mucins (Yu et al. 2012). It is no surprise therefore that the microbiome—the trillions of microorganisms (bacteria, fungi, archaea, protozoa, viruses) and their millions of genes and proteins that reside within our mucosae, skin, and secretions at the interface with the world—has come under increasing focus as a bellwether of health and disease.

In the NOD mouse, the incidence of autoimmune diabetes is markedly altered by changes in the microbiome in combination with diet. The incidence of spontaneous diabetes in NOD mice differs greatly between colonies around the world and is inversely correlated with exposure to microbial infection (Pozzilli et al., 1993). The high incidence of diabetes in NOD mice housed under pathogen-free conditions is reduced by conventional conditions of housing and feeding (Suzuki, 1987). Under such conditions, bacterial colonization of the intestine is accompanied by maturation of mucosal immune function (Kawaguchi-Miyashita et al., 1996). In germ-free on a defined, sterile diet the incidence of disease compared to specific pathogen-free (SPF) mice is accelerated and increased from 70% to 100% (Mariño et al., 2017). Provision of a diet high in butyrate and acetate to NOD mice in SPF conditions almost totally prevented diabetes (Mariño et al., 2017). The counterpart in humans may be modern Finland and its Russian neighbor Karelia. Finland has the highest incidence of T1D in the world, currently 57.6 cases/100,000 population  $\leq$  14 years ([www.diabetesatlas.org](http://www.diabetesatlas.org)). In 2005, there was a 6-fold difference in the incidence of T1D between Finland and Karelia, despite overlap in ethnic background and a similar distribution of high-risk HLA genotypes (Kondrashova et al., 2005). This marked difference in the incidence of T1D is associated in Finnish children with decreased gut bacterial microbiome diversity, a dominance of the phylum Bacteroidetes over Firmicutes and a deficiency of butyrate- and mucin-producing bacteria (Kostic et al., 2015). These changes were seen after the appearance of autoantibodies, suggesting that they followed rather than preceded the disease process. However, a further small study in Finnish children identified a relative abundance of *Bacteroides dorei*, which peaked around 7–8 months of age with the introduction of solids and preceded the appearance of islet autoantibodies (Davis-Richardson et al., 2014). Gut *Bacteroides* species are abundant in Finnish children, including *B. dorei*, which produces a lipopolysaccharide (LPS) endotoxin that inhibits the immunostimulatory activity of *Escherichia coli* LPS, known to protect against diabetes development in NOD mice (Vatanen et al., 2016). Individuals with T1D and even those with islet autoantibodies at risk for T1D, have impaired barrier function with increased “leakiness” through intercellular gap junctions (Bosi et al., 2006), consistent with the descriptions of the altered composition and decreased diversity of the microbiome in T1D. We noted some years ago that “gut leakiness,” reflected by increased titers of antibodies to food components, was present even in T1D and celiac disease relatives with the HLA A1-B8-DR3-DQ2 risk haplotype (Harrison and Honeyman, 1999). This is consistent with more recent evidence for a relationship between the microbiome and host genome. The question, does “gut leakiness” precede the development of islet autoimmunity, and how does it relate to the microbiome and to T1D genetics, has not been fully answered. We found that among asymptomatic children with islet autoantibodies those who progressed most rapidly to diabetes had lower gut microbial diversity with deficiency of the *Prevotella* genus and increased gut permeability (Harbison et al., 2018).

The presentation of clinical T1D peaks in winter (Moltchanova et al., 2009), attributed to environmental factors such as increased number of virus infections and a decrease in vitamin D. However, given the long presymptomatic stage of disease, these would appear to represent nonspecific precipitants. Viruses, in particular enteroviruses, are proposed as a cause of T1D but the evidence remains circumstantial (Honeyman 2005; Roivainen and Klingel 2010). Viral mechanisms in T1D could be direct or indirect, for example, infection of  $\beta$  cells, infection of the exocrine pancreas with bystander death of  $\beta$  cells, mimicry between T-cell epitopes in a viral protein and beta-cell autoantigens, or activation of endogenous retroviruses in  $\beta$  cells by environmental agents. If an exogenous virus was clearly identified then protective vaccination in early in life would be an approach to primary prevention. However, if a specific enterovirus strain was shown to be diabetogenic, creating a vaccine may be challenging because among the many thousands of strain variants, the only one for which a vaccine currently exists is poliovirus. The first virus to be associated with T1D was rubella (Forrest et al., 1971). Children with congenital rubella born to mothers who contracted rubella early in pregnancy had evidence of infection in the brain, pancreas, and other tissues and 20% developed insulin-dependent diabetes (Menser et al., 1978). Subsequently, almost twice this proportion was reported to develop islet cell antibodies (ICAs) (Ginsberg-Fellner et al., 1985). Children with congenital rubella and ensuing diabetes had a higher frequency of the T1D susceptibility HLA class I phenotype A1 (Menser et al., 1974), on the risk haplotype HLA A1-B8-[DR3-DQ2]. Rubella vaccine virtually eliminated

congenital rubella but obviously not T1D; clearly many other environmental factors must be involved, mumps virus epidemics have been associated with T1D onset after 2–4 years and introduction of a mumps vaccine was associated with a plateau in the rising incidence of T1D in Finland, but this was temporary and mumps vaccination has clearly not prevented T1D. Rotavirus (RV) is the commonest cause of gastroenteritis in young children. The discovery of strong sequence similarities between T-cell epitopes in the VP7 protein of rotavirus and GAD and IA-2 islet antigens in autoantibody-positive children led to speculation that mimicry with rotavirus might contribute to islet autoimmunity. Subsequently, in the Australian BabyDiab Study, rotavirus infection was associated with the first appearance of or an increase in islet autoantibodies in children (Honeyman et al., 2000). Moreover, rotavirus infects  $\beta$  cells in islets of mice, pigs, and monkeys, and was recently shown to cause transient involution of the pancreas and hyperglycemia in a toll-like receptor (TLR)-3-dependent manner in mice (Honeyman et al., 2014). Ubiquitous rotavirus infections that drive cross-reactive immunity to islet autoantigens are unlikely to be diabetogenic but could complement and sustain the immune response following direct infection of  $\beta$  cells. Recently, in Australian children aged less than 4 years, it was shown that the number of incident cases of T1D has decreased by 14% (RR 0.86) following the introduction of oral RV vaccine in 2007 (Perrett et al., 2019). As with mumps, the significance of this observation requires ongoing surveillance, and confirmation from an ongoing case-control linkage study.

## PREVENTION OF TYPE 1 DIABETES

Progress in understanding mechanisms of beta-cell destruction, the ability to identify individuals at high risk for T1D, and proof-of-principle for preventative therapies in the NOD mouse model set the scene for preventing or arresting autoimmune beta-cell damage in humans. This goal is relevant not only to individuals at risk but to those with clinical diabetes, in order to preserve residual beta-cell function, permit possible beta-cell regeneration and prevent recurrent autoimmune disease after therapeutic beta-cell replacement or regeneration. It will be eminently more achievable with increasing acceptance that T1D is an autoimmune disease that begins early in life, which is when intervention for primary or secondary prevention should logically begin and not at the time of end-stage pathology and clinical presentation. Newer biologic agents that are disease-sparing in autoimmune diseases such as rheumatoid arthritis would never be expected to reverse end-stage joint pathology. The caveat is that any form of treatment given to asymptomatic, at-risk children must have an excellent safety profile—*“Primum non nocere”* (first do no harm)—because even in islet autoantibody-positive children prediction of clinical disease is not 100%.

Population heterogeneity is a critical consideration in the design and interpretation of clinical trials. In addition to HLA genes, over 50 genetic loci are associated with T1D, but very little is known about how they contribute to disease development in different environments or influence prevention strategies. Although a restricted set of HLA genes is shared among individuals with T1D, HLA-based heterogeneity in age at clinical presentation is well known (Honeyman et al., 1995; Tait et al., 1995). This suggests that T1D comprises disease subtypes and that prevention will most likely require a more “personalized” approach. Indeed, it is known that the natural history of declining beta-cell function after diagnosis depends on age, HLA status, autoimmune status including number and level of islet autoantibodies, residual beta-cell function, and insulin resistance (Greenbaum and Harrison, 2003). Inclusion of T1D relatives in secondary prevention trials has been based on age (<40) and islet autoantibodies ( $\geq 2$ ), for a predicted 5-year incidence of ~40%, but more refinement is possible by building subtype analysis into trial design. Up to 10% of adults presenting with diabetes have what appears to be a slowly progressive form of T1D, associated mainly with GAD65 autoantibodies, which initially is noninsulin-requiring (Gottsater et al., 1995; Hagopian et al., 1993; Tuomi et al., 1993; Turner et al., 1997). They have higher residual beta-cell function at diagnosis than younger patients with classical T1D, which implies a wider and perhaps more penetrable therapeutic window for secondary prevention (Fourlanos et al., 2005). The “personalized” approach requires new robust surrogate assays of disease mechanisms to identify people most likely to benefit from a specific therapy and allow the design of more practical, cheaper, and efficient boutique trials, rather than larger, expensive trials powered on the endpoint of diabetes.

The number of candidate agents that fulfill scientific and ethical criteria for primary or secondary prevention trials is limited and recruiting individuals for these trials is a significant logistical exercise. Consequently, of the many clinical trials undertaken for “prevention” of T1D since the 1980s, most have been tertiary trials in individuals with recent-onset clinical T1D. A comprehensive listing of these trials is provided (Table 70.3), in which classification by agent necessitates combining the categories of secondary and tertiary prevention. The primary outcome measure in

**TABLE 70.3** Trials for Prevention of Type 1 Diabetes

	Participants (n)	Follow-up (months)	Outcome	Reference
<b>PRIMARY PREVENTION</b>				
Cow's milk elimination (trial to reduce IDDM in the genetically at-risk TRIGR)	FDRs with HLA risk (150)	≥ 36	No change in incidence of islet autoantibodies or diabetes	Hummel et al. (2011)
Elimination of bovine insulin from infant formula (FINDIA study)	HLA at-risk infants (1113)	36	Decrease in incidence of islet autoantibodies	Vaarala et al. (2012)
Weaning to hydrolyzed casein formula vs cow's milk + 20%casein formula (TRIGR study)	HLA at-risk infants (2159)	138 m (median)	No change in incidence of islet antibodies or of diabetes	Knip et al. (2011), Knip et al. (2014), and Knip et al. (2018)
<b>SECONDARY AND TERTIARY PREVENTION</b>				
<b>Nonspecific immune suppression</b>				
Azathioprine (2 mg/kg/day for up to 12 months)	RD (24)	12	Increased basal and glucagon-stimulated C-peptide, and more remissions	Harrison et al. (1985)
Cyclosporine (7.5 mg/kg/day for up to 9 months)	RD (122)	9	More remissions	Feutren et al. (1986)
Azathioprine (2 mg/kg/day for a year) + prednisolone (decreasing dose over 10 weeks)	RD (46)	12	Increased meal-stimulated C-peptide and decreased insulin dose	Silverstein et al. (1988)
Cyclosporine (20 mg/kg/day for 1 year)	RD (188)	12	Increased glucagon-stimulated C-peptide and more remissions, especially in recently diagnosed	Canadian–European Randomized Control Trial Group (1988)
Azathioprine (2 mg/kg/day for 1 year)	RD (49)	12	Increased meal-stimulated C-peptide	Cook et al. (1989)
Azathioprine, thymostimulin, or the combination	RD (45)	12	Increased glucagon-stimulated C-peptide and more remissions in combination group	Moncada et al. (1990)
Cyclosporine (10 mg/kg/day for up to 2 years)	RD (219)	24	Increased meal-stimulated C-peptide and more remissions	Assan et al. (1990)
Cyclosporine (10 mg/kg/day for 4 months)	RD (43)	36	No difference in glucagon-stimulated C-peptide, HbA1C, or insulin dose	Chase et al. (1990a)
Prednisolone (15 mg/day for 8 months) or indomethacin (100 mg/day for 8 months)	RD (25)	24	Decreased insulin dose and increased urine C-peptide in prednisolone group	Secchi et al. (1990)
Cyclosporine (10 mg/kg/day for 1 year)	RD (23)	12	Increased meal—but not glucagon—or glucose-stimulated C-peptide. No difference in insulin dose	Skyler and Rabinovitch, (1992)
Anti-CD5 mAb/ricin A chain anti-T-cell therapy (not blinded)	RD (15)	12	Dose-dependent preservation of meal-stimulated C-peptide	Skyler et al. (1993)
Prednisone (1 mg/kg/day tapered over 50 days)	RD (32)	12	Increased glucagon-stimulated C-peptide, but no remissions	Goday et al. (1993)
Anti-CD4 mAb + prednisolone	RD (12)	12	No difference in insulin dose, or islet antibody titers	Kohnert et al. (1996)
Methotrexate (5 mg/m <sup>2</sup> /week; not blinded)	RD (10)	36	No effect on basal or meal-stimulated C-peptide. Insulin dose increased.	Buckingham and Sandborg (2000)
Teplizumab (OKT3γ1(Ala-Ala) anti-CD3 mAb; not blinded)	RD (18)	12	Increase in meal-stimulated C-peptide in first year. IL-10 detected in serum	Herold et al. (2002)
Teplizumab [OKT3γ1(Ala-Ala) anti-CD3 mAb]	RD (42)	24	Improved C-peptide response to mixed meal, decreased HbA1c and decreased insulin dose	Herold et al. (2005)

(Continued)

**TABLE 70.3** (Continued)

	Participants (n)	Follow-up (months)	Outcome	Reference
Otelixizumab (CHAgly anti-CD3 mAb)	RD (80)	48	Improved C-peptide response to glucose. Clamp/glucagon up to 36 months. Decreased insulin dose with similar HbA1c	Keymeulen et al. (2005, 2010)
Rituximab (anti-CD20 mAb)	RD (87)	24	Increased C-peptide response to mixed meal at 12 but not 24 months. Decreased HbA1c and insulin dose	Pescovitz et al. (2014) and Pescovitz et al. (2009)
Mycophenolate mofetil ± daclizumab (anti IL-2 receptor mAb)	RD (126)	24	No effect on basal or meal-stimulated C-peptide. Similar HbA1c and insulin dose	Gottlieb et al. (2010)
Abatacept (CTLA4-Fc fusion protein)	RD (112)	24	Increased C-peptide response to mixed meal. Decreased HbA1c and insulin dose	Orban et al. (2011)
IL-2 + rapamycin	RD (7)	12	Transient decrease in C-peptide response to mixed meal associated with increased numbers of circulating regulatory T cells	Long et al. (2012)
Teplizumab [OKT3 $\gamma$ 1 (Ala-Ala) anti-CD3 mAb]	RD (516)	24	Increased C-peptide response to a mixed meal at 18 and 24 months with decreased insulin use and HbA1c	Roep et al. (2013) and Sherry et al. (2011)
IL-1 antagonism with canakinumab or anakinra	RD (138)	12	No difference in C-peptide response to a mixed meal, HbA1c or insulin dose	Moran et al. (2013)
Teplizumab [OKT3 $\gamma$ 1 (Ala-Ala) anti-CD3]	RD (52)	24	Increased C-peptide response to mixed meal. Decreased HbA1c and insulin dose	Herold et al. (2013)
Alefacept (anti-CD2)	RD (49)	24	Increased C-peptide response to mixed meal and decreased insulin dose and rate of severe hypoglycemia	Rigby et al. (2013) and Rigby et al. (2015)
Ladarixin (IL-8 antagonist)	RD (72)	12	Ongoing	NCT02814838
Teplizumab [OKT3 $\gamma$ 1 (Ala-Ala) anti-CD3]	AR (170)	48–72	Ongoing	NCT01030861
<b>Nonspecific immune stimulation</b>				
BCG vaccine	RD (26)	18	No effect on glucagon-stimulated C-peptide, insulin dose, or HbA1C	Elliott et al. (1998)
BCG vaccine	RD (94)	24	No effect on mixed meal-stimulated C-peptide, insulin dose, or HbA1C	Allen et al. (1999)
Q fever vaccine	RD (39)	12	No effect on glucagon-stimulated C-peptide or insulin dose	Schmidli et al. (unpublished)
<b>Nonspecific immune regulation</b>				
Thymopoietin	RD (32)	6	Decreased insulin antibodies and insulin dose. More remissions. No difference in C-peptide or HbA1c	Giordano et al. (1990)
Gammaglobulin	RD (16)	6	Increased basal C-peptide Decreased insulin dose, unchanged HbA1c	Panto et al. (1990)
Linomide	RD (63)	12	Decreased HbA1c and insulin dose. No difference in glucagon-stimulated C-peptide	Coutant et al. (1998)
HSP60 p277 peptide (DiaPep)	RD (35)	10	Decrease in glucagon-stimulated C-peptide and insulin dose in placebo but not treated group	Raz et al. (2001)
HSP60 p277 peptide (DiaPep)	RD (48 and 99)	18	No effect on C-peptide response to a mixed meal or on insulin requirement	Schloot et al. (2007)

(Continued)

**TABLE 70.3** (Continued)

	Participants (n)	Follow-up (months)	Outcome	Reference
1,25-dihydroxy vitamin D3	RD (20)	18	No effect on C-peptide response to a mixed meal or insulin requirement	Walter et al. (2010)
HSP60 p277 peptide (DiaPep)	RD (146)	12	No effect on C-peptide response to a mixed meal	Buzzetti et al. (2011)
Antithymocyte globulin (6.5 mg/kg)	RD (58)	24	No effect on C-peptide response to a mixed meal	Gitelman et al. (2016) and Gitelman et al. (2013)
Antithymocyte globulin (2.5 mg/kg) + g-CSF (6 mg fortnightly for 6 doses)	RD (25)	24	Borderline ( $P = .05$ ) improvement in C-peptide response to a mixed meal at 12 but not 24 months	Haller et al. (2016) and Haller et al. (2015)
Antithymocyte globulin (ATG; 2.5 mg/kg) ± G-CSF (6 mg fortnightly for 6 doses)	RD (89)	12	Increase in C-peptide response to a mixed meal and decrease in HbA1c; addition of G-CSF did not enhance effects	Haller et al. (2018)
Rapamycin ± vildagliptin	RD (60)	3	Ongoing	NCT02803892
CD34 <sup>+</sup> stem cell mobilization with plerixafor (anti-CXCR4, CXCR7 agonist), alemtuzumab (anti-CD52), anakinra (anti-IL-1), etanercept (anti-TNF), liraglutide	RD (60)	24	Ongoing	NCT03182426
<b>Antigen-specific immune regulation</b>				
Parenteral insulin (i.v. vs. s.c. 2 weeks)	RD (26)	12	Increased meal-stimulated C-peptide, decreased HbA1c	Shah et al. (1989)
Parenteral (s.c.) insulin	RD (49)	60	Increased glucagon-stimulated C-peptide and improved insulin sensitivity and glycemic control	Linn et al. (1996)
Parenteral (s.c.) insulin and sulfonylurea (glipizide)	RD (27)	12	Increased basal and glucagon-stimulated C-peptide, more remissions	Selam et al. (1993)
Parenteral (s.c.) insulin	RD (10)		Increased C-peptide response to oral glucose, HbA1c unchanged	Kobayashi et al. (1996)
Parenteral insulin (i.v. vs s.c. 2 weeks)	RD (19)	12	Increased meal and glucagon-stimulated C-peptide and decreased HbA1c	Schnell et al. (1997)
Parenteral (s.c.) insulin	AR (14)	84	Delay in onset of diabetes. No effect on islet antibody levels	Füchtenbusch et al. (1998)
Oral insulin	RD (80)	12	No effect on basal C-peptide, HbA1c, insulin dose, or insulin antibodies	Pozzilli et al. (2000)
Oral insulin	RD (131)	12	No effect on basal, glucagon-or meal-stimulated C-peptide, HbA1c, insulin dose, or islet antibody levels	Chaillous et al. (2000)
Gluten elimination	AR (7)	24	No effect on islet antibody levels	Hummel et al. (2002)
Parenteral (s.c.) insulin (DPT-1)	AR (339)	44	No effect on diabetes development	Diabetes Prevention Trial-Type 1 Diabetes Study Group (2002)
Intranasal insulin (Melbourne INIT I)	AR (38)	48	Increased antibody and decreased T-cell responses to insulin	Harrison et al. (2004)
Oral insulin (DPT-1)	AR (372)	52	No effect on diabetes development overall. Post hoc analysis revealed >4-year delay in diabetes onset in participants with insulin autoantibodies	Skyler et al. (2005)

(Continued)

**TABLE 70.3** (Continued)

	Participants (n)	Follow-up (months)	Outcome	Reference
Parenteral (s.c.) GAD65-alum	RD (47)	6	Increase in fasting and stimulated plasma C-peptide with intermediate dose of 20 µg	Agardh et al. (2005)
Intranasal insulin (DIPP)	AR (224)	21	No effect to delay progression to diabetes	Nanto-Salonen et al. (2008)
Parenteral (s.c.) GAD65-alum	RD (70)	30	Delay in loss of C-peptide secretion, in those treated within 6 months of clinical diagnosis	Ludvigsson et al. (2008)
Parenteral (s.c.) insulin B chain 9–23 “altered peptide ligand” NBI-6024-0101 (Neurocrine)	RD (188)	25	No effect on C-peptide response to mixed meal	Walter et al. (2009)
Parenteral (s.c.) insulin B chain in incomplete Freund’s adjuvant	RD (12)	24	No effect on C-peptide response to mixed meal. Development of sustained insulin-specific antibody and T-cell responses	Orban et al. (2010)
Intranasal insulin (INIT III)	RD (52)	24	No effect on metabolic parameters. Suppression of T-cell responses to insulin and antibody responses to subcutaneous insulin	Fourlanos et al. (2011)
Parenteral (s.c.) GAD65-alum	RD (334)	15	No effect on metabolic parameters	Ludvigsson et al. (2012)
Parenteral (s.c.) GAD65-alum	RD (145)	12	No effect on C-peptide response to mixed meal	Wherrett et al. (2011)
Parenteral (i.m.) proinsulin plasmid DNA	RD (80)	12	Transient improvement in C-peptide response to mixed meal concomitant with a decrease in the CD8 T-cell response to proinsulin	Roep et al. (2013)
Oral insulin (TrialNet Study TN07)	AR (560)	72–96	No effect of oral insulin overall, but significant delay in T1D in participants with islet cell antibody and FPIR < 60 µU/mL	Krischer et al. (2017)
Intralymphatic GAD65-alum + oral vitamin D	RD (6)	15	Stable C-peptide response to mixed meal and decreased HbA1c and insulin dose when compared to historical control group	Ludvigsson et al. (2017)
Intranasal insulin (INIT II)	AR (110)	≥ 60	Nasal insulin dose-related insulin antibody response, then suppressed consistent with tolerance induction, but no effect on diabetes incidence	Harrison et al. (2018)
Gluten-free diet	AR (60)	24	Ongoing	NCT02605148

AR, Islet autoantibody-positive first-degree relative; DENIS, Deutsche Nicotinamide Intervention Study; DIPP, Diabetes Prediction and Prevention Project; DPT-1, Diabetes Prevention Trial Type 1; ENDIT, European Nicotinamide Diabetes Intervention Trial; FDR, first-degree relative; FPIR, first phase insulin response to i.v. glucose; GAD, glutamic acid decarboxylase; IDDM, insulin-dependent diabetes mellitus; INIT, Intranasal Insulin Trial; mAb, monoclonal antibody; RD, person with recently diagnosed diabetes. T1D, type 1 diabetes. Participant numbers are shown in parentheses.

primary and secondary trials is (the absence of) clinical diabetes, in tertiary trials the retention, or increase of residual beta-cell function. Trials of tertiary prevention with more than 70 different agents since the early 1980s (Table 70.3) have failed to demonstrate sustained preservation of residual beta-cell function, although several biologic agents, anti-CD20 (rituximab) and anti-CD3 monoclonal antibodies, anti-thymocyte globulin (ATG) and CTLA-4-Ig (abatacept), slowed the decline of beta-cell function for at least 1–2 years after diagnosis providing hope that earlier intervention might prevent or delay progression to clinical disease. Published randomized primary, secondary, and tertiary trials are summarized in Table 70.4; recent, ongoing trials are registered on ClinicalTrials.gov. In the following we will adhere to the strict definition of prevention and discuss only approaches to prevent clinical T1D.

## PRIMARY PREVENTION

Evidence for an etiological role of environment in T1D is persuasive and primary prevention could be targeted at environmental factors thought to initiate or promote islet autoimmunity. In countries with a high prevalence of T1D, neonatal screening for the highest risk HLA class II genes can identify over half the children destined to develop T1D (Kimpimäki et al., 2001). However, the modest predictive value of genetic testing would justify a primary intervention only if it was safe.

**TABLE 70.4** Comparison of Human Type 1 Diabetes With the NOD Mouse Model

Feature	Human	NOD mouse
Preclinical stage	Yes	Yes
Gender	M > F after puberty	F > M
Genetic susceptibility		
MHC class II aa57 non-Asp	Yes (HLA DQ8)	Yes (I-Ag <sup>7</sup> )
Polygenic non-MHC	Yes	Yes
Environmental influence on gene penetrance	Yes	Yes
Disease transmission via bone marrow	Yes	Yes
Mononuclear cell infiltration of islets (insulitis)	Moderate	Marked
Other organs	Sometimes	Yes
Impaired immune regulation	Yes	Yes
Autoantigens		
(Pro)insulin	Yes	Yes
GAD	Yes	Yes
Clinical response to autoantigen-specific therapy	Not yet shown	Yes

GAD, Glutamic acid decarboxylase; MHC, major histocompatibility complex.

## Diet and Gut Microbiome Modification

In the 1980s it was proposed that early exposure of the infant to cow's milk and/or the lack of breastfeeding predisposed to T1D. Two metaanalyses of multiple studies in which T1D prevalence was associated retrospectively with infant feeding revealed only a marginal increase in relative risk (Gerstein, 1994; Norris and Scott, 1996). In the Denver-based Diabetes Autoimmunity Study in the Young, infant feeding patterns retrospectively analyzed up to 6 months of age were not related to the development of islet autoantibodies up to 7 years of age (Norris et al., 1996). Furthermore, in the Australian BabyDiab Study (Couper et al., 1999) and the German BabyDiab Study (Hummel et al., 2000), no association was found between infant feeding patterns and the development of islet autoantibodies. Nevertheless, to answer whether cow's milk exposure is a risk, the multicountry Trial to Reduce IDDM in the Genetically At-Risk was initiated. Newborns with a T1D first-degree relative and HLA risk alleles, initially exclusively breast-fed, were randomized to either a casein hydrolysate formula (Neutramigen) comprising milk proteins of reduced complexity or a conventional cow's milk-based formula until 6–8 months of age and were followed for 10 years. This approach was based on protection from diabetes in NOD mice fed a hydrolyzed casein diet (Lefebvre et al., 2006). Initially, in a preliminary analysis, hydrolyzed casein-based formula was claimed to reduce the rate of islet autoantibody seroconversion (Knip et al., 2010), implying it protected against T1D. However, in the final study report (Knip et al., 2018), this dietary modification was not associated with any change in the incidence of islet autoantibodies or diabetes. Human milk has many components and properties beneficial to the developing infant, including nondigestable human milk oligosaccharides that have a prebiotic effect to promote antiinflammatory Bifidobacteria in the colon (O'Callaghan and van Sinderen, 2016). Breast milk also contains endogenous insulin (Shehadeh et al., 2001), which might induce "oral tolerance" to insulin and so protect against the development of T1D (discussed below). Thus, rather than cow's milk promoting T1D, human milk may be protective through a variety of mechanisms.

As discussed, the gut microbiome differs in composition, diversity, and function between children at risk for T1D and case-controls. Microbiome "dysbiosis" may be partly reversible by "un-westernizing" the modern diet to increase the amount and diversity of natural, unprocessed food types known to promote an "antiinflammatory" gut microbiome. This could be boosted by supplementation with prebiotics as demonstrated with butyrate/acetate in the NOD mouse (Mariño et al., 2017) and with bespoke probiotics based on knowledge of microbiota known to be deficient in children at risk for T1D. Scientific studies of these approaches are on the drawing board.

Dietary gluten has also been implicated as an environmental trigger of T1D. Antibodies to wheat gluten proteins are found in a proportion of T1D patients at the time of diagnosis (MacFarlane et al., 2002) and coeliac disease and T1D share the HLA risk haplotype A1-B8-DR3-DQ2 and often coexist. In addition, in individuals with coeliac disease the prevalence of autoimmune diseases including T1D was reported to correlate with duration of exposure to gluten (Ventura et al., 1999). However, the German BABYDIET Study found that delaying the introduction of gluten beyond 12 months of age had no effect on the cumulative incidence of islet autoantibodies or clinical T1D (Hummel et al., 2002). At the population level, compelling evidence links vitamin D deficiency to T1D and other autoimmune diseases. Vitamin D is derived primarily from ultraviolet B light-induced synthesis in the skin and its deficiency is increasingly recognized, not just in populations living furthest from the equator but in people anywhere who avoid sunlight, work and play mainly indoors, are dark-skinned, and living in temperate climes or cover their skin for cultural or religious reasons. The recommended daily allowance of vitamin D has decreased over the past 50 years from 5000 to 400 IU (Hypponen et al., 2001). This is the minimum dose required to prevent rickets following adequate prenatal intake but is inadequate for the physiological immune modulating and antiinflammatory actions of vitamin D (Holick, 2004). Three European studies demonstrated an inverse relationship between vitamin D intake and the incidence of T1D. In a birth cohort study from Northern Finland, an area with only 1900 hours direct sunlight annually and the highest incidence of T1D in the world, T1D status was related to prerecorded data on infants 7–24 months of age given vitamin D in doses below, above, or at the then recommended 2000 IU daily (Hypponen et al., 2001, p. 170). The 2000 IU dose was associated with a low relative risk of 0.12 (95% CI 0.03–0.47). In a multinational European case-control study, the odds ratio for T1D was significantly reduced in children given vitamin D (EURODIAB Substudy 2 Study Group, 1999). The risk for T1D in Norwegian children was significantly lower if their mothers had taken cod liver oil (a source of vitamin D) during pregnancy (Stene et al., 2000). Randomized controlled trials of vitamin D supplementation are required in individuals genetically at-risk for T1D but are unlikely to ever be undertaken given the general public awareness of vitamin D deficiency and the widespread availability of vitamin D.

## Virus Vaccination

As discussed, if a virus or viruses are shown to initiate or promote islet autoimmunity, vaccination would be the means of primary prevention. Enteroviruses and rotavirus remain candidates. However, even though rubella and mumps viruses were implicated vaccination did not alter the incidence of T1D, which either questions the original evidence or indicates that multiple environmental agents in addition to viruses contribute to the etiology of T1D.

## Antigen-Specific Immunotherapy

This approach employs islet antigens as tools to induce therapeutic immune tolerance, based on extensive proof-of-concept studies in the NOD mouse. Shown to be safe but not yet efficacious for secondary prevention, it is likely to have greater potential in the context of primary prevention, as discussed below.

## SECONDARY PREVENTION

Secondary prevention has focused on first-degree relatives of a T1D proband, who have autoantibodies against one or more islet antigens. A prerequisite for intervention in asymptomatic individuals is a high likelihood of developing clinical disease. Prediction is determined by measuring autoantibody and metabolic markers of T1D (Table 70.1). In young first-degree relatives, the 5-year risk of diabetes is of the order <25%, 25%–50%, and >50% if autoantibodies are present to 1, 2, and 3 islet antigens, respectively. For single specificities, autoantibodies to insulin (IAA) are the most predictive. A measure of insulin secretion, first-phase insulin response (FPIR) to intravenous glucose, further refines risk prediction. In addition, in autoantibody-positive relatives with normal FPIR, the highest risk was shown to be independently associated with insulin resistance (Fourlanos et al., 2004). Importantly, stratification of autoantibody-positive individuals based on insulin resistance to better identify “progressors” could improve trial design and power.

While detection of autoantibodies is fundamental to preclinical diagnosis and disease prediction, about 10% of new-onset T1D patients of European descent have no detectable antibodies. Moreover, while first-degree relatives who share susceptibility genes and environmental risk factors have at least a 10-fold higher prevalence of T1D

than the background population, they represent no more than 15% of people diagnosed with T1D. Identifying the other 85% using available predictive tests is more challenging because the lower prevalence of disease in the general population may in turn lower the predictive value of screening tests compared to relatives (Bayes' theorem). Emerging studies to screen young children in the general population for islet autoantibodies (Ziegler et al., 2016) are based on the fact that preclinical diagnosis averts the classic clinical presentation of life-threatening ketoacidosis (Winkler et al., 2012). The predictive value of islet autoantibodies in the general population has not been widely investigated but will be important if effective means of secondary prevention are found.

The ideal prevention strategy in autoimmune disease is autoantigen-based immunotherapy, in which an autoantigen is administered to induce protective immune tolerance; this has been called "negative vaccination" (Harrison, 2008). The rationale is that autoantigen-driven immunoregulatory mechanisms are physiological and can be boosted or restored to prevent pathological autoimmunity. Approaches include administration of an autoantigen by a "tolerogenic" route (e.g., mucosal), cell type (e.g., resting dendritic cell), mode (e.g., with blockade of costimulation molecules) or form (e.g., as an "altered peptide ligand"), all of which have been shown to prevent or suppress experimental autoimmune diseases in rodents (Faria and Weiner, 1999; Harrison and Hafler, 2000; Krause et al., 2000). Mechanisms encompass deletion and/or induction of anergy in potentially pathogenic effector T or induction of regulatory T cells (Tregs) (iTregs). Autoreactive T cells that are activated strongly by antigen may undergo apoptotic cell death and deletion, while those that survive or respond "partially" may become anergic (von Herrath and Harrison, 2003). Of potential importance clinically is the ability of iTreg generated to specific antigen to exert antigen-nonspecific "bystander suppression." Thus, in response to specific antigen iTreg can, by direct cell contact or release of soluble immunosuppressive factors, impair the ability of antigen-presenting dendritic cells to elicit effector T-cell responses to any antigen locally at the site of the lesion or in the draining lymph nodes. Bystander suppression does not require that the autoantigen used to induce tolerance is necessarily the major or primary pathogenic autoantigen.

## Mucosa-Mediated Antigen-Specific Tolerance

The mucosal immune system shaped by the microbiome actively generates physiological immune tolerance. Most attempts to induce clinical autoantigen-specific tolerance have been mucosa-based. Numerous studies have shown that NOD mice can be partially protected from diabetes by mucosal administration of islet autoantigens. A large body of evidence indicates that (pro)insulin is a key target antigen driving beta-cell destruction but, paradoxically, can be used as an immunotherapeutic tool (Narendran et al., 2003). Zhang et al. (1991) initially reported protection after oral porcine insulin. Bergerot et al. (1994) then showed that human insulin induced CD4 Tregs that transferred protection to naïve mice. Protection following oral insulin was found to be associated with decreased expression of IFN- $\gamma$ -secreting Th1 T cells in the pancreas and pancreatic lymph nodes (Hancock et al., 1995; Ploix et al., 1998). Oral insulin-induced CD4 Treg have also been shown to prevent immune-mediated diabetes induced by lymphocytic choriomeningitis virus (LCMV) infection of mice expressing the viral nucleoprotein of LCMV under control of the rat insulin promoter in their  $\beta$  cells (Homann et al., 1999). The majority of T cells in the islets of oral insulin-treated mice without diabetes were shown to secrete Th2 (IL-4, IL-10) and Th3 (TGF- $\beta$ ) cytokines, in contrast to IFN- $\gamma$ -secreting Th1 cells in islets of mice that developed diabetes. The protective effect of oral insulin was enhanced by simultaneous feeding with IL-10 (Slavin et al., 2001), bacterial component OM-89 (Bellmann et al., 1997; Hartmann et al., 1997), or Schistosome egg antigen (Maron et al., 1998), all of which promote Th2 responses. Fusion of insulin to cholera toxin B-subunit (CTB) significantly improved the ability of oral insulin to prevent diabetes (Bergerot et al., 1997). Oral CTB–insulin conjugates in NOD mice induced a shift from a Th1 to a Th2 immunity associated with the induction of regulatory CD4 T cells (Ploix et al., 1999). NOD mice were protected from diabetes by feeding potatoes that transgenically expressed CTB–insulin conjugates (Arakawa et al., 1998). Oral GAD65 has also been reported to suppress diabetes development in NOD mice (Ma et al., 1997). Although it is generally believed that neonates are less susceptible to mucosal tolerance induction, oral administration of insulin, insulin B-chain, or GAD65 peptide during the neonatal period suppressed diabetes development in NOD mice (Maron et al., 2001). This suggests that mucosal administration of islet autoantigen in milk could be used to treat very young infants at risk of developing T1D.

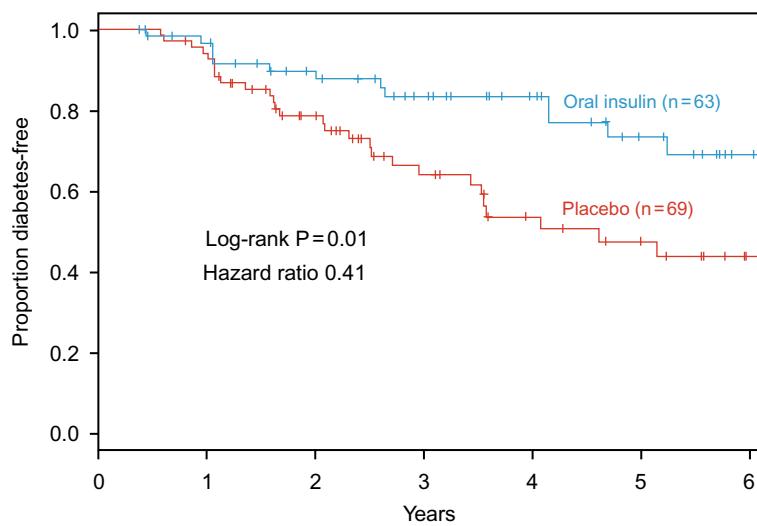

NOD mice are also protected from diabetes by naso-respiratory administration of islet autoantigens. This route of administration to the mucosa is direct avoids antigen degradation in the stomach. When insulin was administered as an aerosol to NOD mice at 8 weeks of age, after the onset of subclinical disease, insulitis, and diabetes incidence were both significantly reduced (Harrison et al., 1996). Aerosol insulin-induced novel antidiabetic CD8

$\gamma\delta$  T cells that suppressed the adoptive transfer of diabetes to nondiabetic mice by T cells from diabetic mice. The type of Treg induced by (pro)insulin depends on the route and form of antigen. Naso-respiratory insulin, which remains nondegraded and conformationally intact, induces CD8  $\gamma\delta$  Treg. On the other hand, oral insulin which is degraded to peptides, or intranasal or oral (pro)insulin peptides, induce CD4 Treg (Hänninen and Harrison, 2000; Martinez et al., 2003). Intranasal administration of the insulin B chain peptide (aa9-23), an epitope recognized by islet-infiltrating CD4 T-cell clones that adoptively transfer diabetes to naïve mice, induce CD4 Treg that protect NOD mice from diabetes (Daniel and Wegmann, 1996). A peptide spanning the B–C chain junction in proinsulin also induced CD4 Treg after intranasal administration (Martinez et al., 2003). This peptide, such as insulin B9-23, binds to the NOD mouse class II major histocompatibility complex, I-A<sup>g7</sup> (Harrison et al., 1997), and is a T-cell epitope in NOD mice (Chen et al., 2001) and humans at risk for T1D (Rudy et al., 1995). T-cell epitope peptides from GAD65 administered intranasally are also protective and associated with the induction of regulatory CD4 Treg and with reduced IFN- $\gamma$  responses to GAD65 (Tian et al., 1996). These “proof-of-principle” studies in the NOD mouse indicate that islet autoantigen proteins or peptides are candidate mucosal “vaccines” for prevention of T1D in humans.

### Trials of Islet Autoantigen-Specific Vaccination in Humans

The large multicenter Diabetes Prevention Trial (DPT)-1 was launched in the United States in 1994 to determine whether antigen-specific therapy with either systemic or oral insulin would delay or prevent diabetes onset in asymptomatic first-degree relatives with islet autoantibodies. Previously, intensive systemic insulin therapy had been reported to prolong the “honeymoon phase” after diagnosis (Shah et al., 1989) and a pilot study of prophylactic systemic insulin had suggested that this approach might be of benefit in at-risk relatives (Keller et al., 1993). Whether systemic insulin would act only as a hormone to control blood glucose and “rest”  $\beta$  cells (making them less sensitive to immune attack) or also as an antigen to induce immune tolerance was not clear, and read-outs to identify immune mechanisms were not employed. In DPT-1, low-dose systemic insulin (annual intravenous insulin infusions and daily subcutaneous injections) was given to high-risk relatives (>50% risk of diabetes over 5 years), matched with an untreated but closely monitored control group, but it had no effect on diabetes incidence (Diabetes Prevention Trial-Type 1 Diabetes Study Group, 2002). In the subsequent randomized controlled DPT-1 trial of oral insulin, islet autoantibody-positive relatives with a 25%–50% 5-year risk of diabetes were given 7.5 mg human insulin or placebo daily for a median of 4.3 years. There was no effect overall, but post hoc hypothesis testing revealed a significant delay of approximately 4 years in diabetes onset in participants who were unequivocally positive for insulin autoantibodies at entry (Skyler et al., 2005) (Fig. 70.2).

That oral insulin only benefited participants with insulin autoimmunity suggests that allelism at the insulin gene susceptibility locus (IDDM2) can shape not only the immune response to endogenous insulin as a target autoantigen but to oral insulin as a potential therapeutic tool. To attempt to confirm the post hoc DPT-1 findings,

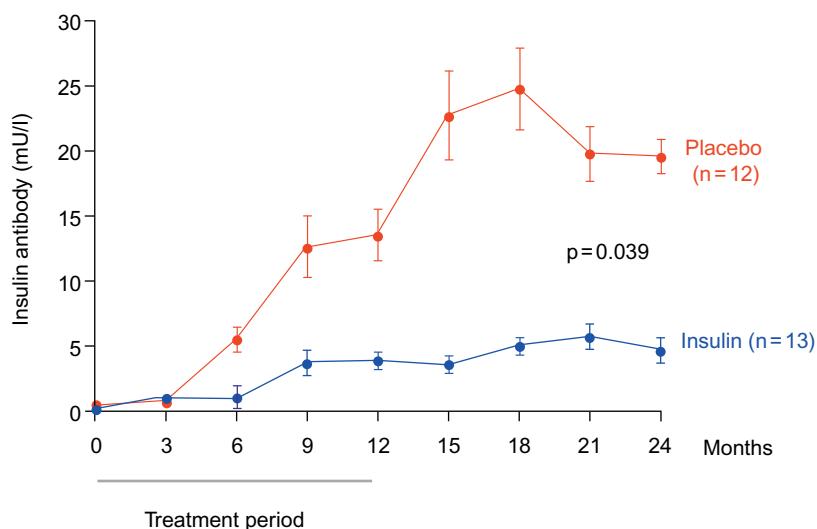

**FIGURE 70.2** Oral insulin vaccination delays development of diabetes in at-risk T1D relatives. *T1D*, type 1 diabetes.

a follow-up international trial of 7.5 mg/d oral insulin was performed by TrialNet between 2007 and 2016. More than 100,000 relatives were screened, of whom 560 met the inclusion criteria, which included the presence of IAA and one or more of GADA, IA-2A, or ICA as measured traditionally by immunofluorescence on pancreas tissue sections. Participants were stratified according to FPIR and presence or absence of ICA. The primary stratum, comprising 389 individuals with ICA and FPIR above threshold, most faithfully represented the post hoc DPT-1 population. The rate of progression to diabetes was highly similar between the placebo groups of the DPT-1 and TrialNet studies. However, oral insulin did not prevent diabetes in the TrialNet primary stratum. Unexpectedly, in the secondary stratum of 55 participants with ICA and low FPIR, oral insulin delayed progression to diabetes by about 2 years. This finding suggests, counterintuitively, that oral insulin might be more effective late rather than early in preclinical T1D. However, given the relatively low number of secondary stratum participants, confirmation of this finding by a dedicated trial will be necessary. Ideally, the TrialNet oral insulin study would have incorporated a higher insulin dose because on a body weight basis the 7.5 mg dose equates to only a few micrograms in the mouse, and milligrams of gavaged insulin were required to induce antidiabetogenic CD4 Treg in NOD mice. Two trials of oral insulin (up to 7.5 mg daily for 12 months) in recently diagnosed patients, attempting tertiary prevention, showed no protective effect on residual beta-cell function (Chaillous et al., 2000; Pozzilli et al., 2000).

Why have trials of oral insulin in T1D, as well as oral myelin basic protein in multiple sclerosis (Weiner et al., 1993) and oral collagen in rheumatoid arthritis (McKown et al., 1999; Trentham et al., 1993) failed to show clinical effects? The answer is probably a combination of reasons: relative ineffectiveness of iTreg against effector T cells in established disease; inadequate dose or bioavailability; coinduction of pathogenic T cells; genetic heterogeneity. Antigen-specific tolerance on its own is clinically ineffective in end-stage disease. If a balance between pathogenic and protective T cells determines clinical outcome then antigen-specific tolerance should be most effective in preventing the onset of disease, not after. The question of dose is discussed below but may be related to route of administration. Oral administration may not be optimal for mucosa-mediated tolerance because proteins are degraded after ingestion and the concentration or form of peptide reaching the upper small intestine may be insufficient to induce mucosa-mediated tolerance. Even with a small peptide, mucosal responses occurred after naso-respiratory but not oral administration (Metzler and Wraith, 1993). In the mouse, nasal administration of the model antigen, ovalbumin, elicited antigen-specific T-cell responses in cervical, mediastinal, and mesenteric mucosal lymph nodes, whereas oral administration elicited responses only in the mesenteric nodes (Hänninen et al., 2001). Irrespective of route of administration, antigen presentation in the mucosa may be a “double-edged” sword simultaneously inducing both iTreg and pathogenic cytotoxic CD8<sup>+</sup> T cells so that a clinical effect is not seen without suppression of the latter, for example, by costimulation blockade with anti-CD40 ligand antibody (Hänninen et al., 2002). Insulin contains potentially pathogenic cytotoxic T-cell epitopes but whether mucosal insulin induces cytotoxic CD8<sup>+</sup> T cells as well as protective Treg is unknown. In the NOD mouse, a proinsulin B-C chain peptide, a “combitope” of CD4<sup>+</sup> (I-A<sup>g7</sup>-restricted) and CD8<sup>+</sup> (K<sup>d</sup>-restricted) T-cell epitopes that induced CD4<sup>+</sup> Treg, was significantly more protective after nasal administration when the C-terminal p9 anchor residue for binding to K<sup>d</sup> was deleted or mutated (Martinez et al., 2003). This indicates that the nature of T-cell epitopes is critical in mucosa-based immunotherapy.

None of the oral autoantigen trials sought evidence for an immune effect. There is a pressing need to evaluate immune responses to mucosal autoantigens in human trials; otherwise, it is not possible to know if an antigen dose is bioactive/available. Induction of insulin antibodies was a marker of bioavailability after aerosol insulin in NOD mice (Harrison et al., 1996) or intranasal insulin in humans (Harrison et al., 2004, 2018; Fourlanos et al., 2011). Irrespective of whether or not they are a marker of immunoprotection, induction of insulin antibodies demonstrates the insulin dose was bioactive. Insulin autoantibodies are a risk marker for T1D and an increase in insulin antibodies after naso-respiratory insulin seems counterintuitive. However, in both the NOD mouse and humans at risk for T1D naso-respiratory insulin, although associated with an increase in insulin antibodies, was also associated with a decrease in T-cell responses to insulin. These findings are entirely consistent with the earliest descriptions of mucosal tolerance and with later landmark studies in humans using keyhole limpet hemocyanin (KLH) as a model antigen. When KLH was administered nasally to human volunteers, it elicited a modest antibody response, but after challenge with subcutaneous KLH both antibody and T-cell responses decreased (Waldo et al., 1994). In a recent randomized trial of nasal insulin in people with recent-onset T1D who did not initially require insulin treatment, those who received nasal insulin had blunted insulin antibody responses to subsequent subcutaneous insulin (Fourlanos et al., 2011) (Fig. 70.3). It will be important to determine if nasal insulin induces insulin-specific Treg and to demonstrate that like nasal KLH nasal insulin suppresses T-cell responses to rechallenge indicative of T-cell tolerance.

**FIGURE 70.3** Nasal insulin vaccination suppresses insulin antibody response to subcutaneous insulin.

The evidence for nasal insulin-induced immune tolerance in humans (Fourlanos et al., 2011) cannot necessarily be extrapolated to endogenous “autoantigenic” insulin but provides a mechanistic rationale for randomized trials of nasal insulin vaccination in individuals at-risk for T1D. Two such trials have been performed with progression to clinical diabetes as the primary outcome. In the T1D Prediction and Prevention Project (DIPP) trial in Finland (Nanto-Salonen et al., 2008), nasal insulin (1 U/kg daily) had no effect on progression to diabetes in islet autoantibody-positive children less than 3 years of age. These children were a very high-risk group and many appear to have had borderline beta-cell function judged by low FPIR to i.v. glucose. In the Australian Type 1 DPT, also known as the Intranasal Insulin Trial II (INIT II) (Harrison et al., 2018) nasal insulin at two doses (40 and 440 U) or nasal placebo was administered daily for 7 days and then weekly for a year, with a further 4 years follow-up, in T1D relatives aged 4–30 with autoantibodies to at least two islet antigens (~40% risk of diabetes over 5 years). The insulin dose in INIT II was substantially higher than in the DIPP trial and the participants were older and had less advanced preclinical disease. Again, nasal insulin induced a significant dose-dependent increase in serum insulin antibody concentration, which peaked after several months then dropped to pretreatment concentrations within the treatment year, consistent with immune tolerance to exogenous insulin. However, this bioeffect did not translate into protection against diabetes and, while unexplained, the rate of diabetes development in the placebo group was substantially lower than expected. As reasoned above, antigen-specific vaccination is most likely to be effective before the onset of the disease process and trials of mucosal insulin in islet autoantibody-negative genetically at-risk children are underway (Bonifacio et al., 2015).

Based on evidence in the NOD mouse that the incidence of diabetes was lowered by systemic GAD65 (Petersen et al., 1994; Tisch et al., 2001) or nasal GAD65 peptides (Tian et al., 1996), the Swedish company, Diamyd P/L, produced recombinant GAD65, and initiated trials of a subcutaneous GAD65-alum (aluminum hydroxide) vaccine (summarized in Table 70.4). Although the initial trials were encouraging, subsequent larger trials failed to substantiate a clinical effect of the vaccine. Again, it is not surprising that the GAD-alum vaccine had no effect after the onset of clinical diabetes. However, these trials appear to have established the safety of the vaccine and, based on GAD65 antibody responses, its bioactivity, thereby justifying an ongoing secondary prevention trial (DIAPREV-IT) of the vaccine in islet autoantibody-positive at-risk children.

## EPILOGUE

T1D prevention trials have taught us that treatment should begin as early as possible in the preclinical stage that “magic bullet” monotherapy is unlikely to be successful and that trials would greatly benefit from mechanistic response markers, especially islet autoantigen-reactive T cells, and noninvasive means of evaluating islet pathology and beta-cell function. Progress in preventing T1D is likely to be incremental, analogous to the evolution of combination treatment regimens for cancer or HIV infection, but more constrained by regulatory

considerations and the relatively slow rate of disease progression. Environmental agents that precipitate or exacerbate autoimmune disease are likely to be ubiquitous and therefore a single strategy, for example, vaccination against a specific virus, is unlikely to be the answer. A prerequisite is the identification of at-risk individuals in early life, for which T1D is a paradigm. Prevention strategies must be safe as well as effective. In this regard, autoantigen-specific vaccination as applied in the oral and nasal insulin trials in T1D provide a glimmer of promise. Lessons learnt from the preclinical diagnosis, prediction, and prevention of T1D should be applicable to other autoimmune diseases.

Rapid advances in immunology and greater understanding of disease etiology and pathogenesis have made the treatment of autoimmune diseases a dynamic and swiftly evolving field. Established therapies such as glucocorticoids (GCs), nonspecific immunosuppressive agents, and disease-modifying rheumatoid drugs (DMARD) are being supplemented or replaced by newer, more targeted biologic and molecular therapies. Progress in elucidation of basic mechanisms of autoimmune diseases has led to rapid development of targets on antigen-presenting cells (APCs), T/B lymphocytes, cytokines, and costimulatory molecules. In addition, improved measures of defining clinical response and identification of biomarkers reflecting clinical outcomes and prognosis have accelerated the development of treatment options for autoimmune diseases. The goal of this

chapter is to review established therapies of autoimmune diseases, with a focus on rheumatic diseases. We will highlight traditional therapies that form the foundation of current clinical practice (see **Table 71.1**), while laying out a context for which newer biologic and molecular targets are now incorporated into the current standard of care.

**TABLE 71.1** Established Immunosuppressive Treatments for Autoimmune Rheumatic Diseases

Drug	Primary mechanism of action	Side effects	Indications
<b>CONVENTIONAL DMARDs</b>			
Antimalarials	Inhibition of TLR-3/7, raising of lysozyme pH affecting antigen processing	Retinopathy and gray skin/nails discoloration. Rarely headache, pruritus, rash, neuropathy, corneal deposition, peripheral myopathy, cardiomyopathy	<i>Systemic lupus erythematosus, rheumatoid arthritis, juvenile idiopathic arthritis, Sjogren's, juvenile dermatomyositis, palindromic rheumatism</i>
Sulfasalazine	Inhibition of prostaglandin synthesis and cyclooxygenase, inhibition of NF $\kappa$ B transcription, reduction of TNF, suppression of B cells	Elevated liver enzymes, leukopenia, agranulocytosis, megaloblastic anemia, oligospermia, sperm dysmotility, GI or CNS side effects	<i>Inflammatory bowel disease (ulcerative colitis), mild rheumatoid arthritis, psoriatic arthritis, juvenile idiopathic arthritis</i>
Leflunomide	Inhibits dihydroorotate dehydrogenase, affecting de novo pyrimidine synthesis	Elevated liver enzymes, diarrhea, rash, hair loss, hypertension, interstitial pneumonitis, class X teratogen	<i>Rheumatoid arthritis</i>
Methotrexate	Inhibits dihydrofolate reductase, interfering with purine and pyrimidine metabolism and amino acid synthesis	Elevated liver enzymes, oral ulcers, diarrhea, mild hair loss, pneumonitis, infections, bone marrow suppression	<i>Rheumatoid arthritis, psoriasis and psoriatic arthritis, seronegative spondyloarthropathies, arthritic/skin manifestations of systemic lupus erythematosus, granulomatosis with polyangiitis, steroid sparing agent</i>
Cyclophosphamide	Alkylating agent that inhibits cell division by cross-linking DNA and reducing DNA synthesis	Infections, bladder toxicity with hemorrhagic cystitis or carcinoma, secondary malignancy, premature ovarian failure, infertility, neutropenia, hair loss, bone marrow suppression, oral ulcers	Systemic lupus erythematosus nephritis or other life-threatening manifestations, <i>rheumatoid arthritis transverse myelitis, systemic sclerosis-related ILD, granulomatosis with polyangiitis, polyarteritis nodosa, rheumatoid vasculitis</i>
Mycophenolate mofetil	Inhibits inosine monophosphate dehydrogenase, affecting de novo purine synthesis in activated lymphocytes	Diarrhea, abdominal cramps, nausea, infection, bone marrow suppression, neoplasia, rash, tremor	Systemic lupus erythematosus nephritis or other serious manifestations, <i>myasthenia gravis, systemic vasculitis</i>
Azathioprine	Purine antagonist, inhibits synthesis of DNA, RNA, proteins, cellular metabolism	Bone marrow suppression, infection, gastrointestinal upset, nausea, neoplasia	Maintenance therapy for systemic lupus erythematosus nephritis, treatment and/or maintenance for other manifestations of SLE, <i>ulcerative colitis, Crohn's disease rheumatoid arthritis, ANCA-positive vasculitis</i>
Cyclosporine	Calcineurin inhibitors; inhibit transcription of IL-2 production, proliferation of T lymphocytes; inhibits production of IL2, IL-4, and CD40 ligand. Voclosporin is in clinical trials for lupus nephritis	Renal toxicity, hypertension, neurologic side effects, skin or lymphoproliferative disorders, significant drug–drug interactions	Refractory ocular and mucocutaneous Behcet's disease, adult systemic lupus nephritis, systemic sclerosis, severe ulcerative colitis, myasthenia gravis; typically not first-line therapy
Tacrolimus			
Voclosporin			
<b>BIOLOGIC DMARDs</b>			
Infliximab	Tumor necrosis factor inhibitor; downregulates inflammatory cytokines, inhibits immunoregulatory functions of TNF	Infusion reactions to IV infliximab (but not to subcutaneous), rash, arthralgias, fatigue, infection, increased risk of lymphoma, skin cancers, neurologic disorders	<i>Rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, plaque psoriasis (inflix, etan, ada), juvenile idiopathic arthritis (etanercept and adalimumab), Crohn's disease, and ulcerative colitis. Uveitis (adalimumab)</i>
Adalimumab			
Golimumab			
Etanercept			
Certolizumab			

(Continued)

**TABLE 71.1** (Continued)

Drug	Primary mechanism of action	Side effects	Indications
Tocilizumab	IL-6R antagonist leading to reduced cytokine and proinflammatory pathways	Neutropenia, thrombocytopenia, elevated liver enzymes, GI perforation, infections, hyperlipidemia, rash	<i>Rheumatoid arthritis, giant cell arteritis, systemic and polyarticular juvenile idiopathic arthritis</i>
Anakinra	Antagonists of IL-1R, therefore inhibits inflammasome	Nausea, diarrhea, vomiting, eosinophilia, leukopenia, headache, infection	<i>Rheumatoid arthritis, neonatal onset multisystem inflammatory disease (anakinra), systemic juvenile idiopathic arthritis, acute or uncontrolled gout.</i>
Canakinumab			<i>Canakinumab is approved for <i>Familial Mediterranean Fever, cryopyrin-associated periodic syndromes, and TNF receptor-associated periodic syndromes</i></i>
Rituximab	Anti-CD20 monoclonal antibody against B cells	Infusion reaction, infections. Reduced vaccination response, mucocutaneous reactions, malignancy, rare PML due to JC virus, cytopenias	<i>Rheumatoid arthritis, granulomatosis with polyangiitis, microscopic polyangiitis, systemic lupus erythematosus</i>
Belimumab	Inhibits cytokine B lymphocyte stimulator protein (BLys, also called BAFF) necessary for B-cell proliferation, survival, and differentiation	Infections. Nausea, diarrhea, fever, insomnia, depression, leukopenia, angioedema, hypersensitivity to IV infusion. Recently available in the United States in subcutaneous injectable form	<i>Mild-to-moderate autoantibody-positive SLE (has not completed testing in lupus nephritis and has not been used in patients with active central nervous system lupus)</i>
Secukinumab	Inhibits IL-17A and the release of IL-17-stimulated chemokines and proinflammatory cytokines	Infections. Neutropenia, nausea, diarrhea, anaphylaxis to IV doses, urticaria, can induce inflammatory bowel disease	<i>Psoriasis, psoriatic arthritis, and ankylosing spondylitis</i>
Ustekinumab	Inhibits IL-12 and IL-23-mediated cell signaling and cytokine production	Infections. Nasopharyngitis, increased risk of nonmelanoma skin cancers, injection site erythema, headache, reversible posterior leukoencephalopathy syndrome, arthralgia, headache, back pain, nausea, diarrhea	<i>Crohn's disease, plaque psoriasis, and psoriatic arthritis</i>
Abatacept	CTLA4Ig fusion protein: binds CD80 and 86, preventing their binding to CD28, thereby inhibiting T-cell activation	Infections. Headache, nausea, malignancy, may induce multiple sclerosis (very rare), vasculitis, nasopharyngitis, dizziness, back pain, extremity pain	<i>Rheumatoid arthritis, juvenile idiopathic arthritis, psoriatic arthritis, lupus arthritis</i>
Apremilast	Inhibits PDE4, results in increased intracellular cAMP levels	Headache, depression, diarrhea, nausea, decreased appetite, infection, rash, weight loss	<i>Psoriasis, psoriatic arthritis</i>
Tofacitinib Baricitinib	Inhibits JAK enzymes, preventing cytokine signaling of immune cells	Infection. Increased liver enzymes, infection, anemia, lymphopenia, hyperlipidemia, headache	<i>Rheumatoid arthritis</i>

**OTHER THERAPIES**

IVIG	Interference with Fc receptors, antiidiotypic antibodies, inhibition of reticuloendothelial clearance	Rate-related infusion reactions, headache, aseptic meningitis, acute renal failure, thrombosis, urticaria, anaphylaxis, especially in IgA-deficient patients	<i>Guillain–Barré syndrome, myasthenia gravis, autoimmune peripheral neuropathies, rheumatic hematologic autoimmune thrombocytopenia, or hemolytic anemia, refractory dermatomyositis or polymyositis, Kawasaki disease in children</i>
------	---	--	---

US FDA has approved therapies for diseases listed in italics or are expected to soon do so. DMARD, Disease-modifying antirheumatic drugs; GI, gastrointestinal; ILD, interstitial lung disease; IL, Interleukin; IVIG, intravenous immunoglobulin; JC, John Cunningham virus; JAK, Janus kinase; NF $\kappa$ B, nuclear factor kappa B; PML, progressive multifocal leukoencephalopathy; TLR, Toll-like receptor; TNF, tumor necrosis factor.

## PRINCIPLES OF IMMUNE SUPPRESSION

As with our oncology colleagues, the goals for physicians treating autoimmune diseases are to induce improvement (remission or low disease activity), while arresting irreversible organ damage and minimizing treatment side effects. Although definitive cure and restoration of permanent immunological tolerance would be ideal, most treatments now do not achieve that goal. Treatments are often nonspecifically antiinflammatory and/or immunosuppressive. Thus the substantive side effects that accompany such treatments require balancing the risks of infection, bone marrow suppression, and other organ toxicity with potential efficacy.

In recent years, the paradigm of “tight control” has emerged, in which goal-directed treatments are based on quantitative and disease-specific measurements that guide providers to rapidly achieve low disease activity or remission. Notably, “tight control” in rheumatoid arthritis (RA) was illustrated in the TICORA study (Grigor et al., 2004) in which 111 patients were randomly assigned to either an intensive or a routine management group. Intensive management consisted of monthly office visits, measurements of disease activity scores (DAS), steroid injections of swollen joints, and every 3 month escalation of treatment by a defined protocol if moderate or high disease activity persisted. In contrast, the routine management group was seen every 3 months, without DAS measurement, and steroid injections and treatment escalation were based on the clinical judgment of the clinician, in contrast to predefined formal targets. After 18 months, patients in the tight control/intensive group showed significantly improved disease activity, physical function, and quality of life, as well as less radiographic progression of arthritis—all at no additional cost compared to routinely managed patients. The BeST study (Goekoop-Ruiterman et al., 2007; Goekoop-Ruiterman et al., 2005) and others (Mottonen et al., 1999; Rantalaiho et al., 2009) similarly illustrated greater remission rates and earlier functional improvement in RA arthritis patients with early, goal-directed therapy emphasizing aggressive treatment to achieve tight control of disease. Given the clear advantages of intensive treatment, the tight control paradigm is reflected in the 2015 update of the American College of Rheumatology’s recommendations for the use of disease-modifying antirheumatic drugs (DMARD) and biologics in the treatment of RA (Singh et al., 2016). With greater integration of quantitative measurements and DAS to define targets for treatment remission, goal-directed therapy as demonstrated in RA may serve as a harbinger for tight control treatment algorithms under study in other autoimmune diseases. Already, there is interest in working groups for establishing similarly objective “tight control” measures for seronegative spondyloarthropathies, systemic lupus erythematosus (SLE), and others.

## GENERAL CONSIDERATIONS

For many autoimmune disorders, chronic inflammation can lead to a variety of nonspecific, constitutional symptoms that include fatigue, muscle pains, weight loss, and/or fever. In fact, 40%–80% of the patients with SLE (lupus) experience such constitutional symptoms at any one time (Von Feldt, 1995). Furthermore, constitutional symptoms are present in a variety of other disorders such as multiple sclerosis, RA, multisystem autoimmune diseases, and vasculitis. General therapeutic principles focus on treating reversible causes of fatigue, weakness, and weight loss, such as anemia, drug toxicities, and ruling out other potential etiologies such as malignancy, infections, or thyroid/endocrine disorders. Proper muscle conditioning with appropriate aerobic exercise, good sleep management, and pain control may improve symptoms. Some studies have shown that stress may induce or exacerbate preexisting lupus symptoms (Blumenfield, 1978; Otto and Mackay, 1967), in which overall stress reduction may be beneficial (Greco et al., 2004).

In addition, management of precipitating environmental factors such as sun exposure and tobacco smoke is important. UV light in SLE patients induces increased apoptosis in skin cells, thus enhancing self-antigenicity of keratinocytes to express self-antigens on their surface that may stimulate an inflammatory response and autoantibody production leading to photosensitivity, cutaneous SLE, and/or generalized flares (Casciola-Rosen et al., 1994; Jones, 1992). Furthermore, genetically prone RA patients that carry an epitope in the hypervariable region of the human leukocyte antigen-DR (HLA-DR) chain, known as the “shared epitope,” have a higher risk of developing RA if they smoke cigarettes (Padyukov et al., 2004). The relative risk for development of RA in current smokers is 2.3–5.6-fold higher than for nonsmokers. In another study, the relative risk for developing RA was 20-fold higher in those with two alleles of the shared epitope, a smoking history, and anti-cyclic citrullinated peptide (anti-CCP) antibodies (Klareskog et al., 2006). Smoking may also increase disease severity (Saag et al., 1997; Wolfe, 2000). The mechanism of interaction between smoking and the shared epitope may primarily affect

citrullination of proteins in inflamed synovial tissue. The association between smoking and RA was most robust in patients with anti-CCP autoantibodies detected in blood (Klarekog et al., 2006). Studies have shown an association with smoking and development of autoantibodies, such as antinuclear antibodies (ANA) (Regius et al., 1988). Smoking may also be associated with increased risk for development of SLE (Ghassy et al., 2001) and Crohn's disease, although it may lessen the risk of developing ulcerative colitis (UC) (Mahid et al., 2006; Tobin et al., 1987). Hence, simple but important lifestyle changes such as reducing sun exposure (for SLE) and avoiding tobacco (for RA, SLE, and Crohn's disease) are important therapeutic considerations in management of autoimmune diseases.

## NONSPECIFIC ANTIINFLAMMATORY DRUGS

### Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are widely used throughout the world either over the counter or via prescription. All major NSAID classes share the common mechanism of inhibiting cyclooxygenase, which metabolizes arachidonic acid to cyclic endoperoxidases to form prostaglandins. Prostaglandins' role in inflammation includes induction of swelling, erythema, neutrophil trafficking, changes in vascular permeability, and inhibition of apoptosis (Harris, 2002; Lu et al., 1995). In addition, other nonprostaglandin mechanisms include NSAID inhibition of nuclear factor kappa B (NF $\kappa$ B)-dependent transcription (Amin et al., 1995), thus decreasing nitric oxide that normally may lead to increased vascular permeability and immune cell trafficking. NSAIDs are used commonly in multisystem autoimmune diseases to treat constitutional symptoms, fever, arthritis, serositis, and headache. The potential adverse effects (AEs) of NSAIDs often limit their use, particularly induction of dyspepsia, peptic ulcer disease (often with bleeding), renal vasoconstriction with acute renal injury, and exacerbation of hypertension and heart failure (Solomon, 2012), with increased risk for myocardial infarction. Thus, for safety concerns, they are recommended most commonly for as-needed (for pain and/or joint inflammation) rather than continual use. According to Epocrates searched on March 2018, a monthly dose of ibuprofen (400 mg tid) costs \$24.00.

### Glucocorticoids

GCs have a broad range of antiinflammatory and immunosuppressive effects on both the innate and adaptive immune system. GC binds to an intracellular receptor, where they can directly affect gene transcription, resulting in inhibition of production of inflammatory cytokines, and effects on posttranslational mRNA stability. Antiinflammatory effects include downregulation of nitric oxide synthesis resulting in reduced blood vessel permeability, decreased leukocyte migration to peripheral tissues, inhibition of inflammatory mediators such as eicosanoids, inhibition of collagenases, and suppression of inflammatory cytokines. Effects of GC on immune cells include inhibition of signaling for T-cell activation and interleukin (IL)-2 synthesis, downregulation of APCs via blockade of costimulatory molecules, immune deviation toward Th2 cytokines, and induction of T-cell apoptosis (Kirouka, 2007). GCs are often used to control acute manifestations of inflammatory and autoimmune disorders, dosed on a mg/kg basis depending on the severity of the disease. Typical dosing regimens may be divided as follows from most potent to least: (1) pulse intravenous (IV) therapy with methylprednisolone 500–1000 mg/day, (2) very high-dose oral GC at 1–2 mg/kg/day prednisone or equivalent, (3) high-dose oral GC at 0.6–1 mg/kg/day prednisone or equivalent, (4) medium-dose GC at 0.125–0.5 mg/kg/day prednisone or equivalent, or (5) low-dose GC at 0.125 mg/kg/day prednisone or equivalent (King and Hahn, 2007). Organ threatening manifestations of disease in SLE, dermatomyositis, large and small vessel vasculitis, and multiple sclerosis often require pulse IV steroids as part of the initial induction therapy for acute flare control. Other common indications include polymyalgia rheumatica, crystalline disease flares, active RA, and Sjögren's extrasalivary gland manifestations.

GCs have numerous AEs on many organ systems, more common with use of GC in high doses or over a long period of time. Major AEs with high dose (prednisone >20 mg/day) include infection, mental disturbances, osteonecrosis, osteoporosis with fractures, and impact on safety with live vaccination. For use of prednisone doses >10 mg/day, there is increased risk of glucose intolerance, peptic ulcer disease, myopathy, glaucoma, and hypertension. Weight gain is found as a common side effect even with the low dose, prednisone >5 mg/day and osteoporosis risk with the doses  $\geq$  5–7.5 mg/day for 3 months (Saag et al., 2011). Recent data (Al Sawah et al., 2015) show that doses of prednisone  $\geq$  7.5 mg of prednisone daily are associated with measurable damage over

time, but doses >20 mg a day cause damage at twice that rate. Most authorities recommend tapering to doses between 0 and 7.5 mg a day for this reason.

According to Epocrates in March 2018, a monthly dose of prednisone 15 mg daily costs \$48.00.

## ESTABLISHED TREATMENTS OF RHEUMATIC DISEASES

### Antimalarials

Antimalarial medications such as hydroxychloroquine, chloroquine, and quinacrine can be used to treat mild-to-moderate manifestations of SLE or RA and other rheumatic disorders. Various mechanisms of action may contribute to their utility in immune modulation, including (1) inhibition of activation of intracellular Toll-like receptor (TLR)-3 and TLR-7, (2) blockade of antigen processing by raising intracytoplasmic pH in lysozymes with resultant decreased lymphocyte proliferation, autoantibody production, and natural killer cells (NK) activity, and (3) inhibition of formation of immune complexes (Fox, 1993; Fox and Kang, 1993; Kyburz et al., 2006). In addition, antiinflammatory effects include inhibition of phospholipases, prostaglandins, blockade of superoxide secretion, suppression of destructive proteolytic enzymes by synoviocytes, and blockade of UV light to protect keratinocytes from increased antigenicity (Wallace, 2007). Hormonal actions may impair insulin release, antiproliferative effects may inhibit graft versus host disease, and intercalation with DNA may block synthesis to allow degradation of ribosomal RNA (Wallace, 2007). Hydroxychloroquine and chloroquine can also inhibit platelet aggregation and adhesion (Edwards et al., 1997; Ernst et al., 1984; Jancinova et al., 1994), adding to their utility for SLE patients with coexisting antiphospholipid syndrome and/or platelet abnormalities.

In SLE, antimalarials are most useful in treating constitutional symptoms, skin lesions, and arthritis, and for reduction of disease flare. In addition, the 2007 LUMINA trial illustrated an association between hydroxychloroquine and improved survival (Alarcon et al., 2007). Pregnant mothers with anti-Ro may use hydroxychloroquine to reduce risk of antibody-associated cardiac neonatal lupus (Izmirly et al., 2010). In RA, antimalarials are typically used in combination with other disease-modifying agents, such as methotrexate (MTX) or sulfasalazine. A large observational study indicated reduced risk of diabetes mellitus among patients who were taking hydroxychloroquine for RA compared to those not taking the medication (Wasko et al., 2007). Antimalarials may also decrease antibody levels in Sjögren's syndrome, as well as improve sicca symptoms by inhibiting glandular cholinesterase (Dawson et al., 2005). Hydroxychloroquine has also been used in systemic onset juvenile idiopathic arthritis (Still's disease), juvenile dermatomyositis, and palindromic rheumatism. One study found that the use of antimalarials in palindromic rheumatism patients was associated with a 20% decreased risk of progression to RA or other connective tissue disease (Gonzalez-Lopez et al., 2000). Side effects vary with specific antimalarials (in general the highest risk of important AEs is associated with chloroquine). These side effects include neuromuscular and cardiac toxicity, skin changes (particularly hyperpigmentation with all, and yellow discoloration with quinacrine), aplastic anemia (quinacrine), and rare ocular effects, including macular damage. Regular ocular screening of patients treated for more than 6 months with chloroquine or hydroxychloroquine is recommended (Marmor et al., 2011). For maximal safety regarding retinal toxicity, doses of hydroxychloroquine should not exceed 5 mg/kg daily (real weight); and risk for retinal toxicity increases after a total cumulative dose of 1000 g. According to Epocrates searched on March 2018, a monthly dose of hydroxychloroquine (400 mg daily) costs \$240.00.

### Sulfasalazine

Sulfasalazine (azulfidine) was originally proposed for use in RA, although ultimately great benefit was seen in treatment for inflammatory bowel disease (IBD). After oral ingestion, the majority of the intact drug reaches the large intestine and is reduced to sulfapyridine and 5-aminosalicylic acid (5-ASA). For IBD, and specifically UC, 5-ASA acts locally in the colon to decrease inflammatory responses via inhibition of prostaglandin synthesis. Interestingly, in contrast to UC, the active metabolite in RA patients is sulfapyridine, although the exact mechanism of action has not been clearly identified. Patients with mild/moderate UC treated with azulfidine or 5-ASA have 50%–65% response rates (MacDermott, 2017). Patients with RA show approximately 50% response rates (20% improvement or better) to sulfasalazine alone, and better response rates (nearly 80%) for triple therapy with sulfasalazine plus MTX plus hydroxychloroquine (Weisman and Rinaldi, 2017). In addition, studies suggest that the parent sulfasalazine drug inhibits NF $\kappa$ B transcription, may inhibit tumor necrosis factor (TNF)- $\alpha$  in

macrophages by inducing apoptosis, and may suppress B-cell function (Hirohata et al., 2002; Lee et al., 2004; Rodenburg et al., 2000; Wahl et al., 1998). In RA, sulfasalazine is often used in combination therapy with other DMARDs for optimal treatment. AEs include elevated liver function tests, leukopenia, agranulocytosis, megaloblastic anemia, and gastrointestinal or central nervous system effects. In men, transient infertility has been observed with qualitative and quantitative abnormalities in sperm including oligospermia and sperm dysmotility. These effects were reversible 1–3 months after discontinuation of sulfasalazine (Ostensen, 2017; Sands et al., 2015).

According to Epocrates searched on March 2018, the monthly cost of sulfasalazine at 1 g bid is \$41.00. The monthly cost of triple therapy with sulfasalazine plus MTX at 15 mg a week orally plus hydroxychloroquine at 400 mg daily is approximately \$300.00, which is considerably less expensive than the widely used MTX-plus-adalimumab (biologic inhibitor of TNF- $\alpha$  which is given 40 mg subcutaneously every 2 weeks which costs approximately \$5000 per month), a combination which costs approximately \$5125.00 per month.

### Leflunomide

Leflunomide (LF) is an oral medication that, once absorbed, is metabolized into its active form known as teriflunomide. The main mechanism of action of teriflunomide is to inhibit the mitochondrial enzyme dihydroorotate dehydrogenase (DHODH), which is an enzyme involved in the de novo pyrimidine synthesis pathway of ribonucleotide uridine monophosphate pyrimidine. Disruption of DHODH prevents activated lymphocytes from moving from the G1 to S phase (Fox, 1998). In addition, the immunomodulatory effects of LF are broad, including inhibition of leukocyte adhesion to endothelial cells and infiltration into synovium, which may be of particular importance in RA (Dimitrijevic and Bartlett, 1996; Grisar et al., 2004; Salmi et al., 1997). In addition, LF preferentially inhibits memory self-reactive lymphocytes, affects dendritic cell antigen presentation, and blocks NF $\kappa$ B activation (Manna and Aggarwal, 1999; Zhang et al., 1997). LF blocks protein tyrosine kinases Jak1 and Jak3, which affect T-cell stimulation via IL-2 receptor activation (Siemasko et al., 1998). LF may also increase the production of transforming growth factor beta, which is a known antiinflammatory cytokine (Cao et al., 1996). In patients with RA, LF is similar in efficacy to MTX; each treatment used alone results in 20% or greater improvement in approximately 50% of the patients. Common side effects include diarrhea, rash, hair loss, and elevated liver enzymes. Less common side effects include hypertension, interstitial pneumonitis, leukopenia, hematologic toxicities, and peripheral neuropathy. LF is contraindicated in pregnant and nursing women and in patients with preexisting liver disease.

LF is approved by the United States Food and Drug Administration (US FDA) for the treatment of RA. In RA, trials have demonstrated efficacy of LF as monotherapy, with comparable outcomes to those of MTX or sulfasalazine monotherapy (Emery et al., 2000; Smolen et al., 1999). Other trials have shown efficacy in psoriatic arthritis (PsA), juvenile polyarthritis, and resistant dermatomyositis, but not ankylosing spondylitis (AS). In [www.goodrx.com](http://www.goodrx.com) searched on March 2018, a month supply of LF at a dose of 20 mg daily orally costs \$200–400.

### Methotrexate

MTX is a folate antagonist that has been used effectively in a variety of autoimmune conditions. Competitive binding blocks the enzyme dihydrofolate reductase from reducing dihydrofolic acid to folinic acid, the active intracellular metabolite involved in purine/pyrimidine metabolism, and amino acid/polyamine synthesis. However, at the doses used in rheumatic conditions, which are often lower than in oncologic chemotherapeutic regimens, the exact mechanism of action is uncertain. Animal models suggest that MTX increases extracellular concentrations of adenosine in inflammatory tissue, which has antiinflammatory effects via dephosphorylation of adenine nucleotides (Cronstein, 1996; Morabito et al., 1998). Other possible mechanisms include inhibition of DNA methylation necessary for cell proliferation, induction of apoptosis of activated peripheral T cells, regulation of IL-1 $\beta$ , increased IL-10 synthesis, inhibition of leukotriene B2 formation and cyclooxygenase-2, and interference with neutrophil function (Cronstein, 1996; Genestier et al., 1998; Mello et al., 2000; Seitz et al., 2001). MTX can be taken orally, subcutaneously, or intramuscularly. In RA, approximately 50% of the patients with RA show 20% or better improvement in joint scores. Side effects include elevation of liver enzymes, especially when concurrently ingesting alcohol, oral ulcers, postingestion nausea, diarrhea, and hair loss. More severe complications include pneumonitis, infections due to immune suppression, bone marrow suppression, and hepatic fibrosis. Folic or folinic acid is often used as supplementation to reduce hematologic and other side effects, although folinic acid may interfere with efficacy. Pregnancy should be avoided, as MTX is a known teratogen.

MTX is used in a variety of rheumatic conditions, most prominently in RA, but also in psoriasis/PsA, peripheral joint disease in spondyloarthropathies, SLE, granulomatosis with polyangiitis (GPA) (formerly called Wegener's granulomatosis), and other large vessel vasculitides. Barring contraindications or allergy, MTX can be considered one of the cornerstones of DMARDs for the treatment of RA. Studies have shown both short-term and long-term efficacy in RA disease measurements, such as joint pain and swelling, quality of life, objective laboratory markers of inflammation, and radiologic progression of disease (Rich et al., 1999; Weinblatt et al., 1992, 1994), as well as possible improvement in survival (Choi et al., 2002). MTX monotherapy is first-line treatment for RA. If there is not adequate improvement in disease activity after several weeks, it is used in combination therapy with other DMARDs, such as sulfasalazine or hydroxychloroquine, or biologics (O'Dell et al., 1996; Weinblatt, 2013). Numerous trials have demonstrated the value of MTX in combination therapy on disease activity measures, reduction of radiographic progression, and functionality. MTX is often used in other disorders to treat peripheral joint arthritis symptoms, such as in psoriasis (35%–40% have 75% or greater clearing of skin lesions), seronegative spondylarthritis disorders, and joint manifestations in lupus patients. In vasculitides such as GPA, oral MTX can be used as initial therapy for nonorgan threatening, nonrenal disease, although its use is associated with a higher relapse rate compared to cyclophosphamide (CYC). Thus MTX is a reasonable alternative for patients who cannot tolerate other more toxic (but more effective) treatment regimens (De Groot et al., 2005; Mukhtyar et al., 2009). In addition, MTX may be used as a steroid-sparing agent in the large vessel vasculitis in giant cell arteritis, although there is conflicting evidence of its efficacy in this setting (Hoffman et al., 2002; Jover et al., 2001). According to Epocrates searched on March 2018, the monthly cost of 15 mg daily of MTX once a week orally is approximately \$22.00.

## Cyclophosphamide

CYC is a potent alkylating agent, used most often to treat life-threatening or organ-threatening manifestations of autoimmune and inflammatory diseases. It can be administered orally or intravenously and is metabolized by the liver mitochondrial P-450 enzyme into several active metabolites with both therapeutic and toxic effects. CYC has direct effects on DNA resulting in cell death and modulates T-cell activation (Fox and McCune, 1994; McCune and Fox, 1989). Significant side effects often limit more widespread use and include an increased risk for opportunistic infections such as *Pneumocystis jiroveci* pneumonia and fungal infections, bladder toxicity with hemorrhagic cystitis and carcinoma of the bladder, neutropenia, increased risk of infertility or premature ovarian failure, and development of malignancy. Short-term therapeutic use of CYC aims for rapid control of the underlying inflammatory process (over a period of a few weeks to months), while seeking replacement of CYC when possible with an acceptable alternative to avoid the significant long-term toxicities.

CYC has been used effectively in the treatment of lupus nephritis, interstitial lung disease in multisystem autoimmune disease, and medium and small vessel vasculitis. In patients with severe lupus nephritis, initial landmark trials from the National Institute of Health demonstrated the superiority of monthly high-dose IV CYC (500–1000 mg/m<sup>2</sup>) for 6 months, followed by two quarterly pulses with GCs, versus GC therapy alone in preserving renal function (Austin et al., 1986; Boumpas et al., 1992; Gourley et al., 1996; Illei et al., 2001). Subsequent studies have investigated the role of low-dose CYC regimens (500 mg IV every 2 weeks for 3–6 months) and found that this regimen compared to the higher dose CYC produces similar rates of renal remission in European patients—for up to 10 years (Houssiau et al., 2010b, 2002). It is not known whether the low-dose regimen is effective in African Americans, Asians, or Latinos with lupus nephritis. Small studies suggest a role for CYC in treatment of central nervous system manifestations of SLE, such as transverse myelitis (Barile and Lavalle, 1992; Kovacs et al., 2000; Neuwelt et al., 1995). CYC has also demonstrated improvement in pulmonary function, dyspnea, skin thickening, and health-related quality of life in patients with symptomatic systemic sclerosis-related interstitial lung disease (Tashkin et al., 2006). CYC is a second-line agent alternative to mycophenolate for most cases of systemic sclerosis-related interstitial lung disease due to its AEs (Tashkin et al., 2016). Systemic vasculitides such as GPA, microscopic polyangiitis, anti-neutrophilic-cytoplasm antibody (ANCA)-positive vasculitis, rheumatoid vasculitis, polyarteritis nodosa, autoimmune-associated mononeuritis multiplex, and optic neuritis are other indications for CYC in which significant clinical improvement and/or survival benefits have been shown (Galindo-Rodriguez et al., 1999; Ribi et al., 2010; Scott and Bacon, 1984; Stone, 2010). CYC may be administered IV at 3–4 week intervals (or longer) or orally on a daily basis: the incidence of urinary bladder toxicity is probably higher with daily oral dosing. Medicare reimbursement for a 1 g/kg dose of CYC IV is approximately \$1200.00 (Afifi et al., 2016).

## Mycophenolate Mofetil (Cellcept)

Mycophenolate mofetil (MMF) was used initially in the 1990s for the prevention of allograft rejection in renal transplantation. In the past decade, MMF has been shown to be an effective therapy in both induction and maintenance of improvement in SLE nephritis, thus allowing for use of an alternative regimen to CYC. MMF reversibly inhibits the enzyme inosine monophosphate dehydrogenase, which is necessary for de novo purine synthesis in activated lymphocytes. Blockade with MMF results in reduced T- and B-cell proliferation, less antibody production, induction of apoptosis of activated T lymphocytes, and hindrance of production and function of adhesion molecules important for lymphocyte migration to inflammatory tissues (Allison and Eugui, 2000). Side effects include diarrhea, nausea, gastrointestinal upset, infections, bone marrow toxicity, neoplasia, and rash. MMF compared to CYC is less likely to cause alopecia and amenorrhea, but rates of infection, serious infection, and death are similar with the two treatments (Touma et al., 2011). MMF is teratogenic and should be stopped if pregnancy is being considered.

The use of MMF has profoundly changed the outcomes and therapeutic landscape in induction therapy of improvement in diffuse proliferative and membranous serious SLE-related glomerulonephritis. Initial studies in Chinese patients suggested that MMF was an effective alternative to CYC (Chan et al., 2000; Hu et al., 2002). Subsequent clinical trials compared CYC to MMF. A recent international, randomized controlled trial (ALMS trial) of 370 SLE patients with active nephritis compared MMF (2–3 g/day) to IV CYC (0.5–1 g/m<sup>2</sup>) monthly for 6 months. This induction therapy showed similar efficacy between the two treatments (Appel et al., 2009). Interestingly, however, proportions of African-Americans and Latino Americans responding to CYC were lower compared to Caucasians and Asians, whereas responses in all four racial groups to MMF were similar (Isenberg et al., 2010). A subsequent metaanalysis confirmed MMF and CYC to be equivalent in efficacy and side-effect profiles (Touma et al., 2011), although MMF was not superior to CYC as suggested by an earlier randomized but not blinded clinical trial (Ginzler et al., 2005). A follow-up analysis from the ALMS trial examining nonrenal lupus activity in the same nephritis patients showed similar efficacy between MMF and CYC on nonrenal manifestations, thus suggesting MMF as a reasonable alternative to CYC for renal and nonrenal SLE (Ginzler et al., 2010). Furthermore, in addition to the above trials demonstrating MMF's utility in induction therapy in SLE, a recent study has demonstrated MMF's superiority in safety and efficacy as maintenance therapy for SLE nephritis compared to CYC (Contreras et al., 2004) and azathioprine (AZA) (Dooley et al., 2011; Houssiau, 2016). The American College of Rheumatology's 2012 guidelines for treatment and management of classes III, IV, and V glomerulonephritis reflect the current state of the art regarding use of MMF (Hahn et al., 2012). It is a first choice for induction therapy (with GCs) and maintenance therapy in lupus nephritis patients who are not Caucasian or Asian, since similar proportions respond in all racial groups. Short-term therapy (6 months) with IV CYC can be chosen instead; higher proportions of Caucasians and Asians respond compared to Blacks and Latinas, but there are good responders in all groups. MMF has been successfully used for treating systemic sclerosis, myositis, uveitis, and vasculitis (GPA maintenance therapy). Because of its antilymphocyte and antifibrotic effects, it has been effective in treating interstitial lung disease associated with many rheumatic diseases (Fischer et al., 2013; Morganroth et al., 2010). MMF has also been used as a steroid-sparing agent for the treatment of other rheumatic diseases and for the treatment of autoimmune hepatitis. MMF is approved by the FDA in adults and children for maintenance of renal, liver, and heart transplants. An induction dose of MMF, 3 g orally daily, costs approximately \$1300 per month according to Epocrates, searched on March 2018.

## Azathioprine (Imuran)

AZA is a prodrug that is metabolized to its active component 6-mercaptopurine (6-MP), a purine antagonist that inhibits DNA synthesis that leads to both cytotoxicity and decreased cellular proliferation. Intracellular metabolism of 6-MP results in decreased numbers of circulating lymphocytes, IL-2 secretion, and immunoglobulin production (Wilke, 2010). It is approved by the US FDA for prevention of renal transplant rejection and the treatment of RA; however, off-label use is common for remission maintenance of many rheumatic diseases such as SLE, polymyositis/dermatomyositis, Behcet's disease, ANCA-associated vasculitis, or as a steroid-sparing agent in many other rheumatic diseases. AEs include nausea, vomiting, bone marrow suppression (particularly anemia), increased risk of infection, and malignancy. Individuals with a homozygous genetic polymorphism of the enzyme thiopurine methyltransferase that reduces the metabolism of AZA may be at greater risk for AZA bone marrow toxicity. Some authorities recommend checking for this genetic polymorphism prior to initiation of therapy. A number of studies have shown efficacy of AZA over placebo in the

treatment of RA (Cade et al., 1976; Urowitz et al., 1973; Woodland et al., 1981), although more recent combination therapies of MTX plus biologics or other DMARDs are better. Recent data in RA suggested combined MTX and AZA had statistically more withdrawals due to adverse events than oral MTX alone (Hazlewood et al., 2016). In addition, AZA can be used for effective maintenance therapy in lupus nephritis (Contreras et al., 2004; Houssiau et al., 2010a), UC and Crohn's bowel disease (Prefontaine et al., 2009; Timmer et al., 2007), ANCA-positive vasculitis (Pagnoux et al., 2008), and autoimmune hepatitis. According to Epocrates, searched on March 2018, a dose of 150 mg daily of AZA costs approximately \$110.00 a month.

### Calcineurin Inhibitors: Cyclosporin A, Tacrolimus, and Voclosporin

Cyclosporin A (CSA) is a cyclic peptide of 11 amino acids that binds with high affinity to cyclophilins, which competitively bind to calcineurin. This leads to inhibition of translocation of transcription factors, NF-AT, thus reducing transcription of early cytokine genes that encode IL-2, TNF- $\alpha$ , interferon (IFN)- $\gamma$ , IL-3, IL-4, CD40, and granulocyte-macrophage colony-stimulating factor (Schreiber and Crabtree, 1992; Timmerman et al., 1996; Wiederrecht et al., 1993). Furthermore, CSA interferes with antigen presentation by APCs. The ultimate net effect is reduction of lymphocyte proliferation. CSA is metabolized by the cytochrome P450 3A4 liver enzymes and has a variety of drug-drug interactions that may interfere with blood concentration levels, thus requiring monitoring of CSA levels. Side effects include renal toxicity, hypertension, neurologic side effects such as tremor, encephalopathy, increased risk of skin or lymphoproliferative malignancies, and heightened risk for infection. However, unlike many alkylating agents and purine antagonists, CSA lacks clinically significant bone marrow suppression. CSA has been used in a variety of established and suspected autoimmune disorders, including RA, PsA, ocular and mucocutaneous Behcet's disease, adult lupus membranous nephritis, systemic sclerosis, atopic dermatitis, severe UC, pemphigus vulgaris, and myasthenia gravis (Magee, 2012). However, concern over long-term side effects, especially of renal toxicity, hypertension, and a myriad of drug interactions, has limited utility in chronic autoimmune diseases, except in patients who have failed more conventional therapies. Tacrolimus, another oral medication that inhibits T lymphocyte activation similarly to cyclosporine, is used widely for prevention of allograft rejection, because its potential AEs are slightly less than those of cyclosporine, with fewer hypertensive effects. Further, in vivo, the immunosuppressive effects are 10–20 times greater than cyclosporine. It is being used for some autoimmune diseases, including induction and maintenance therapy for lupus nephritis, RA, and autoimmune hepatitis (Lee et al., 2011; Li et al., 2012). In Chinese and Japanese studies, tacrolimus was equivalent to high-dose IV CYC in lupus nephritis (Wang et al., 2012) and in combination with low-dose mycophenolate was very effective in inducing partial or complete remissions (in 83% compared to 63% on IV CYC) (Liu et al., 2015). A dose of 5 mg daily costs approximately \$3000 per month according to Epocrates, searched on March 2018.

Voclosporin, another calcineurin inhibitor, is part of the next generation of treatments in this class of drugs. Previously known by other names, including ISA247, its structure is the same as cyclosporine except at the amino acid-1 residue. This difference allows for higher binding to calcineurin, and higher potency compared to cyclosporine (Papp et al., 2008). The AEs are similar to other calcineurin inhibitors, including headache, hypertension, diarrhea, and respiratory infections. Voclosporin has been used as therapy in plaque psoriasis, noninfectious uveitis, and renal allograft rejection (Schultz, 2013). There are ongoing studies for its use in lupus nephritis.

## BIOLOGIC AGENTS

With increasing understanding of the pathogenesis of autoimmune rheumatic diseases, several biologic agents have been developed. They can be classified based on their mechanism of actions, cytokine-targeted therapies, B-cell-targeted therapies, and T-cell-targeted therapies.

### Cytokine-Targeted Therapies

Therapies interfering with TNF, IL 1, IL6, IL 12, IL 23 are currently available for rheumatic diseases particularly for RA, AS, juvenile chronic arthritis, psoriasis, and PsA.

## Tumor Necrosis Factor Inhibitors

TNF inhibitors are a class of biologic drugs utilizing monoclonal antibodies (mABs) or TNF-binding fusion proteins to neutralize and block various proteins in autoimmune disease processes. The target protein of these therapeutic mABs is TNF- $\alpha$ , a pleiotropic cytokine with proinflammatory and immunoregulatory functions. TNF- $\alpha$  interacts with two receptors, either p55 (TNF receptor 1) or p75 (TNF receptor 2), resulting in various downstream signaling pathways as part of this inflammatory process (Taylor, 2010). TNF inhibitors have a structure based on the immunoglobulin molecule, including two identical heavy chains and two identical light chains. There are two functional regions in each antibody: the variable region (Fab) and the constant region (Fc). Interaction of the Fc receptors with the Fc portion of the mAb results in blocking the interaction between TNF- $\alpha$  and its receptors as the therapeutic target of this class of molecules. Currently, there are five FDA-approved TNF inhibitors in the United States. Infliximab is a chimeric IgG1 mAb made of a murine Fab region linked to a human IgG1 kappa constant region. Adalimumab is a fully human recombinant Fab with a human IgG1 kappa constant region. Golimumab also is fully humanized with a human IgG1 kappa constant region. Etanercept is a recombinant fusion protein consisting of the TNF receptor 2 and the Fc fraction of a human IgG1 constant region. Certolizumab is a humanized IgG4 Fab fragment linked to polyethylene glycol. They are administered intravenously or subcutaneously. TNF inhibitors are indicated for autoimmune disease including RA, PsA, AS, plaque psoriasis, juvenile idiopathic arthritis, Crohn's disease, and UC (Willrich et al., 2015). In RA, the TNFi usually used with MTX results in at least 20% improvement in 60%–70% of the patients, 50% improvement in 40%–50%, and 70% improvement in 20%–30%. Placebos result in improvement rates of 1%–12%. In RA, TNFi are better than MTX alone; most TNFi work better when combined with MTX. In patients with early disease (less than 3 years), remissions (defined as very low disease activity using international standard measures) occur in as many as 50% with etanercept plus MTX. They also reduce the damage that RA causes in joints (erosions and cartilage loss) (Schur, 2017). For treatment of psoriasis, the mAb anti-TNFs are more effective than the fusion protein (etanercept). The most common AEs of TNFi include acute and delayed infusion/injection reactions such as rash, arthralgias, fatigue, and myalgias. Infection with bacteria, fungus, and viruses also occurs due to blockage of the immune response, with a notable increased incidence in mycobacterial tuberculosis infections. In fact, the physician must rule out active tuberculosis before administering any of the TNF inhibitors. Other less common AEs include an increased risk of malignancy and neurological disorders. TNF inhibitors should be avoided in patients with known demyelinating disease. The monthly costs of TNFi are high. According to [www.goodrx.com](http://www.goodrx.com) searched on March 2018, approximate monthly cost of etanercept usual dose of 50 mg a week subcutaneous (autoinjector) is \$5400, adalimumab 40 mg every 2 weeks sc is \$5000, remicade IV at 10 mg/kg (given at 6–8 week intervals) is \$6000, and certolizumab (preferred for patients during pregnancy) is \$4000.

## Tocilizumab (Anti-IL6R: Actemra)

Tocilizumab is a humanized anti-IL-6 receptor mAB targeting the IL-6 pathway. IL-6, a pleiotropic cytokine, is important in the pathogenesis of RA, and other autoimmune diseases. There are two different IL-6-mediated signaling pathways (Calabrese and Rose-John, 2014). In classical signaling, IL-6 binds to the membrane bound receptor (mIL-6R) via the signal transduction protein gp130, leading to dimerization and further intracellular signaling. The second pathway relies on the proteolytic cleavage of mIL-6R, leading to the generation of soluble receptor for IL-6 (sIL-6R). Tocilizumab competitively inhibits IL-6 binding to mIL-6R and sIL-6R thereby blunting downstream proinflammatory effects. A recent clinical trial in giant cell arteritis showed tocilizumab treatment induced improvement in 56% compared to 14% on placebo, at both 6 and 12 months of treatment (Stone et al., 2017). In patients with RA, tocilizumab used in combination with MTX has been studied in randomized controlled trials compared to placebo. Findings showed the efficacy of tocilizumab in combination with MTX compared to placebo, as remission of disease based on 20%, 50%, and 70% improvement was 2.5, 3.2, and 6 times higher, respectively, in this group (Singh et al., 2011). In patients with RA, tocilizumab as monotherapy was studied in a randomized clinical trial compared to MTX, yielding 69% with 20% improvement, 44% with 50% improvement, and 28% with 70% improvement (Jones et al., 2010a). The AEs most commonly reported have been infections including pneumonia, cellulitis, herpes zoster, gastroenteritis, and diverticulitis. Other side effects include an elevation in lipid levels and cytopenias. Effective blockade of IL-6R can also decrease hepcidin levels and result in an elevation in hemoglobin production (Navarro-Millan et al., 2012). In addition to use in RA, tocilizumab has been recently approved by the US FDA for giant cell arteritis. It may also be used in other forms of

vasculitis, and in systemic and polyarticular juvenile idiopathic arthritis. Dosed at 162 mg subcutaneously every 2 weeks (prefilled syringe), the price of a 1 month supply is approximately \$2200 according to [www.goodrx.com](http://www.goodrx.com) searched on March 2018.

## IL-1 Antagonists

IL-1 is one of the proinflammatory cytokines underlying the inflammatory symptoms of RA, systemic juvenile inflammatory arthritis (JIA), and autoinflammatory diseases. Anakinra (Kineret), rilonacept (Arcalyst), and canakinumab (Ilaris) are currently available IL-1 antagonists. Anakinra is a recombinant human IL-1 receptor antagonist; it blocks IL-1 activity by competitively inhibiting IL-1 binding to the IL-1 receptor (IL-1R). Blocking IL1 also serves to inhibit clinical response to inflammasome activation; thus these agents can be useful in inflammasome-mediated conditions such as acute gout. Rilonacept is dimeric fusion protein that incorporates in extracellular domains of both IL-1R and IL-1 R accessory protein fused to the Fc portion of an IgG molecule. Canakinumab is a human mAB that targets IL-1  $\beta$ . All these agents are administered by subcutaneous injection. Anakinra is effective in systemic JIAs ([Nigrovic et al., 2011](#); [Vastert et al., 2014](#)). Anakinra can be used in combination with MTX. However, it is less effective than other biologic DMARDs in adult RA ([Singh et al., 2009](#)). Increasing data suggest that IL-1 inhibition is an effective alternative for patients with familial Mediterranean fever who do not respond to or cannot tolerate colchicine ([Gul et al., 2015](#); [Hashkes et al., 2012](#); [van der Hilst et al., 2016](#)). The choice of IL-1 inhibitor depends upon a combination of factors including regulatory or insurance requirements, route of administration, and cost. Canakinumab may be preferred due to its efficacy and convenience since it is given every 4–8 weeks. Beneficial effects of IL-1 inhibition were seen in patients with acute gout in open-label pilot studies using anakinra, 100 mg daily given subcutaneously until symptoms of acute gouty arthritis improved ([So et al., 2007](#)). Rilonacept and canakinumab are approved by the US FDA for the treatment of cryopyrin-associated periodic syndromes or catastrophic antiphospholipid syndrome (CAPS). Anakinra was also used off-label with success in CAPS. AEs include anaphylaxis/hypersensitivity reactions, infections, injection site reaction, and neutropenia. Canakinumab can also cause nasopharyngitis, headache, vertigo, and diarrhea. The monthly cost of Anakinra dosed at 100 mg subcutaneously daily is \$4156 according to [www.goodrx.com](http://www.goodrx.com) searched on March 2018.

## Secukinumab (Anti-IL17A: Cosentyx)

Secukinumab is a fully humanized (IgG1 $\kappa$ ) mAB directed against IL-17A. IL-17A is a cytokine and the primary effector of Th-17 cells as part of the pathogenesis of several autoimmune diseases including psoriasis, PsA, and AS. More specifically, IL-17A has several functions in these diseases such as keratinocyte trafficking, acting on chemokines such as CCL20 and CXCLs ([Maldonado-Ficco et al., 2016](#)). Selective blocking of IL-17A by secukinumab has demonstrated efficacy in these autoimmune diseases. For example, secukinumab in patients with moderate-to-severe plaque psoriasis induced 75% or greater improvement in the surface area of plaques in almost 80% of the individuals, compared to 44% with etanercept and 5% on placebo (using the psoriasis activity scoring index (PASI) score, a standard measurement of extent of psoriasis). The efficacy of secukinumab (and other IL17 inhibitors that are currently available) in plaque psoriasis is probably the best to date among the biologics ([Feldman, 2017](#)). Secukinumab showed significant but not dramatic response in patients with PsA in previous clinical trials with 20% improvement noted in 54% and 51% of the 300 and 150 mg dosed groups, respectively, as compared to placebo ([McInnes et al., 2015](#)). AEs of secukinumab include neutropenia, and infections notable for candidiasis ([Baeten et al., 2015](#)). According to [www.goodrx.com](http://www.goodrx.com) (searched on April 2018), a monthly dose of secukinumab at 150 mg subcutaneously weekly costs \$4700. However, the biologic can be withheld for a few weeks after the first 5 weeks if there is good response, so the high monthly cost may be intermittent.

## Ustekinumab (Anti-p40 for IL-12 and IL-23 Signaling: Stelara)

Ustekinumab binds to the p40 subunit of IL-12 and IL-23. This then prevents binding to the IL-12 and IL-23 receptors, inhibiting IL-12 and IL-23-mediated cell signaling, activation, and cytokine production, including Th1 and Th17 production of IFN- $\gamma$ , IL-17, and IL-22 ([Yeilding et al., 2012](#)). In patients with active PsA, multicenter placebo-controlled trials showed significant improvement compared to placebo at doses of 45 and 90 mg with 42% and 49%, respectively, achieving 20% improvement, compared to 22% on placebo with 20% improvement

(McInnes et al., 2013). In psoriasis, ustekinumab treatment of moderate-to-severe plaque disease results in 67% of the patients achieving 75% or greater reduction of total skin involved (PASI score) (Feldman, 2017). AEs include infections, such as nasopharyngitis. There is also increased risk of nonmelanoma skin cancers as demonstrated in postmarketing data (Baker and Isaacs, 2017). Ustekinumab has been FDA-approved for use in Crohn's disease, plaque psoriasis, and PsA. A single injection of ustekinumab subcutaneous is approximately \$10,600, but it is given once every 12 weeks for psoriasis and PsA, making the monthly cost \$3533 ([www.goodrx.com](http://www.goodrx.com) searched on April 2018).

## B-Cell-Targeted Therapies

Targeting autoreactive B cells or B-cell maturation signals has become successful therapy for autoimmune rheumatic conditions and will be discussed briefly here and in further detail in the next chapter.

### Rituximab (Rituxan)

Rituximab is a chimeric anti-CD20 mAB, which causes depletion of B cells via various mechanisms, including Fc gamma receptor-mediated antibody-dependent cytotoxicity, antibody-dependent complement-mediated cell lysis, and B-cell apoptosis (Cragg et al., 2005). Rituximab selectively depletes CD20+ B cells, which play a role in autoantibody-mediated diseases including the chronic synovitis associated with RA (Tsokos, 2004). Results of the RAVE and RITUXVAS trials in patients with ANCA vasculitis show that rituximab is an effective and safer alternative to CYC, especially in patients with relapsing disease (Jones et al., 2010b; Stone et al., 2010). Of note, in prospective, controlled randomized trials, rituximab was not shown to be superior to placebo for treatment of SLE patients with active disease (renal or nonrenal) who were receiving GC plus hydroxychloroquine plus an immunosuppressive drug (Merrill et al., 2010; Rovin et al., 2012). However, many open-label studies attest to the efficacy of rituximab in SLE. In addition, there may be patients with lupus nephritis who respond to rituximab infusions in combination with MMF, without additional daily GCs (Beckwith and Lightstone, 2014). Prospective trials are in progress. The US FDA has approved rituximab for non-Hodgkin's lymphoma, B-cell chronic lymphocytic leukemia, RA, GPA, and microscopic polyangiitis. Adverse reactions include infusion reaction, infections, hypogammaglobulinemia, and late onset neutropenia. A "round" of rituximab which consists of once-a-week-for-4-weeks or the same total dose given once every 2 weeks during the 4 weeks is approximately \$38,000 (not including infusion costs). Some patients maintain improvement for many months or years and do not need a second dose; in many rheumatic disease patients, the round is repeated every 6 months.

### Belimumab (Anti-BLyS: Benlysta)

Belimumab is a fully human mAB directed against soluble B lymphocyte stimulator protein (BLyS)/B-cell activating factor (also called B cell-activating-factor (BAFF)); hence, it depletes maturing B cells by inhibition of BLyS, which is required for survival and maturation of most B-cell subsets. In 2011, belimumab became the first drug in 50 years to be approved for the treatment of active SLE (excluding patients with active renal or central nervous system (CNS) disease) (Furie et al., 2011; Hahn, 2013; Navarra et al., 2011). Of note, belimumab is meant for lupus patients who are antinuclear antibody or anti-double stranded DNA positive and interestingly showed less response in African-American patients. A recent study showed that responses are durable for a 4-year period—the follow-up period of the study (Merrill et al., 2012). AEs with belimumab include infusion reactions to the IV biologic (a subcutaneous version has just become available in 2017), infections, and depression. To date, blockade of both soluble and cell-bound BLyS and of the April receptor for BlyS plus the BAFF receptor have not been effective and/or safe enough to replace belimumab. The cost of IV belimumab once a month is approximately \$4070 ([www.goodrx.com](http://www.goodrx.com), searched on April 2018). Prices were not available at the time of this writing for the subcutaneous form, which will probably come into wide usage.

## T-Cell-Targeted Therapies

### Abatacept (CTLA4-Ig Blocks Second Signals: Ocrevus)

Abatacept (CTLA4-Ig) is a fully human soluble fusion protein that is effective for the treatment of RA. It consists of the extracellular domain of CTLA4 and the Fc portion of IgG1. CTLA4-Ig binds CD80 (B7-1) and

CD86 (B7-2) on APCs preventing these molecules from binding to their ligand, CD28, on T cells. This interferes with optimal T-cell activation resulting in decreased production of proinflammatory cytokines (Lenschow et al., 1996). Abatacept is effective, safe and produced statistically significantly less radiographic progression in RA. The US FDA has approved it for use in RA and polyarticular JIA patients who are inadequate responders to DMARDs (Maxwell and Singh, 2010). Abatacept may be used as an alternative to a TNF inhibitor. Abatacept can be administered intravenously every 4 weeks or it can be administered subcutaneously weekly. AEs include infusion reactions, infections, and headache. According to [www.goodrx.com](http://www.goodrx.com) searched on April 2018, the monthly cost of abatacept 125 mg subcutaneously weekly is \$4200.

## OTHER TREATMENT OPTIONS

### Apremilast (Otezla)

Apremilast is an orally available small molecule that specifically targets phosphodiesterase (PDE4) which results in an increased level of cAMP intracellularly in multiple cell types (T cells, mononuclear cells, others). Consequently, the increase in intracellular cAMP decreases the production of several proinflammatory mediators (TNF- $\alpha$ , IL-12, IL-23, IFN- $\gamma$ , and inducible nitric oxide synthase), and it increases the production of antiinflammatory cytokines (IL-10) (Schafer et al., 2010). This compound is effective in psoriasis and PsA and is US FDA approved for the treatment of active PsA or plaque psoriasis (moderate to severe), and/or PsA (Edwards et al., 2016). Apremilast is started at low dose with titration up to 30 mg twice daily. Modest efficacy has been shown in AS in a double-blind, placebo-controlled unpowered phase II study, but there was no statistical significance (Pathan et al., 2013). Its efficacy was also demonstrated in Behcet's disease (oral and genital ulcers) (Hatemi et al., 2015). The drug is well tolerated with diarrhea, nausea, headache, and weight loss being the most common side effects. No specific lab monitoring is required. The monthly cost of Apremilast at 30 mg bid orally is \$3100 according to [www.goodrx.com](http://www.goodrx.com) searched on April 2018.

### Tofacitinib (Inhibitor of Janus Kinase Activation Pathway: Xeljanz)

Tofacitinib is a novel orally administered disease-modifying agent which inhibits Janus kinase (JAK) enzymes, therefore decreasing signaling by a number of cytokine and growth factor receptors, resulting in reduction of a variety of inflammatory mediators. Tofacitinib was shown to be effective and can be used as monotherapy or combined with MTX (our usual approach) or other nonbiologic DMARDs in patients with moderately to severely active RA who have had an inadequate response to MTX (Fleischmann et al., 2012; Kremer et al., 2013). It is taken in a dose of 5 mg twice daily or 11 mg extended release daily. The relative safety of tofacitinib appeared similar to that of other biologic disease modifying agents, including increased risk of infection and abnormal liver function tests. Other side effects include neutropenia, lymphopenia, hyperlipidemia, and, possibly, increased serum creatinine and gastrointestinal perforations. The ACR recommends that tofacitinib be used in patients with RA who have failed to respond adequately to MTX plus a TNF-inhibiting or non-TNF-inhibiting biologic (including abatacept, rituximab, tocilizumab) (Singh et al., 2016). Thus it is not yet viewed as first-line therapy for most patients with RA. Several additional Jak–Stat inhibitors, some more specific for molecules that do not inhibit hematopoiesis, are in development. Baricitinib has recently been approved by the FDA for treatment of RA. According to [www.goodrx.com](http://www.goodrx.com) searched on April 2018, the monthly cost of tofacitinib at 5 mg bid orally is \$4100.

## INTRAVENOUS IMMUNOGLOBULIN

The use of intravenous IV immunoglobulin (IVIG) in autoimmune diseases has several possible mechanisms of action in suppression of inflammatory and autoimmune processes, including interference with Fc receptors on effector cells, supply of antiidiotypic antibody activity against serum autoantibodies, inhibition of reticuloendothelial clearance of antibody-covered platelets via Fc receptors, and regulation of expression of proinflammatory cytokines and blockade of adhesion molecules in inflammatory states (Silvergleid and Berger, 2011). In addition, other effects of IVIG include solubilization and clearance of immune complexes, altered T-cell subsets, and increased T regulatory cells. IVIG is useful in a wide range of autoimmune and autoinflammatory diseases such as Guillain–Barré syndrome, myasthenia gravis, autoimmune peripheral neuropathies, Kawasaki disease,

hematologic conditions such as autoimmune thrombocytopenia, hemolytic anemia or neutropenia, and antibody-mediated CNS diseases resulting from interference with neurotransmitter function. Small studies have shown that IVIG is a reasonable second-line therapy for refractory dermatomyositis or polymyositis (Cherin et al., 2002; Dalakas et al., 1993). AEs of IVIG treatment include allergic reactions, including anaphylaxis (particularly in males who are IgA deficient), headache, nausea, chills or flushing, aseptic meningitis, thrombosis, and renal dysfunction. Most of these reactions are mild and transient, reversible events. Serious reactions are rare (Silvergleid and Berger, 2011). According to Epocrates, searched on April 2018, the cost of a single “round” of IV Ig varies from \$3500 to \$8000, depending on the dose and the supplier. This does not include infusion costs.

## COMMENT REGARDING COSTS OF THERAPIES: BIOSIMILARS

As shown above, the cost of medications for treatment of a common inflammatory rheumatic disease, RA, can vary from \$300 to \$5000 per month. All of the recently developed treatments—biologics and small molecules—are on that expensive side. The costs are also quite variable depending on what contract has been made between the payer, the pharmacy provider, and the pharmacy benefits manager companies. Biosimilars have been developed which USA and European oversight bodies have approved for patient use. To date, biosimilars do not differ from the biologic they mimic in efficacy or toxicity (Cohen et al., 2017). Now the question becomes can they be priced to an advantage for the patients and providers—perhaps 30% less in cost? The answer appears complex, with a small number of European countries paying for only one biosimilar and not the original biologic for patients with RA. A recent study from the United Kingdom showed that using infliximab and etanercept biosimilars (in rheumatic diseases) saved the National Health Service 38.8 million pounds over 2 years (Aladel et al., 2017). In the United States, there is friction between choice, profit, and affordability, with some issues being decided in part by the legal system. Somewhere in the not-too-distant future, a compromise will have to be reached that allows care to be increasingly excellent but more affordable for patients, providers, and societies.

## MOVING TOWARD MORE BIOLOGICAL AND MOLECULAR THERAPIES

Over the past few decades, progressive advancement in our understandings of immunopathogenesis has led to a significant expansion of potential therapeutic targets. This scientific progress has ushered in widespread use of new biologic and molecular treatments specifically targeting B and T cells, costimulation and signal transduction molecules, maturation factors, cytokines, and TLRs on APCs. For example, anti-TNF therapy is now routinely used in RA and seronegative spondyloarthritides, as monotherapy or in combination therapy with traditional DMARDs as discussed above (Singh et al., 2016). Such new therapeutic targets are the subject of the next chapter and continue to improve the standard treatments and outcomes for many autoimmune diseases.

## INTRODUCTION

Autoimmune diseases represent a major therapeutic challenge. In many cases the disease is severe enough to significantly reduce longevity. In other cases the disease causes major handicaps and discomfort that justify the usage of aggressive treatments generating their own hazards. The past treatments were mainly palliative (substitutive), antiinflammatory, or immunosuppressive without any specificity for the pathogenic mechanisms of the disease.

Over the last decades, modern technologies have made new agents available, in particular monoclonal antibodies (MAbs) directed to key immune cell receptors or cytokines, which have created a true revolution and fostered major advancements in the treatment of rheumatoid arthritis, multiple sclerosis, systemic lupus erythematosus (SLE), psoriasis, and inflammatory bowel diseases. Many of these treatments that have been approved and are part of the regular armamentarium clinicians use to treat autoimmune patients have been described in previous chapters.

We will return to some of these treatments in a more holistic perspective to understand how the use strategies have been adapted and continue to adapt to achieve better efficacy and fewer side effects. We will also discuss strategies still in development that may, in a not too distant future, fill important gaps. In particular an ambitious goal is to induce or, in the case of established autoimmune diseases, to restore immune tolerance to target auto-antigens. This may be defined operationally as the possibility to harness the pathologic immune response following a short-term treatment while keeping intact the capacity of the host to respond normally to exogenous antigens. Restoration of self-tolerance has the major advantage of avoiding the side effects linked to chronic immunosuppression and, most importantly, to provide a real cure for the disease.

## MONOCLONAL ANTIBODIES USED CLINICALLY: WAYS TO MAKE THEM MORE EFFICIENT

Murine MAbs produced by mouse or rat hybridomas (Kohler and Milstein, 1975) specific for immune cell receptors were introduced in clinical practice close to 40 years ago and their use initially developed in the field of solid organ transplantation. Two major side effects, namely, the sensitization against the xenogeneic molecule and the cytokine-releasing potential observed with some particular specificities, explain why the use of rodent MAbs remained initially mostly confined to transplantation with only very few attempts in autoimmunity. The advent of humanized and human MAbs that are less immunogenic and better tolerated has completely changed the picture and allowed a more widespread use of these interesting therapeutic tools. At variance with conventional immunosuppressants, some MAbs specific for relevant lymphocytes receptors are unique in their capacity to induce, under adequate circumstances, immune tolerance to soluble proteins, foreign tissue alloantigens, and autoantigens (Cobbold et al., 2006; Chatenoud, 2003, 2010; Chatenoud and Bluestone, 2007).

MAbs display a wide spectrum of pharmacological and biological activities highly relevant to their capacity to “reprogram” the immune system. Thus depending on their fine specificity, MAbs will remove target cells, inhibit or block the functional capacity of the target without depleting it, neutralize major cytokines, and/or serve as receptor agonists triggering activation signals for specialized T-cell subsets and in particular regulatory T cells (Tregs) (Sakaguchi et al., 2008; Bach, 2003).

The repeated administration of murine MAbs invariably triggered a humoral immune response, a major clinical consequence of which was the neutralization of the antibody's therapeutic activity. Interestingly, this was not a global antimouse or antirat response; it was very restricted in its specificity with essentially antiisotypic and antiidiotypic antibodies being produced (Chatenoud et al., 1986a,b; Benjamin et al., 1986). Antiidiotypic antibodies that compete with the therapeutic antibody for antigen binding represent the neutralizing component of the response while antiisotypic antibodies are mostly nonneutralizing (Baudrihaye et al., 1984). Another peculiarity of this humoral response is its oligoclonality (Chatenoud et al., 1986a,b; Villemain et al., 1986), which explains that, at variance with what observed in patients immunized to polyclonal antilymphocyte globulins, serum sickness was a rare consequence of sensitization to MAbs since the amount of immune complexes formed would be insufficient to elicit a generalized reaction. Antimonoclonal IgE responses associated with symptoms of anaphylaxis were reported but remained a very uncommon observation (Abramowicz et al., 1992, 1996).

Until humanized MAbs or more recently fully human antibodies became available the only way to cope with the problem of sensitization was to associate adequate doses of chemical immunosuppressants (Hricik et al., 1990). Two types of humanized antibodies have been derived from molecular engineering. Chimeric MAbs express intact rodent variable regions linked to human immunoglobulin constant domains (Morrison et al., 1984). In fully reshaped or complementarity determining region (CDR)-grafted antibodies the rodent hypervariable regions interacting with the antigen (CDRs) are included within human heavy and light chain immunoglobulin frameworks (Riechmann et al., 1988). Fully human MAbs have been produced by different means. First, mice have been invalidated for the expression of endogenous (mouse) immunoglobulin genes and concurrently made transgenic for sufficient human constant and variable immunoglobulin-encoding sequences to provide for antibody diversity; B cells from these immunized mice produce human antibodies that can be used in conventional fusions to obtain hybridomas yielding high-affinity MAbs derived from *in vivo* antigen-driven selection (Lonberg et al., 1994). Second, there is a fully *in vitro* approach using cDNA libraries expressed on filamentous phages to derive high-affinity antibodies to a wide variety of antigens, including those for which the conventional hybridoma technology fails due to poor immunogenicity (Marks et al., 1991). Third, human–mouse chimeras can be established using normal mice irradiated and reconstituted with bone-marrow cells from severe

combined immunodeficiency (SCID) mice; after human lymphocytes from presensitized donors are inoculated, these mice are boosted with the antigen of interest, and sensitized human B cells recovered and used for conventional fusions (Lubin et al., 1994).

Humanized MAbs and fully human MAbs have significantly reduced though not totally avoided the risk of deleterious antiidiotypic responses. Both chimeric and reshaped humanized MAbs may be immunogenic when administered alone, without associated immunosuppressants (Herold et al., 2002; Keymeulen et al., 2005; Elliott et al., 1994). As for murine antibodies, combining low doses of chemical immunosuppressants, as is regularly done with anti-tumore necrosis factor (TNF) in rheumatoid arthritis, is a very efficient way to overcome sensitization (Feldmann, 2002; Nashan et al., 1997; Vincenti et al., 1998). Importantly, the frequency of immunization varies according to the fine specificity of the MAbs. For example, immunization is common for humanized CD3 and CD52 antibodies (Somerfield et al., 2010; Herold et al., 2002; Keymeulen et al., 2005). It is lower for anti-TNF antibodies, especially in rheumatoid arthritis because of the regular association with conventional immunosuppressants such as methotrexate (Feldmann, 2002). At variance, in inflammatory bowel diseases the problem is relevant because the immunization leads to the neutralization of the therapeutic effect, and the possibilities of switching to other immunotherapies are more limited than in rheumatoid arthritis, as soluble TNF receptors are ineffective in this indication.

### Engineering Fc Regions of Monoclonal Antibodies to Avoid Side Effects and Prolong Half-Life

Antibody engineering allows the design of tailor-made antibodies to fit at best therapeutic indications. Antibodies expressing human Fc portions have a significantly prolonged half-life. In addition, the choice of the human Fc portion will influence the antibody effector capacities, that is, its activity in terms of complement fixation, opsonization, and antibody-dependent cell cytotoxicity. In addition, in the case of CD3 antibodies, humanization can circumvent problems due to their intrinsic mitogenic and cytokine-releasing capacity that leads in vivo to a "flu-like" syndrome. This syndrome was regularly observed with murine CD3 MAbs such as OKT3, and although transient, it represented a major and troublesome side effect that totally precluded the use of CD3 MAbs for indications other than organ transplantation (Chatenoud et al., 1990; Abramowicz et al., 1989; Chatenoud, 2003). This mitogenic capacity is linked to the ability of the Fc portion of CD3 MAbs to interact with monocyte Fc receptors (Chatenoud, 2003). Thus "nonmitogenic," non-Fc binding, CD3 antibodies were obtained by inserting adequate mutations into the Fc domains to hamper Fc receptor binding (Alegre et al., 1994; Bolt et al., 1993; Chatenoud, 2003). Clinical use of two different Fc-mutated CD3 MAbs, teplizumab (OKT3 $\gamma$ 1Ala-Ala) and otelixizumab (ChAglyCD3), in autoimmunity and transplantation, confirmed that their use was free of major side effects (Friend et al., 1999; Herold et al., 2002; Sherry et al., 2011; Keymeulen et al., 2005; Woodle et al., 1999; Hering et al., 2004).

### Engineering Variable Regions of Monoclonal Antibodies to Increase Affinity

In case the affinity of a given MAbs is too low for in vivo use, phage display technology is an interesting approach to generate an improved fully human reagent with no requirement for prior immunization or use of hybridoma technology. Phage display can be used to mimic artificially the processes used in vivo by the immune system to obtain high-affinity antibodies. This has been achieved by shuffling the heavy or light chains by random or directed mutagenesis of CDR (Barbas et al., 1994), as done by error prone polymerase chain reaction. Using such artificial affinity maturation of phage antibody repertoires, affinities of MAbs in the nanomolar to picomolar range have been generated that are perfectly suitable for therapeutic use (Foote and Eisen, 1995; Barbas, 1995).

### Engineering Variable Regions of Monoclonal Antibodies to Decrease Immunogenicity

Herman Waldmann's group made a very important observation in the mid-1980s, showing that immunization against idiotypic determinants of therapeutic MAbs, that as discussed earlier neutralizes the therapeutic effect, was essentially observed with MAbs recognizing cell-surface determinants but not with MAbs directed against soluble molecules (Benjamin et al., 1986). Building on these data, more recently, the working hypothesis they proposed is that a few mutations in key CDRs transforming a given cell-binding MAb into a nonbinder would generate a "tolerizing" form of the MAb. To directly test the hypothesis, humanized mice expressing the human

CD52 molecule as a transgene at the T-cell surface were first used. Injection in these mice of the human IgG1 version of humanized CD52 MAb ablated mouse T lymphocytes as expected and induced a humoral response to the foreign antibody (mouse anti-CD52 idiotype response). In sharp contrast, mice previously injected with nonbinding mutants of the human IgG1 CD52 MAb (the “tolerogens”) did not mount a humoral response when treated with the conventional therapeutic cell-binding CD52 Mab (Gilliland et al., 1999; Waldmann, 2019). Remarkably, the clinical proof-of-concept was obtained in patients presenting with multiple sclerosis and treated with the IgG1 CD52 antibody, alemtuzumab. A noncell binding MAb mutant, the “tolerogen,” injected prior to alemtuzumab treatment very significantly reduced the humoral response of the patients to both a first and a second course of alemtuzumab (Somerfield et al., 2010). Despite its effectiveness, it is clear that this two-step strategy is complicated to implement on a regular basis. In order to overcome the practical problem of consecutive administration of two different MAbs the authors engineered an antibody molecule they named “Stealth” with a covalently attached blocker antigen mimotope into the binding site leading to a transiently nonbinding MAb at the time of infusion that renders it “tolerogenic” (Waldmann, 2019). Within a few days the mimotope detaches itself from the antibody molecule, which thus “recovers” all its binding capacity and therefore its therapeutic potential (Waldmann, 2019). The Stealth version of the CD52 MAb is T-cell depleting in the humanized CD52 transgenic mouse but not immunogenic (Waldmann, 2019). It would be highly relevant for obvious reasons to further implement this technology on different MAbs specificities.

## THE ADEQUATION OF THE ANTIBODY SPECIFICITY TO THE TARGET DISEASE: FROM IMMUNOSUPPRESSION TO IMMUNE TOLERANCE

It is interesting to step back and observe that the biological products which made their way to approval were launched into a given autoimmune disease and then showed a more or less pronounced therapeutic efficacy in other autoimmune diseases. This is important because these results have strongly influenced our understanding of the pathophysiological heterogeneity within given autoimmune diseases. Indeed, for each pathology the response or not to a given treatment turned out a precious tool to define subgroups of patients, more commonly defined as patient’s endotypes. Defining subgroups of patients leads to the characterization of biological markers that make it possible to identify these different individual before any treatment, to better adapt the therapies and also the possible therapeutic combinations. This ultimately means moving toward a personalized treatment of autoimmunity to improve therapeutic efficacy, thereby reducing side effects.

Another important point that should guide our thinking concerns the type of therapeutic effect obtained. Is it immunosuppression, with the necessity of repeating the treatment at regular intervals and, as a result, ultimately exposing patients to particularly infectious risks? Do some of the available biologics show an effect that is closer to operational tolerance with short term treatment leading to an effect which may be more long-lasting in the absence of chronic immunosuppression? Is this effect of operational tolerance more easily observed in certain subgroups of patients at precise stages of different diseases? This is the kind of thinking that we can finally have nowadays after years of experience with these quite numerous therapeutic tools applied for the regular treatment of autoimmune diseases (Chapter 71, Treatment of Autoimmune Disease: Established Therapies).

To illustrate these points, we shall address three indications where biological therapies have changed patient management while opening up in-depth thinking on how to improve their use on the basis of a better understanding of the pathophysiology of the disease.

### The Breakthrough in Rheumatoid Arthritis

There is no doubt that the story of MAbs to TNF in rheumatoid arthritis consequent on the pioneering experimental and clinical work of Feldmann and Maini (Brennan et al., 1989; Feldmann, 2002) is a straightforward and beautiful one that constituted a real revolution in the field.

The seminal finding was that neutralizing antibodies to TNF significantly decreased the production of most proinflammatory cytokines, that is, interleukin (IL)-1, IL-6, IL-8, GM-CSF, normally produced in vitro cultures of cells that infiltrate synovial membranes in rheumatoid arthritis (Brennan and Feldmann, 1992; Feldmann, 2002). The relevance of this finding to events in vivo was validated in mice that expressed a human TNF transgene and developed a form of chronic arthritis fully preventable by MAbs to TNF (Brennan and Feldmann, 1992; Feldmann, 2002). In addition, in collagen-induced arthritis, neutralizing antibodies to murine

TNF given at onset of disease decreased the severity of objective and histopathological features (swollen joints and bone erosions) (Piguet et al., 1992; Williams et al., 1992, 1994). These data rapidly led to first clinical trials and to the approval of infliximab both in the United States and Europe. Other biologic agents against TNF were developed, in particular two fusion proteins linking the TNF receptor molecules p55 or p75 to a human IgG constant region (lenercept and etanercept/Enbrel) (Furst et al., 2003; Moreland et al., 1996, 1997). However, only etanercept was developed in the clinic and was approved.

It soon became apparent that while the therapeutic effect of TNF blockers was important, it was of limited duration and required regular treatment. Then rapidly the number of new candidates tested and retained has increased with abatacept, rituximab, tocilizumab, and also small molecules blocking the Janus kinase, signaling pathway such as tofacitinib coming into the scene.

Regardless of therapeutics *per se*, practice has evolved to treat patients at early stages of the disease, defined as early rheumatoid arthritis, in order to avoid progression to irreversible lesions, thus obtaining better long-term results. Presently, patients presenting early rheumatoid arthritis are mostly stratified according to their autoantibody patterns and, more recently, on very early joint lesions detected by sensitive imaging methods (de Brito Rocha et al., 2019; Ma et al., 2014; Seegobin et al., 2014). The absence or presence of anticitrullinated peptide antibodies (ACPA) and the seroconversion are important prognostic markers to monitor the effect of treatment. Furthermore, recent studies highlight that the effect of early antirheumatic therapy on ACPA seroconversions varies if responses against cyclic citrullinated peptides and citrullinated peptides derived from vimentin (cVim), fibrinogen, and  $\alpha$ -enolase (CEP-1) are distinguished. The disappearance of particular ACPA reactivities (anti-cVim) in early rheumatoid arthritis is linked to a better radiological outcome (Kastbom et al., 2016). This is the best demonstration that the characterization of robust biomarkers derives very quickly from the use of effective treatments.

It is now well established that anticitrullinated peptide antibodies (ACPA), rheumatoid factors, and some other specificities, for example, antibodies to carbamylated proteins, may be detected many years before onset of joint lesions (Rantapaa-Dahlqvist et al., 2003; Catrina et al., 2017); ACPAs are the first autoantibody to appear, rapidly followed by the occurrence of rheumatoid factors (van de Stadt et al., 2011). The group of Klareskog proposes that the distinct patterns of autoantibody development before disease onset might provide insight into disease pathogenesis, contemplating in particular that pathogenic local immunity toward citrullinated proteins is initiated at other sites than the joints and more particularly in the lungs (Catrina et al., 2017). Therapeutic tools targeting these very early disease-triggering immune events, therefore targeting “prerheumatoid arthritis,” before joint inflammation appears could lead to a real cure of the disease (Catrina et al., 2017).

It is interesting before concluding to go back to the experimental setting to mention an unexpected and interesting observation. In established collagen-induced arthritis, combination of a suboptimal dose of anti-TNF (which had no significant effect *per se*) with a short course with monoclonal anti-T-cell antibodies such as CD4 and CD3 MAbs greatly improved joint inflammation and helped heal paw-swelling and bone erosions in the long term (Williams et al., 1994; Depis et al., 2012). Thus neutralizing inflammation, as done with anti-TNF, effectively “sensitizes” the immune system in rheumatoid arthritis to T cell–directed immunointervention. Given the capacity of CD3 antibodies to restore tolerance, which will be described in more detail below, it is relevant to contemplate that combining agents targeting inflammation and T cells could be a novel and very powerful tool to achieve a long-term therapeutic effect in rheumatoid arthritis, even in established disease, thereby approaching operational tolerance.

## The Breakthrough in Multiple Sclerosis

The introduction of natalizumab (Tisabry), a humanized antibody specific for the  $\alpha 4$ -chain of  $\alpha 4\beta 1$  integrin (VLA-4) expressed by leukocytes, in 2004 was a decisive step in the use of biotherapies as major disease-modifying drugs in multiple sclerosis. Integrins are adhesion molecules of fundamental importance to the recruitment of leukocytes in inflammation. The alpha4beta1 integrin VLA-4 is a leukocyte ligand for endothelial vascular cell adhesion molecule-1 (VCAM-1), fibronectin, and osteopontin. The interaction between VLA-4 at the surface of activated lymphocytes and monocytes with its ligand VCAM-1 is essential for cell migration into inflamed parenchyma. Promising data in experimental models of blockade of VLA-4 prompted use of natalizumab in patients with relapsing–remitting or relapsing secondary progressive multiple sclerosis. A marked reduction in the number of new brain lesions [gadolinium-enhanced magnetic resonance imaging (MRI)] was observed in treated patients (Miller et al., 2003).

Unfortunately, natalizumab is highly immunosuppressive and discontinuation of treatment precipitates relapses. Patients therefore receive repeated treatments to maintain remission. Reports rapidly focused on the risk of opportunistic brain infection caused by the polyoma JC virus (JCV). The use of natalizumab was temporarily stopped. In 2006 a panel of experts assessed 3417 patients with multiple sclerosis, Crohn's disease, or rheumatoid arthritis, who had received the antibody for an average of 17 months, and did not identify additional cases of progressive multifocal leukoencephalopathy (PML). Given the beneficial effect of the antibody on the progression of multiple sclerosis, this reassuring assessment led to the antibody being reintroduced (Brandstädter and Katz Sand, 2017). The benefit/risk ratio of the drug being regarded as positive, natalizumab remains a therapeutic option of interest in multiple sclerosis, subject however to strict patient selection, for example, exclusion of patients with anti-JCV antibodies and limiting the duration of treatment [the risk is higher in patients treated for more than 2 years (Brandstädter and Katz Sand, 2017)].

It is interesting to discuss the case of the other major therapeutic tool for multiple sclerosis, the CD52 antibody Campath-1 (alemtuzumab), which is also immunosuppressive but whose long-term therapeutic efficacy does not require frequent treatment cycles such as natalizumab. We are here on a biological product which could, we will discuss it further, with a favorable combination, bring us closer to a situation of operational tolerance.

Antibodies to CD52 target a small (12 amino acids) glycosylphosphatidylinositol-anchored protein of undefined function expressed at the surface of human B and T cells and monocyte/macrophages. CD52 MAbs are highly depleting and have potent efficacy in long-term acceptance of organ allografts and maintaining remission in established and otherwise intractable autoimmune diseases, notably multiple sclerosis and vasculitis (Calne et al., 1998; Lockwood et al., 1993, 1996; Mathieson et al., 1990). The first rat MAb to CD52, Campath-1H, was characterized in 1983. A fully reshaped humanized version, Campath-1H (human IgG1), was derived by genetic engineering (Riechmann et al., 1988) and is marketed as alemtuzumab (Lemtrada). Its depleting capacity has led to its extensive use in vivo to treat CD52<sup>+</sup> hematologic malignancies and in vitro to purge bone-marrow transplants to prevent graft-versus-host disease.

Initial trials included patients with long-standing relapsing/remitting multiple sclerosis unresponsive to conventional treatments. Long-term follow-up showed a marked decrease in the appearance of new lesions in the central nervous system as assessed by MRI scanning that correlated with the persisting and significant depletion of peripheral CD4<sup>+</sup> T lymphocytes (Coles et al., 1999a,b, 2004). Phase III trials have been completed, and alemtuzumab has been approved for treatment of relapsing/remitting multiple sclerosis (Cohen et al., 2012; Coles et al., 2012).

Treatment with alemtuzumab elicits some side effects including a long-lasting lymphopenia not associated with increased rate of opportunistic infections, a transient cytokine release syndrome after the first injection (Coles et al., 1999a,b), and a neutralizing antiidiotypic immunization is observed in a significant proportion of patients (Somerfield et al., 2010). Another more unexpected side effect was the development of autoimmune disorders, particularly autoimmune thyroiditis (in up to 30% of patients with multiple sclerosis) or more rarely autoimmune cytopenias (Coles et al., 1999a,b; CAMMS223 Trial Investigators et al., 2008; Jones et al., 2009). In one of the trials in multiple sclerosis, several cases (2.8%) of idiopathic thrombocytopenic purpura have been reported (CAMMS223 Trial Investigators et al., 2008; Cuker et al., 2011). The occurrence of these complications is independent of the therapeutic effect of the antibody but appears to be related to treatment-induced lymphopenia. These autoimmune manifestations occur in patients in whom homeostatic cell proliferation following depletion induced by the antibody is more important. This phenomenon is dependent on IL-21, a cytokine for which circulating levels are increased before treatment in patients who will develop the posttreatment autoimmune manifestations. It has been therefore proposed to use IL-21 pretreatment levels may serve as a predictive parameter to identify patients at risk of this type of side effect (Jones et al., 2009).

Campath-1H also proved very effective in severe systemic small vessel vasculitis, in which the pathogenesis depends mainly on T cell-mediated mechanisms. The long-term remissions that were obtained when combining antibodies to CD52 and CD4 were particularly impressive (Lockwood et al., 1993, 1996; Mathieson et al., 1990).

In conclusion, alemtuzumab appears to be a treatment of choice in relapsing/remitting multiple sclerosis and also for severe autoimmune diseases such as vasculitis refractory to other treatment.

It is obvious that the lymphopenia induced by alemtuzumab, and especially the period of reconstitution post-lymphopenia, poses a clinical problem (i.e., thyroid disease). In the transgenic mouse model that expresses human CD52 on the surface of T lymphocytes, it has also been shown that lymphopenia prevents the induction of immune tolerance against organ allografts because reconstitution is accompanied by a significant homeostasis proliferation of T lymphocytes with emergence of pathogenic lymphocytes. This is a situation that can be effectively circumvented, at least in mice, by combining to alemtuzumab a MAb-neutralizing IL-7 that is mandatory to drive homeostatic proliferation (Piotti et al., 2014). This is a therapeutic combination that would be very interesting to test in clinic as soon as an antibody-neutralizing IL-7 becomes available.

## The Breakthrough in Autoimmune Diabetes

The story of CD3 MAbs is paradoxical and remarkable. They were the first therapeutic antibody introduced in clinical practice in 1981, about 4 years before the molecular complexities and the key functional role of the CD3 molecule were discovered (Clevers et al., 1988). OKT3, a mouse IgG2a MAb directed to human CD3 (Kung et al., 1979), was initially used to treat and prevent renal allograft rejection (Cosimi et al., 1981; Debure et al., 1988; Vigeral et al., 1986). This occurred without any in vivo preclinical data available due to the tight species-specificity of anti-T-cell MAbs in general and CD3 antibodies in particular. Chimpanzees are in fact the only nonhuman primates harboring T lymphocytes cross-reacting with MAbs to human CD3. In addition, antibodies to mouse CD3 were difficult to produce, the first one being characterized by Leo et al. (1987). Over the 1980s, controlled studies clearly demonstrated that MAb OKT3 was a potent immunosuppressant very efficient at reversing early acute renal allograft rejection episodes (Cosimi et al., 1981; Ortho, 1985), an indication for which this MAb was rapidly licensed both in the United States and Europe. Through the study of OKT3-treated patients an enormous knowledge was gained on the mode of action of murine anti-T-cell monoclonals and their side effects. These studies have been invaluable for the design of more refined approaches using humanized MAbs. As other immunosuppressants developed, the use of OKT3 was abandoned, essentially because of its cytokine-releasing potential (Chatenoud et al., 1989, 1990; Abramowicz et al., 1989).

CD3 MAbs used in vitro in functional studies and in vivo, both in the experimental and the clinical setting, are specific for the  $\epsilon$  chain of the CD3 complex. The experimental work conducted in different rat and mouse models suggested that more than simply depressing all immune responses, CD3 MAbs could also induce immune tolerance to both alloantigens and autoantigens (Nicolls et al., 1993; Plain et al., 1999; Goto et al., 2013; You et al., 2012). Perhaps more impressively, CD3 MAbs could restore self-tolerance in established autoimmunity (Belghith et al., 2003; Chatenoud et al., 1994, 1997; Chatenoud, 2003). Based on these data, CD3 MAbs have again entered the clinical arena but now as well-tolerated humanized nonmitogenic MAbs (Alegre et al., 1994; Bolt et al., 1993) used not only in transplantation, but also in autoimmunity in protocols aimed at antigen-specific long-term effects rather than just immunosuppression.

### **CD3 Monoclonal Antibodies and Autoimmune Diabetes**

Trials have been conducted using CD3 MAb to treat patients with recent-onset type 1 diabetes based on our data in diabetes-prone nonobese diabetic (NOD) mice that spontaneously develop autoimmune diabetes. Short-term (5 days) treatment of overtly diabetic NOD mice with low doses (5–20  $\mu$ g/day) of CD3 MAbs, in either their mitogenic (whole 145 2C11) or nonmitogenic version [F(ab')2 fragments of 145 2C11], induced disease remission by restoring self-tolerance (Belghith et al., 2003; Chatenoud et al., 1994, 1997; Chatenoud, 2003). The effect was long-lasting and specific to  $\beta$ -cell autoantigens (Belghith et al., 2003; Chatenoud et al., 1994, 1997; Chatenoud, 2003). Immune mechanisms mediating this tolerogenic capacity evolve in two distinct consecutive phases (Chatenoud, 2010; Chatenoud and Bluestone, 2007). The first, the induction phase, coincides with antibody administration and results in clearing of insulitis, explaining the rapid return to normoglycemia, with a transient Th2 polarization which is irrelevant to the long-term effect since there is prolonged remission of disease after anti-CD3 treatment of IL-4 deficient NOD mice (NOD IL-4 $^{-/-}$ ) (Belghith et al., 2003; Chatenoud, 2003). The second maintenance phase results in upregulation and/or appearance of specialized subsets of CD4 $^{+}$ CD25 $^{+}$ FoxP3 $^{+}$  and CD4 $^{+}$ CD62L $^{+}$ FoxP3 $^{+}$  Treg that mediate transferable active tolerance, and that effectively control pathogenic effector cells as shown by cotransfer experiments in immunodeficient NOD SCID mice (Belghith et al., 2003; Chatenoud et al., 1994, 2001). The proportions of CD4 $^{+}$ CD25 $^{+}$ FoxP3 $^{+}$  Treg increase in pancreatic and mesenteric lymph nodes of CD3 MAb-treated tolerant mice (Belghith et al., 2003). Interestingly, CD4 $^{+}$ CD25 $^{+}$ FoxP3 $^{+}$  Treg induced by CD3 MAb may not derive exclusively from conventional natural regulatory CD4 $^{+}$ CD25 $^{-}$ FoxP3 $^{+}$  T cells but also, and perhaps even essentially so, from CD4 $^{+}$ CD25 $^{-}$  precursors that differentiate in the periphery (Belghith et al., 2003; You et al., 2007). In fact, CD3-specific MAb treatment induces diabetes remission also in NOD mice deficient for the costimulation molecule CD28 (NOD CD28 $^{-/-}$ ) that are devoid of thymic CD4 $^{+}$ CD25 $^{+}$ FoxP3 $^{+}$  Treg (Belghith et al., 2003). The immunoregulatory cytokine TGF $\beta$  appears to be a key player in this T cell-mediated regulation. Thus CD4 $^{+}$  T cells from mice tolerant after CD3 MAb treatment consistently produce high levels of TGF $\beta$ , and in vivo neutralization of TGF $\beta$  after injection of specific MAbs fully prevents anti-CD3-specific-induced remission (Belghith et al., 2003; Kuhn et al., 2011).

Clinical trials have been conducted to explore modalities that would reproduce this remarkable effect. Results from an open trial using teplizumab (OKT3 $\gamma$ 1Ala-Ala) in patients that present recent-onset type 1 diabetes were very encouraging (Herold et al., 2002, 2005). Thus at 1 year after a short-term treatment, a significant preservation

of the  $\beta$ -cell mass was observed in treated patients compared with controls (Herold et al., 2002, 2005). The results of a European multicentric randomized placebo-controlled trial using the otelixizumab (ChAgyCD3) MAb, also in recent-onset autoimmune type 1 diabetes fully confirmed the expectations. Results obtained at 18 months of follow-up showed not only a significant preservation of the  $\beta$ -cell mass in otelixizumab versus placebo-treated patients but also an impressive decrease in the insulin needs that lasted for up to 4 years after the end of the short-course treatment (Keymeulen et al., 2005, 2010). Another important study also showing the efficacy and the good safety profile of teplizumab was the Autoimmunity-Blocking Antibody for Tolerance (AbATE) protocol, 2-year results of which were reported in 2013 (Herold et al., 2013). In AbATE the treatment group received a 14-day course of teplizumab at study entry and at 1 year. A post hoc analysis of the data identified metabolic and immunological variables that differentiated individuals who responded to treatment with teplizumab from the nonresponders; 45% of the drug-treated patients were classified as responders, and these individuals had lower HbA1c and lower insulin requirements prior to treatment, suggesting the presence of a functionally larger beta-cell mass at the time of treatment initiation (Herold et al., 2013). Recently, the long-term follow-up (7 years on average, range up to 9 years) of patients included in AbATE was reported (Perdigoto et al., 2018).

Phase III trials were launched by two biotech companies in association with large pharmaceutical companies using designs, which were quite different from that of the previous Phase II studies. The Phase III trial using otelixizumab (Tolerx/GlaxoSmithKline trial) used a reduced dose with the aim to reduce side effects. This dose, which has not been validated for efficacy in a proper Phase II placebo-controlled study, was 16 times lower than the one used in the successful Phase II academic trial (3.1 mg compared to 48 mg).

The Phase III study using teplizumab (Macrogenics/Eli Lilly trial) had a composite end point chosen arbitrarily (i.e., insulin requirement  $\leq 0.5$  U/kg/day and HbA1c  $\leq 6.5\%$ ) that had not been previously validated in a controlled trial and which seemed to be unfortunate choice (Bach, 2011).

Importantly, a post hoc analysis of the data from the teplizumab study was performed using the conventional end points validated by all previous trials in the field, namely, C-peptide production and insulin needs, which evidenced a significant therapeutic effect (Sherry et al., 2011). A better response was observed in patients presenting the highest stimulated C-peptide at inclusion (e.g., less than 6 weeks of insulin therapy since diagnosis) and in children and young adults (8–17 years). The response was dose-dependent, that is, only observed in patients receiving the higher dose tested of 17 mg (cumulated, equivalent for a 70 kg individual) (Sherry et al., 2011; Daifotis et al., 2013). A second Phase III trial using teplizumab is presently ongoing to extend the data of Protégé.

In a parallel effort, TrialNet conducted a prevention trial using teplizumab in young subjects “at risk of developing hyperglycemia” but screened as beta-cell autoantibody positive in families including at least one type 1 diabetic probant (Triolo et al., 2019). The rational here is to intervene earlier in disease progression to recruit patients with a higher number of functioning beta cells. The consensus is in fact that a large fraction of beta cells have been destroyed by the autoimmune process when hyperglycemia is first diagnosed: this is the case for patients enrolled in the Phases I, II, and III trials we described earlier. Estimates suggest that about 30% of the functional beta-cell mass is still present in such patients. Under these circumstances, it may be difficult to objectively evaluate any long-term efficacy due to an already reduced beta-cell mass at the beginning of treatment, hence the interest to perform trial in subjects/patients who have already an ongoing immunological disease but who are not yet hyperglycemic. The TrialNet study recruited 76 patients who were randomized to receive a single course of 14 days of teplizumab (17 mg; cumulated, equivalent for a 70 kg individual) or placebo. The end point will address whether teplizumab, compared to placebo, may significantly delay and/or prevent progression to hyperglycemia. The trial is completed, the data are being analyzed, and results will be available mid-2019.

As a whole, nearly 800 patients (166 young children aged 8–11 years, and 308 adolescents aged 12–17 years) included in the various trials have received teplizumab. This further points to the therapeutic efficacy of the drug and its favorable safety profile of teplizumab, confirmed by the results of the 7-year follow-up of AbATE (Perdigoto et al., 2018).

In conclusion, autoimmune diabetes is confronted to the dramatic increase in incidence in industrialized countries that is in addition affecting an increasingly younger patient population (Bach, 2002, 2018; Patterson et al., 2018). Presently, chronic insulin therapy, the only palliative treatment available, is far from satisfactory. There is yet no immunotherapy on the market. This lack of approved therapies to tackle the cause of the disease, namely, the autoimmune reaction, must be corrected as soon as possible. CD3 MAbs appear as very good candidates to start solving the issue. Major hopes for the future are also based on combination therapies. Potential candidates are numerous, including new biologicals, autoantigens, and also cell therapy (i.e., Treg). It is worth noting that a number of the proposed combination therapies include a CD3 MAb (Hu et al., 2013; Mamchak et al., 2012; You et al., 2013; Besancon et al., 2018).

Time will tell if the promising results obtained in autoimmune diabetes suggesting that CD3 MAb induces an “operational” restoration of immune tolerance can be extended to other autoimmune diseases.

## The Surprises and the Expectations of B Lymphocyte Targeting

Rituximab is a human–mouse chimeric MAb, specific for the CD20 B-cell antigen, which causes rapid depletion of B lymphocytes. Rituximab (MabThera) was approved to treat severe refractory CD20-positive non-Hodgkin’s B-cell lymphoma. The use of CD20 MAb has been extended to first-line therapy and maintenance therapy in lymphoma, for stem-cell transplantation procedures, and also for a variety of autoimmune disorders, including rheumatoid arthritis, immune thrombocytopenic purpura, autoimmune hemolytic anemia, SLE, vasculitis, dermatomyositis, multiple sclerosis, and autoimmune type 1 diabetes (De Vita et al., 2002; Leandro et al., 2002, 2005; Pescovitz et al., 2009; Rastetter et al., 2004; Silverman and Weisman, 2003; Gelfand et al., 2017; Greenfield and Hauser, 2018; Sabatino et al., 2019). Among these there are obvious indications since the pathophysiology of the disease involves pathogenic autoantibodies, and therefore it seems appropriate to destroy the B cells producing these autoantibodies. The surprise was that in some of these indications, such as SLE, the effectiveness of CD20 antibody was rather disappointing compared to the very encouraging results observed in multiple sclerosis a condition wherein pathogenic T cells more than autoantibodies are regarded as the main pathogenic actors. At a fundamental level, these results highlight the pathogenic role of B lymphocytes not only as antibody-producing cells but also as antigen-presenting cells, which hitherto had been considered of marginal importance.

In SLE a first report, further supported by a series of off-label trials, described that B-cell depletion was successfully obtained in patients using rituximab and that disease remission could be achieved (Leandro et al., 2005). In most studies, better therapeutic efficacy correlated with the degree of B-cell depletion achieved and a good clinical response was accompanied by improvement in laboratory parameters. However, two multicenter randomized placebo-controlled trials, one in patients with moderate-to-severe nonrenal disease and the other in proliferative lupus nephritis, did not confirm such benefit (Merrill et al., 2010; Rovin et al., 2012). Numerous reasons may explain this discrepancy that have been cogently reviewed by Furtado and Isenberg (2013). These include differences in the clinical profile of patients, their ethnicity, the cumulative dose of rituximab administered, the duration of follow-up, the degree of B-cell depletion achieved, and, last but not the least, the choice of end points such as criteria for response and flares as well as their assessment (Furtado and Isenberg, 2013). Selecting end point criteria is in fact a major problem since there is a variety of scores to grade disease severity, and a very good clinical experience is mandatory to apply them wisely (Furtado and Isenberg, 2013). A consensus still exists for not abandoning the track of B cell in SLE. It is considered vital however that clinical trials make the most of the controversial experience with rituximab.

The quest to find agents that will better and more efficaciously target B cells in SLE continues with agents targeting B-cell growth factors and with new-generation CD20 MAbs. One example, atacicept is a recombinant molecule (formerly referred to as transmembrane activator and CAML interactor (TACI)-Ig) coupling a human Fc fragment and soluble TACI that is the receptor for the cytokines BlyS/BAFF (B-lymphocyte stimulator/B-cell activating factor) and APRIL (a proliferation-inducing ligand). Results showing evidence of efficacy were recently reported in a Phase IIb study together with good safety (Merrill et al., 2018). New-generation CD20 MAbs include humanized antibodies, for example, ocrelizumab, veltuzumab, and obinutuzumab, and one fully human MAb ofatumumab. These CD20 antibodies have increased binding affinity to the Fc receptor on B cells and increased complement-dependent cytotoxicity and/or antibody-dependent cellular cytotoxicity ability. The next 4–5 years will be decisive for concluding.

In multiple sclerosis a Phase II trial showed that a single course of rituximab reduced inflammatory brain lesions and clinical relapses (Hauser et al., 2008). Ocrelizumab has recently been granted US Food and Drug Administration (FDA) approval for both relapsing/remitting and primary/progressive multiple sclerosis. Further studies are in progress to better define the utility of ocrelizumab over the other biological therapies available (Gelfand et al., 2017; Greenfield and Hauser, 2018; Sabatino et al., 2019). From a more fundamental point of view, these clinical data underscore the importance of advancing rapidly on the issue of the role of B cells in multiple sclerosis.

## BONE-MARROW TRANSPLANTATION

Autoimmune diseases include genetic components expressed in lymphoid and macrophage lineages qualify as stem-cell disorders. This explains that, in particular, before the availability of biological disease-modifying drugs

that patients with serious autoimmune diseases have been considered for high-dose immunosuppression followed by hemopoietic stem-cell transplantation (HSCT) (Ikehara et al., 1990; Ikehara, 1998; Tyndall and Gratwohl, 1997). In the clinic the strategy stemmed from observations in patients with malignancies and concurrent autoimmune diseases (McAllister et al., 1997). Experimental results also showed that whether allogeneic or autologous HSCT induced a high rate of disease remission provided adequate conditioning regimens were administered (van Bekkum, 1998; Karussis et al., 1992, 1993; Ikehara et al., 1985).

The First International Symposium on Haemopoietic Stem Cell Therapy in autoimmune diseases took place in 1996 (Tyndall and Gratwohl, 1997) and inaugurated collaborations Autoimmune Diseases Working Party (ADWP) of the European Society for Blood and Marrow Transplantation (EBMT); guidelines were proposed that participating centers reported their results in a dedicated registry. The EBMT ADWP database now includes over 2500 patients treated during the past 20 years (Alexander et al., 2018). Among 2606 HSCT procedures reported, 2417 patients have undergone autologous HSCT and 133 patients allogeneic HSCT. Main indications for autologous HSCT were multiple sclerosis, scleroderma, Crohn's disease, and SLE. A similar registry was created in North America (Center for International Blood and Marrow Transplant Research).

The source of the stem-cell transplant is mostly peripheral cells mobilized using cyclophosphamide in combination with hematopoietic growth factors, granulocyte-colony stimulating factor (G-CSF) alone, or combined with granulocyte macrophage-colony stimulating factor (GM-CSF). According to different studies, the grafts are either purged of mature T cells, which may contain autoreactive effectors, by selection of CD34<sup>+</sup> cells with or without additional MAb-dependent T-cell depletion, or are not manipulated. Pretransplant conditioning regimens, for which the aim is to ablate as completely as possible the diseased (autoreactive) component of the immune system, include total body irradiation, chemotherapy-based regimens such as BEAM (Carmustine (BCNU), etoposide, cytosine arabinoside, melphalan), cyclophosphamide with or without antilymphocyte globulins and with or without other drugs, or total body irradiation and busulfan (Daikeler et al., 2011).

Results from both pilot and large trials show benefit in patients with systemic sclerosis in favor of HSCT over cyclophosphamide (Alexander et al., 2015, 2018).

The first studies performed in patients with severe multiple sclerosis with significant functional disability allowed assessment of risk/safety ratio but not of efficacy. Subsequently, with the implementation of the procedure in patients with less severe disease, significant clinical benefit was observed in some groups of patients, including those with aggressive recurrent/relapsing forms of the disease. A recent long-term retrospective study that included unselectively any transplants performed between 1996 and 2005 ( $n = 281$ ) in both relapsing-remitting and progressive multiple sclerosis patients reported long-standing remissions (Muraro et al., 2017a,b). These data were confirmed by a meta-analysis (Sormani et al., 2017). These data and those from the retrospective analysis of the EBMT registry indicate that autologous bone-marrow transplantation is an option only in patients with severe and active multiple sclerosis unresponsive to other treatments (Daikeler et al., 2011; Mancardi et al., 2018). Trials comparing HSCT with the more recently introduced high-efficacy disease-modifying treatments such as alemtuzumab are being planned, although their development is hampered by difficulties in accessing financial support (Muraro et al., 2017a,b).

Patients with severe SLE received an autologous stem-cell transplantation. Two major studies reported a disease-free survival rate at 5 years of 50%. The transplant not only induced an improvement in serological markers of disease activity but also a prolonged remission (at least 5 years) of lung damage and of the associated anti-phospholipid syndrome. These data are fully confirmed by those of the EBMT registry (Alexander et al., 2018). Overall, when SLE is achieved, remissions last long term also in absence of chronic immunosuppression. However, these results must be considered side by side to the risk of mortality that ranges 4%–12%. One controlled trial is currently in progress in Germany, comparing HSCT with best available biologicals, including rituximab (NCT00750971) (Alexander et al., 2018).

Before the introduction of biological therapies (MAbs or fusion proteins blocking TNF), rheumatoid arthritis was one of the first indications for autologous stem-cell transplantation. The procedure was well tolerated and induced good clinical responses (Van Laar and Tyndall, 2003). Nowadays, given the progress with TNF blockers and other new biological therapies, autologous stem-cell transplants are rare (Alexander et al., 2018).

To be complete, one should quote the results of a trial in autoimmune insulin-dependent diabetes that included 23 patients aged 13–31 years (Couri et al., 2009; Voltarelli et al., 2007, 2008). Autologous hematopoietic stem cells mobilized with cyclophosphamide and G-CSF were injected intravenously after conditioning with cyclophosphamide and rabbit antithymocyte globulin. During the follow-up, 20/23 were weaned from insulin treatment; 12 patients were insulin independent for 14–52 months. Eventually all patients relapsed and return to insulin dependency. Concerning side effects, two patients developed bilateral nosocomial pneumonia, three developed late

endocrine dysfunction, and nine developed oligospermia (Couri et al., 2009; Voltarelli et al., 2007, 2008). Thus although this therapy afforded disease remission with insulin independency for 1–4 years, the conditioning regimen required was heavy, comparable to that used in life-threatening autoimmune diseases. Considering the risk/benefit ratio, it is difficult to recommend such a strategy for wide application in type 1 diabetes even limited to adolescent and adults. For obvious reasons, it is inappropriate for use in children.

In conclusion, despite the fact that this strategy showed spectacular results that approach operational tolerance in patients with severe autoimmune diseases, the important and often vital side effects explain that over recent years, it represented less and less an alternative. In addition, the possibilities now accessible that we will discuss below to generate, using genetic engineering, tools of cellular therapy “à la carte” further question the future use of bone-marrow transplantation in autoimmunity.

## SOLUBLE AUTOANTIGENS

This strategy has given and still gives rise to many studies and, at first glance, it may seem a paradox. In order to understand the rationale here, we have to go back to the early 1960s when challenging the prevailing dogma that clonal deletion during lymphocyte development was the main, if not the exclusive, mechanism explaining immune tolerance, Dresser described the first results showing that in the adult host, the immune system can be “inactivated” rather than “activated” upon challenge with an antigen, depending on the modalities of administration of the antigen in question (Dresser, 1962). The concept of tolerance was therefore extended to also encompass states of unresponsiveness termed “immune paralysis,” observed instead of the usual immunization, when an antigen was delivered according to particular protocols. The classical example is that of tolerance to human gammaglobulins (IgG) observed in adult mice upon intravenous injection of deaggregated IgGs. Not only the mice thus treated do not produce antibodies against human IgG but, remarkably, they become refractory to any immunization with this antigen, even when it is inoculated in the presence of complete Freund’s adjuvant, a condition that is otherwise very immunogenic leading to massive production of specific antibodies. These seminal experiments were confirmed by many other authors using different antigens. All reiterated in the various models that antigen-specific B cells in tolerant animals were still present but functionally inactive. Regarding the respective role of B and T lymphocytes in this tolerance, the data showed that both compartments were concerned: the tolerance was more rapidly induced and persisted longer in T cells than B cells (Chiller et al., 2013).

It may be important to recall here that reprogramming the immune system toward immune tolerance using antigen-specific therapy has been successfully applied for several decades now in allergy where “desensitization” is common practice.

Things turned out more complex in autoimmunity. Thus immunological tolerance to a wide spectrum of autoantigens can be induced upon administration of the autoantigen by different routes, for example, parenteral, nasal, or oral. The approach has proven very successful in several animal models of spontaneous or experimentally induced autoimmunity. Thus the onset of diabetes in NOD mice can be prevented by administration of insulin or glutamic acid decarboxylase (GAD) using various routes of administration s.c., i.v., nasal, or oral (Tisch et al., 1993, 1994; Charlton et al., 1994; Kaufman et al., 1993; Tian et al., 1996). Similarly, experimental autoimmune encephalomyelitis (EAE) can be effectively prevented by administration of soluble myelin antigens (Smilek et al., 1991, 1992; Weiner et al., 1995; Wraith, 1995; Wraith et al., 1989; Miller et al., 1992). Mechanistic studies confirmed the working hypotheses that soluble autoantigen treatment had a direct effect on pathogenic lymphocytes and on antigen-presenting cells involved in the autoreactive reaction. Depending on the experimental model, the route of delivery, the dose administered or the antigen-presenting cells involved a functional inhibition of autoreactive T lymphocytes was observed. This occurred notably through triggering of anergy and/or Th1/Th2 immune deviation (Tisch et al., 2001; Tian et al., 1997), and elimination of antigen specific autoreactive T cells (especially when high doses of autoantigen are used) (Bercovici et al., 2000) and stimulation of various subsets of specialized Treg either FoxP3+ or FoxP3- (this is particularly the case in oral tolerance protocols where TGFβ-dependent and producing FoxP3- Treg), formerly termed Th3, play a major role (Weiner et al., 1991, 1995). Much attention was focused on autoantigen-presenting cells as their functional capacities greatly vary depending on the anatomical sites and they are therefore important immune actors explaining the differences in effect depending on the route of administration of autoantigens (mucosal, subcutaneous, intradermal, intravenous, intraperitoneal).

Based on these data translation to the clinic was attempted using different autoantigens under various forms, for example, proteins, peptides or altered peptide ligands and was rapidly confronted to major problems which were predictable from the experimental data collected. These included limitation of the therapeutic window to

early disease stages with loss of effectiveness as disease progresses; a long lag time to achieve efficacy, which may represent a problem in the case of acute autoimmune responses; risk of disease acceleration by triggering rather than down-regulating the autoimmune response; the potential risks of sensitization (e.g., anaphylaxis and/or production of neutralizing antibodies leading to serious problems when the autoantigen molecule, for example, insulin is physiologically relevant).

It is undoubtedly in insulin-dependent diabetes and multiple sclerosis that the largest amount of clinical data has been accumulated to date.

In insulin-dependent diabetes Phases I, II and even Phase III protocols that included large number of patients were conducted with great methodological rigor. The trials included both patients presenting with overt hyperglycemia in whom, as previously discussed, the insulin-secreting beta cell is largely reduced and in "at risk individuals" (Chaillous et al., 2000; Ludvigsson et al., 2012; Nanto-Salonen et al., 2008; Pozzilli et al., 2000; Skyler, 2002; Walter et al., 2009; Krischer et al., 2017; Wherrett et al., 2011). These are subjects screened as beta-cell autoantibody positive in families including at least one type 1 diabetic patient; when two or more beta-cell autoantibodies are detected these high risk individuals have about a 70% risk to develop hyperglycemia within 5–7 years (Triolo et al., 2019). The problem is that results were disappointing. None of the autoantigens used in autoimmune diabetes gave, when reaching the stage of Phase III trials, any positive therapeutic effect in terms of decreasing disease progression even in at risk individuals whom, as detailed earlier, present at an earlier disease stage. No side effects were observed in these trials.

Better defining the stage of disease were soluble antigen therapy in autoimmune diabetes may lead to effectiveness is very carefully considered. Subjects at risk already presenting with beta-cell autoantibodies may be at a too late stage as active beta-cell destruction is already ongoing, autoantibodies being the markers of this destruction. Hence the aim of the Pre-POINT study conducted by the groups of Ziegler and Bonifacio, a double-blind, placebo-controlled, dose-escalation, Phase I/II international clinical pilot study enrolling 25 islet autoantibody-negative children aged 2–7 years with a family history of type 1 diabetes and susceptible human leukocyte antigen class II genotypes (Bonifacio et al., 2015). The children received a daily oral administration of 67.5 mg of insulin or placebo. The treatment was safe (no hypoglycemia), an immune response to insulin was observed (Bonifacio et al., 2015). These data pave the ground for a Phase III trial to determine whether oral insulin can prevent islet autoimmunity and diabetes in such children.

In multiple sclerosis early clinical use of an altered peptide ligand of myelin basic protein was hampered by serious side effects including an aggravation/relapse of the disease and hypersensitivity reactions which forced stopping the trials (Bielekova et al., 2000; Pedotti et al., 2001; Smith et al., 2005). A myelin basic protein peptide that exhibited a good safety profile did not meet the efficacy end points in a Phase III trial enrolling patients with secondary progressive disease (Freedman et al., 2011).

What conclusions should we draw? Should the strategy be abandoned? Should we somehow throw the baby with the bath water? The answer is of course no; the experimental data cannot be ignored and pursuing efforts to approach effective autoantigen-specific immunotherapeutic approaches are fully warranted.

The problem has probably been the one of an overwhelming enthusiasm for a strategy that was expected to deliver immune tolerance without exposing to the side effects of long-term immunosuppression. Such enthusiasm led to a too rapid clinical translation that ignored major elements of the equation, not the least being the chemical formulation of the autoantigen administered and also the question of selecting subgroups of patients who would be more sensitive to the effect of treatment. Finally, one should not discard the possibility of combining antigen-specific therapy with other immune-interventions which may potentiate efficacy (Manchak et al., 2012).

Concerning the chemical formulation of autoantigen, the results of Wraith's group are very interesting. Step by step, based on robust experimental data in humanized mice these authors have shown that complications linked to unwanted immune reactions are not seen when CD4+ T-cell epitopes (e.g., synthetic peptides) that mimic naturally processed T-cell epitopes, for example, apitope (antigen processing independent epitope) are used. These are peptides that bind directly to major histocompatibility complex class II on immature dendritic cells which prime tolerogenic T-cell circuits. In vivo these soluble peptides inhibit both Th1 and Th2 immune responses and enhance secretion of the immunoregulatory cytokine IL-10.

The authors identified a cocktail of 4 peptides (ATX-MS-1467), behaving as apitopes, that suppress EAE in a humanized mouse model (Streeter et al., 2015). Furthermore, a Phase I trial of antigen-specific immunotherapy with ATX-MS-1467 has shown that treatment with this apitope cocktail is safe and so far the data on the clinical efficacy in Phase II studies are promising (Streeter et al., 2015; Chataway et al., 2018; Wraith et al., 2015). Apitopes are in development for treatment of Grave's disease; presently experimental preclinical data are encouraging (Jansson et al., 2018).

Another completely different way to tackle the problem of autoantigen-specific therapies is to design strategies that through particular targeting of specific epitopes may trigger sustained expansion or reprogramming of pre-existing autoreactive regulatory immune cells. Autoantigen delivery using nanoparticles appears as a promising path toward this aim as demonstrated in experimental models (Neef and Miller, 2017; Pearson et al., 2018; Clemente-Casares et al., 2016; Newbigging et al., 2016; Serra and Santamaria, 2018; Verdaguer et al., 1997).

Many laboratories are rapidly making substantial progress in both the design of tools to apply at tolerogenic nanoparticles to mouse models of autoimmunity. The reader is referred to the work of the groups of Miller and Santamaria that are both contributing very extensively to this area (Neef and Miller, 2017; Pearson et al., 2018; Clemente-Casares et al., 2016; Newbigging et al., 2016; Serra and Santamaria, 2018; Verdaguer et al., 1997). Major efforts are also devoted to mechanistic studies to unravel the cellular and molecular key steps involved in the therapeutic effect. Autoantigen-specific therapies have many more things to reveal to us and still represent conceptually a fabulous approach, whether used alone or in combination, to approach immune tolerance in clinic.

## CELL THERAPY AND ANTIGEN RECEPTOR GENE-MODIFIED T CELLS

### Cell Therapy Using Regulatory T Cells

After a long “crossing of the desert” during the 1990s, the existence of T lymphocytes that were called suppressors and which we now call regulatory T lymphocytes is no longer questioned. It is the discovery in 2003, simultaneously by three independent groups, that the FoxP3 transcription factor is a lineage marker of the CD4 + CD25 + T cells in the thymus and that it has a fundamental role in the expression of the regulatory function also in the periphery which has unlocked the situation (Hori et al., 2003; Fontenot et al., 2003; Khattri et al., 2003). Tregs underpin a fundamental mechanism of peripheral tolerance. Suffice is to observe the major, often life-threatening, polyautoimmune syndrome IPEX (immunodysregulation, polyendocrinopathy, enteropathy, X-linked) that is caused by loss of function mutations of FoxP3 (Wildin et al., 2001).

The list of autoimmune diseases where the number or the functional capacity of Treg was shown to be abnormally reduced is long; this has sometimes been ascribed to a deficit in key Treg growth factors, in particular IL-2, or an excess of proinflammatory cytokine in the environment. Hence, the rationale for the attempts to use cell therapy with ex vivo expanded Tregs. Particular interest was focused in autoimmune diabetes. Experimental data in the NOD mouse showed the efficacy of expanded Treg, and in particular autoantigen-specific Treg, to treat established disease (Bluestone and Tang, 2004; Tang et al., 2004). Circulating Tregs were grown in culture in the presence of CD3 and CD28 antibodies and IL-2. Phase I studies have shown the safety of the inoculum and suggested of course preliminary clinical activity (Bluestone et al., 2015; Marek-Trzonkowska et al., 2013). The implementation of Phase II trials was, therefore, warranted, and the results from such a study are expected in 2019 (NCT02691247).

Even if it concerns a single case it is interesting to quote here a recent report of adoptive polyclonal Treg treatment of a patient presenting SLE with active skin disease (Dall'Era et al., 2018). Deuterium tracking of infused Tregs revealed the migration of highly activated Tregs into diseased skin expressing a shift from Th1 to Th17 responses (Dall'Era et al., 2018).

### Cell Therapy Using Antigen Receptor Gene–Modified T Cells

In recent years the field of cell therapy has entered a new era, given on the one hand, the advances in our understanding of the molecular mechanisms that underlie the function of different immune cell subpopulations (effector T cells and Tregs) and, secondly, the incredible amount of technical resources that cell bioengineering has developed. The culture *in vitro* of specialized subsets of immune cells, and of antigen receptor gene–modified T cells, that can be reinfused into patients with an autoimmune disease is becoming a reality.

It all started in the field of oncology when it became possible to express at the surface of effector T cells with killing abilities an antigen receptor [T-cell receptor (TCR)] or chimeric antigen-specific receptors (CARs) specific for the tumor antigen. These CAR T cells expressed at their surface a fusion protein including an extracellular antibody domain specific to the antigen of interest (in this case the CD19 B-cell antigen) linked by a transmembrane domain to an intracellular-signaling portion that activates the T cell upon antigen binding. Initial trials were performed in 2013, using CAR T cells targeting the CD19 receptor and treating patients with B-cell acute lymphoblastic leukemia and then non-Hodgkin's lymphoma and chronic

lymphocytic leukemia (Brentjens and Curran, 2012; Brentjens et al., 2013; Gill and June, 2015). Based on the impressive results obtained in 2017, the FDA approved this adoptive cell-based gene therapy tisagenlecleucel (Kymriah) for acute lymphoblastic leukemia and in 2018 for non-Hodgkin's lymphoma. This breakthrough also explains the great efforts made to extend this fascinating technology to solid tumors, infectious diseases, organ transplantation, bone-marrow transplantation, and autoimmunity (Maldini et al., 2018; Bluestone and Tang, 2018).

In autoimmunity, one possibility would be to take advantage of CAR T cells to kill autoimmune pathogenic effector lymphocytes as recently proposed in a very elegant paper by Ellebrecht et al. (2016). These authors focused on pemphigus vulgaris a dermatological autoimmune disease where autoantibodies directed to desmoglein 3 (Dsg3) are the pathogenic effectors in the disease. Dsg3 is expressed on keratinocytes in the basal lower levels of the epidermis. Anti-Dsg3 autoantibodies provoke the loss of keratinocyte cell–cell adhesion in the basal and immediate suprabasal layers of the deeper epidermis, leaving the superficial epidermis intact, thereby causing the blisters that are the hallmark of the disease. Ellebrecht et al. engineered T cells to express a chimeric autoantibody receptor, CAAR T cells, selectively destroy B lymphocytes producing anti-Dsg3 autoantibodies both in vitro and in vivo in humanized mouse models. As compared to the conventional CAR T cells discussed earlier in the case of hematological malignancies, CAAR T cells produced by Ellebrecht et al. expressed an extracellular domain that included Dsg3, the autoantigen which upon binding to the specific autoantibodies on the autoreactive B-cell surface triggered the signaling machinery of the T cell through the intracellular domains of the CAAR that in this case included molecules CD3 $\zeta$  and CD137 (Ellebrecht et al., 2016). One of the humanized models used was set up with NSG (NOD-SCID-gamma) immunodeficient mice engrafted with human skin xenografts; injection of Dsg3 CAAR T cells in these recipients and no direct toxicity to keratinocytes was observed, supporting the lack of “off-target” effect of the approach and confirming its safety. The case of pemphigus vulgaris was ideal proof-of-concept for the CAAR T-cell strategy as the autoantigen structure has been very well dissected together with the specific binding sites of the pathogenic autoantibodies which, in addition, are known to be oligoclonal (Hammers et al., 2015). As discussed in a commentary I wrote on this interesting and provocative piece of work, it would be very important to identify other autoimmune diseases whose treatment could be enriched by this new tool that are CAAR T cells. The obvious first candidates are autoimmune diseases where autoantibodies, with well-identified autoantigen epitopes, are pathogenic. This is certainly the case for myasthenia gravis. Another potential target is a disease affecting the fetus in autoimmune pregnant mothers presenting with SLE or Sjögren syndrome known as the autoantibody-associated neonatal lupus syndrome (e.g., congenital heart block) (Ambrosi et al., 2014; Skog et al., 2016). Here maternal autoantibodies to the Ro/SSA autoantigen, including the unrelated Ro52 and Ro60 proteins that cross the placenta are the pathogenic effectors (Ambrosi et al., 2014; Skog et al., 2016). Concerning the other autoimmune diseases in which autoantibodies have a clear pathogenic effect, it will be mandatory to attempt applying the CAAR T-cell technology to have better definition and molecular characterization of key autoantigen epitopes.

The CAAR T-cell technology may also be exploited to target autoreactive B cells which rather than producing pathogenic autoantibodies act as autoantigen-presenting cells. The prototypic situation is for instance that of insulin-dependent diabetes a disease where the pathogenic effectors are exclusively autoreactive CD4 $^{+}$  and CD8 $^{+}$  T lymphocytes that selectively destroy insulin-secreting beta cells within pancreatic islets of Langerhans. The autoantigens that are the targets of the autoreactive T cells are well characterized (e.g., insulin/proinsulin, GAD, the IA-2 phosphatase). Autoantibodies against these antigens are present, from early stages of the disease, and they are used to screen patients with genetic susceptibility who present early stages of beta-cell destruction and who are at risk to develop hyperglycemia within a relatively short time frame (Triolo et al., 2019). It is very well established that autoantibodies are not pathogenic but compelling experimental and clinical evidence has been accumulated to show that B cells play a key role in the disease as autoantigen-presenting cells. Thus CD20 antibodies, which eliminate B cells, have a transient yet clear therapeutic effect in NOD mice as well as in patients with recent-onset type 1 diabetes. Applying CAAR T-cell treatment at early disease stages when only few anti-beta-cell autoantibody specificities are detected one could expect to target B cells before they become fully committed at efficacious autoantigen presentation and at mediating autoantigen spreading and progression to massive beta-cell destruction.

Last but not least TCR or CAR gene transfer could be implemented to improve Treg therapy by generating antigen-specific Tregs which as discussed earlier have proved more effective in experimental models. Of course, a major obstacle will be that of defining very precisely the epitopes that are recognized by autoantigen-specific Treg. The task is not simple, but interesting data are emerging in autoimmune diabetes (Yeh et al., 2017).

## PERSPECTIVES AND CONCLUSIONS

As a conclusion, it is hoped if not anticipated that emergent therapies based on the progress of biotechnology, including gene and cell therapy, will progressively complement and in some cases even replace conventional treatments. The rapidity with which TNF blockers have become accessible to patients with rheumatoid arthritis and Crohn's disease is most encouraging. The multitude of these drugs and their potential clinical applications are remarkable. Nevertheless, there are still numerous problems concerning the development and evaluation of the various drugs being studied.

Major efforts should be made to identify the best applications and promote their development for the benefit of patients beyond commercial constraints.

Increasing efficacy without side effects is the major long-term goal. Well-designed combination therapy appears as a sensible approach. The list of candidates is longer every day going from conventional chemical immunosuppressants to other biological and in particular cases cell therapy (Treg).

Each disease has its own therapeutic profile, but manifestations differ between subgroups of patients as their response to treatment also do. An in-depth rejuvenation of the field of immunotherapy will come from our ability to characterize robust and reliable biomarkers to identify key subgroups of patients within a given disease entity and propose the most appropriate single or combination therapy. This is the essence of personalized medicine to offer to every patient the possibility of remission, as sustainable as possible, with the fewest side effects. The fact that our therapeutic arsenal was enriched with products such as CD3 antibodies that may achieve long-term remissions in the absence of chronic treatment is a major asset to go step by step and in well-identified subgroups of patients, toward clinical operational tolerance.

## INTRODUCTION

Previous editions described various candidate autoimmune diseases or rare ill-defined conditions with autoimmune features—cameos. Since then, several have been developed as full chapters; others together with some new entities are retained as cameos because of their rarity, controversial evidence for an autoimmune causation, or autoimmunity being just one of several contributing elements to pathogenesis.

## AUTONOMIC NEUROPATHY

Unmyelinated autonomic nerve fibers that innervate cardiovascular, gastrointestinal, urogenital, thermoregulatory, sudomotor, and pupillary structures are subject to neuropathies of disparate cause affecting nerve fibers or ganglionic structures, resulting in autonomic failure (dysautonomia). It is well recognized that paraneoplastic dysautonomia occurs usually in association with other paraneoplastic expressions (Freeman, 2005). The accompanying autoantibody is usually to nicotinic acetylcholine receptors (AChR) in autonomic ganglia (Vernino et al., 2000) or to the Hu family autoantigen (ANNA-1) or peripherin, or less often to presynaptic voltage-gated calcium channels (Iorio and Lennon, 2012). Alternatively, an autoimmune autonomic neuropathy occurs spontaneously independently of neoplasia (Vernino et al., 2000). Some 50% of patients with autoimmune gangliopathy are reactive with autonomic ganglia that are similar structurally to AChR pentamers at the neuromuscular junction, and among the spontaneous cases, one or another clinical expression of dysautonomia may be the more prominent, often intestinal hypomotility causing gastric stasis or constipation. In a reported case of neuropathic gastric stasis with type 1 diabetes, histological examination revealed a complete and presumably autoimmune depletion of

interstitial cells of Cajal of the myenteric plexus (He et al., 2001). Experimentally, rabbits immunized with the a3 subunit of the AChR developed an autonomic neuropathy (Lennon et al., 2003) that was passively transferable to mice with IgG from serum of affected rabbits and, from limited data, with sera from diseased humans (Vernino et al., 2004).

## BIRDSHOT RETINOPATHY

The slender reasons, additional to the piquancy of the title, for considering this rare ocular disease among the cameos is the presumed dependency for pathogenesis on the retinal S antigen and the remarkably high disease association with the class I major histocompatibility complex (MHC) molecule, human leukocyte antigen (HLA) A29. Autoimmune inflammatory eye diseases (see Chapter 54: Ocular Disease) comprise responses to antigens in uvea or retina, but serological responses to a putative characterized autoantigenic molecule are not readily demonstrable as in other autoimmune diseases. Birdshot retinopathy affects predominantly individuals of northern European background and occurs usually in mid-adult life, and there is a slight female excess. It is rare, accounting for only about 1% of all cases presenting clinically as “uveitis.” Birdshot retinopathy is seen at retinoscopy as multiple separate cream-colored spots on the postequatorial fundus. Opportunity for pathologic examination is most infrequent; the retina is predominantly affected, and microscopy reveals a T lymphocytic and granulomatous infiltrate (Gasch et al., 1999). A claimed serologic reactivity in vitro to retinal S antigen is not well documented. The risk conferred by the class I MHC allele HLA A29 (50–224-fold) is higher than that for any other disease and is greater for the A29.1 than the A29.2 subtype of HLA29. There are only a few other human diseases wherein a demonstrable HLA association is with a class I rather than a class II HLA molecule, including spondyloarthropathies (B27, Chapter 36: Spondyloarthritides) and psoriasis (Cw6, Tillikainen et al., 1980). Birdshot retinopathy is attributed to specific reactivity of CD8<sup>+</sup> cytotoxic T cells against the retinal S antigen. The provocation for this disease is unknown.

## CYSTITIS, INTERSTITIAL

Hunner's (1914) report of chronic recurrent edematous ulceration of the bladder in eight young women is taken to be the first on putative autoimmune cystitis; *interstitial* was subsequently added to accommodate the accompanying diffuse fibrosis of the bladder wall. Hand (1949) described a larger case series, 204 women and 19 men, representing almost 5% of urologically investigated patients in his clinic. Oravisto et al. (1970) reported on 54 cases from a urology clinic over a 10-year period, all female aged 1680 years, mean 59, with symptoms of urinary frequency and urgency, suprapubic pain, and hematuria; cystoscopic appearances were included comprising a greatly reduced bladder capacity and a bladder wall with stellate scars, clusters of granulations, and punctuate hemorrhages likened to an “angry scratch.” Microscopically, the bladder wall reveals mucosal ulcerations, edema, lymphoid-plasma cell infiltrates and prominence of mast cells (Sant and Theoharides, 1994), and, in longstanding cases, fibrosis. The best evidence for autoimmunity in interstitial cystitis is the disease association with systemic lupus erythematosus (SLE) (Fister, 1938; Shipton, 1965; Boye et al., 1979), Sjögren's syndrome, and autoimmune thyroiditis (Oravisto, 1980). In 129 cases Peeker et al. (2003) supplemented these associations with cases of “hypersensitivity/allergic disorders,” rheumatoid arthritis (RA), and inflammatory bowel diseases. The high population frequency of interstitial cystitis (12 per 1000, overall, predominantly among women, ≈90%) has led in the United States to a patient support group being founded (Interstitial Cystitis Association). Subtypes of interstitial cystitis are sometimes cited for case classification into ulcerative (typical) or nonulcerative types, and into primary (sole disorder) or secondary (associated with SLE or other immune-mediated disease) (de la Serna and Alarcon-Segovia, 1981; Alarcon-Segovia et al., 1984). Biomarkers are needed to assess accuracy of diagnosis and efficacy of treatment, with formal criteria for diagnosis being specified by the National Institute of Diabetes and Digestive and Kidney Diseases of the NIH (United States). Serologic studies have not been helpful. Bladder-specific autoantibodies were reported by Silk (1970) but have not been confirmed. Frequencies of antinuclear antibody (ANA) were raised according to Oravisto et al. (1970) and Jokinen et al. (1972). However, in a more contemporary study Ochs et al. (1994) assembled 96 patients whose sera were tested for ANA by immunofluorescence on tissue sections and on HEp-2 cells, and additionally, a cultured bladder epithelial cell line was used for Western blotting. Autoantibodies specific to bladder cells were not demonstrable, but there was an increased frequency, 36% versus 8% in female controls, of non-tissue-specific autoantibodies (cutoff titer 1:40); the reactivities were mostly ANA with staining patterns usually speckled or nucleolar, unlike what pertains in SLE, and tests for

anti-mitochondrial antibodies (AMA) were positive in three cases. The findings of [Ochs et al. \(1994\)](#) were not seen as indicative of a primary autoimmune attack on the bladder wall but rather as a consequence of an undefined chronic inflammatory process, with autoantibodies secondarily augmenting this process.

Experimental models of autoimmune cystitis have been attempted in mice and rats, first by direct immunization with bladder wall extracts ([Bullock et al., 1992](#)), and later by introduction of transgenically encoded protein antigen ([Liu et al., 2007](#)). Immunization of Balb/c AN mice with bladder extract-induced cystitis is shown histologically by edema, fibrosis, and lymphocytic and mast cell infiltrations; specific reactivities of serum antibodies or T cells were not described, but disease was transferable adoptively by lymphoid cells from affected mice. Cystitis was similarly inducible in Lewis rats and was adoptively transferable with splenocytes ([Luber-Narod et al., 1996](#)). More recently [Liu et al. \(2007\)](#) developed mice that transgenically expressed on bladder epithelial cells the model “self” antigen ovalbumin (URO-OVA). Such mice are unresponsive to OVA stimulation. Adoptive transfer studies were performed where in naïve OVA-specific T cells showed proliferation and infiltration into the bladder mucosa but no cystitis, whereas transfer of activated OVA-specific T cells did induce an inflammatory cystitis. Their model was further developed to demonstrate that bladder epithelium was capable of presenting a self-antigen in association with MHC class I, that activation of T cells occurred in bladder regional lymph nodes, and that features of the ensuing cystitis simulated those of the human counterpart.

In conclusion, human interstitial cystitis remains on the fringe of autoimmunity, since neither pathogenic nor disease-specific marker autoantibodies are regularly demonstrable, immune-mediated mechanisms of bladder wall damage in humans remain obscure, and lacking are genetic analyses and well-controlled studies of efficacy of corticosteroid or immunosuppressive drugs—yet the experimental transgenic models are persuasive. Perhaps there exist as yet undefined cocontributory mechanisms of pathogenesis such as a harmful constituent of urine to which the bladder wall could be persistently exposed.

## Endometriosis

Endometriosis was so named to convey the idea that fragments of sloughed uterine endometrium become distributed in the pelvic peritoneum and sites further afield ([Sampson, 1921](#); [Ridley, 1968](#); [Giudice and Koo, 2004](#)). The estimated frequency of this disease is 12% of all women and one of five women of reproductive age. Clinical expressions include (1) gynecologic symptoms, pelvic pain, menorrhagia, dysmenorrhea, and dyspareunia; (2) dysfunction of the pelvic colon or bladder; (3) infertility; and (4) repeated pregnancy loss. Definitive diagnosis requires laparoscopic surgery. Unsurprisingly, dysfunctions of the immune system are implicated in pathogenesis at various levels ([Giudice and Koo, 2004](#)) and include compromised natural killer cell activity resulting in decreased surveillance/removal of ectopic tissue ([Wilson et al., 1994](#)), activation of peritoneal macrophages and upregulation of proinflammatory cytokines, and there are various pointers to autoimmune reactivity.

Thus [Weed and Arquembourg \(1980\)](#) surmised that “nonself” ectopic endometrial implants in the pelvis generated endometrial tissue-specific antibodies, with ensuing infertility. In general autoimmunity has not been held to explain the actual occurrence of displaced endometrium in the pelvis but rather particular consequences of this displacement. Yet despite considerable immunological investigation in the 1980s, results were relatively unimpressive ([Dmowski, 1987](#)). Even so, impetus was given to the autoimmune concept by [Grimes et al. \(1985\)](#), whose case-control study showed that endometriosis was associated with a twofold (but nonsignificantly) increased risk for developing SLE, and by increased frequencies of nontissue-specific autoantibodies, [Gleicher et al. \(1987\)](#) found that among 59 cases, 28.5% gave a positive test for ANA and 45.5% for lupus anticoagulant, and [Taylor et al. \(1991\)](#) compared 71 age-matched cases with 109 control women and reported that there was a very significantly increased frequency of autoantibodies to nuclei, ribonucleoproteins (Ro and La), to smooth muscle antigens, and to anticardiolipin and lupus anticoagulant.

While [Gleicher et al. \(1987\)](#) asserted that endometriosis “fulfils all the classic characteristics of an autoimmune disease,” [Taylor et al. \(1991\)](#) took a more reserved interpretation of the reported autoantibody responses. A serological study failed to show any disease-specific autoimmune serological reactivity ([Switchenko et al., 1991](#)). However, [Fernandez-Shaw et al. \(1993\)](#) reported sera of women with endometriosis specifically reacted with the cytoplasm of endometrial glands, whereas all control sera were negative, concluding that the demonstrable anti-endometrial antibodies could be reactive *in vivo* and impair fertility.

Interest in endometrium-specific autoimmune reactants over the last decade has faded. The most recent information on the immunopathology of endometriosis, obtained using a gene array procedure, is that of [Hever et al. \(2007\)](#). These authors compared endometriosis tissue with normal endometrium and found that the former was enriched in plasma cells and activated macrophages. The gene arrays did not point to the presence of mature B

or T cells but did show that there was activation of genes for the B-cell activating cytokine BAFF/BLyS, and the likely source of the various nontissue-specific autoantibodies described in endometriosis.

In conclusion endometriosis perhaps has less relevance to autoimmunity than to physiological immunology by indicating that autoantibodies may in fact serve to remove unwanted/ectopic tissue (Grabar, 1975), in this case displaced uterine endometrium.

## Epilepsy

Autoimmunity became implicated from the early 1990s in seizure disorders when a severe form of childhood encephalitis with seizures (Rasmussen disease, RD) was linked with antibodies to excitatory glutamate receptors in the CNS. Rabbits immunized simply to raise antibodies to glutamate receptor subunit 3 (GluR3) developed seizures and histological encephalitis, and this led to a search for autoantibodies to glutamate receptors in RD in children (Rogers et al., 1994). This is reminiscent of the discovery of the causation of myasthenia gravis by autoantibody to the AChR after the unexpected occurrence of myasthenia in rabbits immunized merely to raise an antiserum to AChR (Patrick and Lindstrom, 1973). However, at present, antiGluR3 figures much less prominently in autoimmune epilepsy in adults than do autoantibodies to various other neuronal antigens such as glutamic acid decarboxylase of 65 kDa (GAD65). Importantly, recognition in blood or cerebrospinal fluid of such autoantibodies is a distinct directive to immunotherapy.

It was the description of epilepsy-relevant autoantibodies during the 1990s that eventually led to the nomination in 2000 of certain epilepsies—particularly refractory and localization-related types—as “autoimmune” (Palace and Lang, 2000; Peltola et al., 2000), after which there have been various corroborative reports specifying associated autoimmune reactants notably anti-GAD65 (Saiz et al., 2008) (and others) in the context of the stiff person syndrome (Ali et al., 2011), voltage-gated potassium channels (VGKC) (Irani et al., 2011; Iorio and Lennon, 2012; Quek et al., 2012) in the context of chronic encephalitis syndromes, or N-methyl-D-aspartate receptor (NMDA-R) implicated mostly in neuropsychiatric dysfunctions other than epilepsy (Diamond et al., 2009; Dalmau et al., 2011). Quek et al. (2012) described 32 patients with an “exclusive or predominant seizure presentation” and suspected neuronal autoimmunity; among these were autoantibodies to VGKC complexes in 56%, GAD65 in 22%, collapsin response-mediator protein in 6%, and NMDA-R in just 3% (one case). “VGKC complexes” is used advisedly as this is a broad term that covers macromolecular assemblies that contain various potentially antigenic constituents (Iorio and Lennon, 2012). A further neuronal antibody species, often paraneoplastic, was characterized in cases of limbic encephalitis with early and prominent seizures being directed to the B1 subunit of the GABAB receptor; the assay used was a cell line transfected with rodent GABA receptor (Lancaster et al., 2010).

The two important points are, first, that “autoimmune epilepsy” should now be regarded as a definitive neurological entity for which there are valid serological diagnostic assays, and second, that immunotherapies can provide substantial relief from seizures in cases in which conventional antiepilepsy drugs have failed.

## Fatigue Syndrome

The “fatigue syndrome” was derived in 1955 from an outbreak of an unexplainable illness at the Royal Free Hospital in London that affected 292 staff members (Medical Staff of the Royal Free Hospital, 1957). The features were severe fatigue, loss of energy, poor exercise tolerance, muscle discomfort, fibromyalgia, and other nonspecific symptoms including malaise, neck stiffness, lymphadenopathy, and fever. A preceding viral illness was often implicated. The name “myalgic encephalomyelitis” (ME) was proposed by “an unusually uncritical Lancet editorialist” (Byrne, 1988). “ME” faded from use, but the fatigue syndrome attracted ongoing attention from patient support groups and various medical specialties: some argued for a functional basis and others for an unknown organic basis. By the 1980s, the syndrome had become accepted as an entity and in 1987 was formally designated as chronic fatigue syndrome (CFS), with recommended diagnostic criteria from the Centers for Disease Control (CDC) in Atlanta, GA (Holmes et al., 1988). The two major criteria for diagnosis were (1) a new onset of fatigue lasting 6 months and reducing activity to less than 50%, and (2) exclusion of any other condition usually producing fatigue, and 11 minor criteria (of which eight should be fulfilled) including eight symptomatic and three physical features, these being mild fever, nonexudative pharyngitis, and palpable cervical or axillary lymph nodes up to 2 cm in diameter. High among claimed causes of CFS are chronic viral infections, notably Epstein–Barr virus; the case for a murine retrovirus, xenotropic murine leukemia virus (XMRV), has been convincingly refuted. Other candidates are allergies, autoimmunity, hyperreactive responses to unusual environmental

exposures, and psychosomatic disorder. Despite evidence in CFS for immune activation and/or impaired indices of cell-mediated immunity (Lloyd et al., 1989, 1990; Buchwald and Komaroff, 1991), data from the conventional indications of inflammatory activity or tissue destruction (erythrocyte sedimentation rate (ESR), C-reactive protein) are non-supportive. Benefit from immunomodulatory treatment with intravenous immunoglobulin, of known efficacy in some well-defined antibody-mediated autoimmune diseases, is controversial, either endorsed (Lloyd et al., 1990) or refuted (Peterson et al., 1990).

Analysis of an autoimmune component in CFS encounters issues such as specification of a clear associated diagnosis and a scarcity of affirmative evidence, perhaps indicative of unpublished negative studies, opposed to which is the known occurrence of fatigue in certain well-accepted autoimmune disorders. The major question then is whether, among cases fulfilling CDC criteria for CFS, there can be regularly identified a highly raised level of any autoantibody specificity, particularly ANA. Positive studies include that of Behan et al. (1985) (50 cases) and another group (60 cases) (Konstantinov et al., 1996; von Mikecz et al., 1997) which cited a frequency of autoantibodies of 83% versus 17% in a control group, predominantly of ANA specificity, and directed particularly to nuclear envelope proteins, together with cytoplasmic staining patterns of intermediate filament-vimentin type thought to be indicative of viral infection. On the other hand, there are negative results for ANA in CFS (Skowera et al., 2002) or only modestly positive results (Vernon and Reeves, 2005).

It is not the purpose here to review all the varied suppositions on the basis of CFS, because none is sufficiently convincing. It can be said that autoimmunity does not provide an explanation for all cases of CFS that autoantibodies when present might reflect some other as yet unidentified cause, and that autoimmunity likely is but one among a conglomerate of causes for CFS.

## Folate Deficiency

Maldevelopment of the embryonic neural tube resulting in spina bifida, anencephaly, or other defects occurs in infants at a prevalence of about one in 1000. It has been widely ascertained that periconceptual folic acid supplements to mothers strikingly alleviate this, even though the mothers usually do not have evident folate deficiency (Rothenberg et al., 2004). The observation was made that antiserum to folate receptors in pregnant rats resulted in embryonic maldevelopment, and this prompted the search for autoantibodies to folate receptors in women in whom a pregnancy had resulted in an infant affected with a neural tube defect (Rothenberg et al., 2004). The procedure used was the specific blocking of ( $^3\text{H}$ ) folic acid to folate receptors on placental membranes and to indicator cell lines. The results were that nine of 12 women (vs two of 20 controls) with affected children had a receptor blocking antibody. The same authors (Ramaekers et al., 2005) in a further study investigated infantile-onset cerebral folate deficiency that develops 4–6 months after birth and is expressed as mental and psychomotor retardation, cerebellar ataxia, dyskinesis, seizures, visual disorder, and autism. There were low levels of 5-methyl tetrahydrofolate in the cerebrospinal fluid but normal levels in serum, and lack of evidence of extracerebral folate deficiency. Serum from 25 of 28 affected children, versus none of 28 controls, contained high-affinity blocking autoantibodies against membrane-bound folate receptors on the choroid plexus, indicating impediment to the passage of folic acid from serum to brain. This could be normalized by oral calcium folinate that led to clinical improvement. Notably, none of five tested mothers had autoantibodies. Perhaps the induction of the antifolate receptor antibodies in these affected children was due to soluble folate-binding proteins in milk, or to other unknown antigens (Ramaekers et al., 2005). This story is indeed a legitimate “cameo” in the world of autoimmunity, since antifolate receptor autoantibody could be generated either in the pregnant mother or the newborn child, causing neural developmental disorders. Indeed Schwartz (2005) was prompted to comment that “autoimmunization lurks behind every pillar.” And there is the added point that the catastrophic consequences in this particular example are remediable by a very simple therapy, folic acid.

## Lichen Sclerosus

“Lichen,” a compound plant (fungi in symbiotic union with algae) that spreads on rocks and trees, gives its name to chronic skin diseases seen mostly as thickened but sometimes atrophic inflammatory patches on skin or mucus membranes with, histologically, damage and cellular infiltration between the epidermis and dermis. There are many variants described of mucocutaneous lichenoid eruptions according to their location and visual appearances. The prototype is lichen planus for which no single specific cause has been identified, although one interesting association is infection with hepatitis C virus (Le Cleach and Chosidow, 2012). The lichenoid eruption

described as lichen sclerosus is, however, consistently linked to autoimmunity. Lichen sclerosus particularly affects the anogenital skin, and the vulval mucosa in women. The population prevalence is at least  $\approx 1$  per 1000 with a female:male ratio of at least 6:1; histologically, there is hydropic degeneration of basal keratinocytes with inflammatory changes (Dalziel and Shaw, 2010). The evidence for autoimmunity specified by Oyama et al. (2003) includes familial occurrence, association with the class II HLA allele DQ7 as seen in other mucus membrane/pemphigoid diseases, and cooccurrence with other autoimmune diseases and/or autoantibodies, mainly of the “thyrogastric” cluster, that is, thyroiditis, pernicious anemia, diabetes, vitiligo, and others, but better immunological data on these disease associations are called for.

Previous findings of “pemphigoid” autoantibodies in skin diseases with basement membrane pathology (see Chapter 60: Autoimmune Bullous Skin Diseases—Pemphigus and Pemphigoid) led a search for analogous autoantibodies to extracellular matrix protein 1 (ECM1) in lichen sclerosus (Oyama et al., 2003). The autoantigen ECM1 was chosen based on the observation that loss-of-function mutations of the gene encoding ECM1 result in a lichen sclerosus-like pathology (lipoid proteinosis, LP). The sera studied were from 86 patients with lichen sclerosus, 85 healthy controls, and 107 “other disease” contrast cases, and the technical procedures included Western immunoblotting (WB) on extracts from normal skin and LP skin that lacks ECM1, and indirect immunofluorescence (IIF) microscopy using affinity purified IgG. In brief, there was a specific signal for anti-ECM1 from lichen sclerosus sera by WB (to the low titer of 1:20), absence of signal using extracts from LP skin lacking ECM1, and specific reactivity by IIF of affinity-purified serum IgG with the basal keratinocyte layer of normal skin. Passive transfer of lichen sclerosus lesions to mice by serum or IgG was a contemplated next step.

## Lymphocytic Mastitis

The female breast is subject to a nonneoplastic multinodular fibrosing disease expressed clinically by recurrent mastalgia and histologically by periductular lymphocytic infiltrations. An early report described the case of a woman with a multisystem-like disease in whom there were dense collections of lymphoid cells within diseased breast tissue, with underlying autoimmunity thus implicated (Shelley and Hurley, 1960), but the idea of an “autoimmune mastitis” was not picked up. The disease (or diseases) characterized by lymphocytic mastitis has acquired several descriptors, granulomatous mastitis—although giant multinuclear cells are actually inconspicuous (Donn et al., 1994), diabetic mastopathy by reason of a frequent association with clinical diabetes (Tomaszewski et al., 1992; Camuto et al., 2000), fibrocystic mastitis, and some cases classed as IgG4 mastitis (Ogura et al., 2010). Lymphocytic mastitis may represent an immunological response to extruded breast milk, or to acinar or ductular breast tissue, but immunocytopathological examination of the characteristic lymphocytic infiltrates has received rather little attention, so the condition remains “idiopathic.”

## Metabolic-Genetic Storage Diseases

Batten disease is a rare, recessively inherited, and fatal neurodegenerative disease of children due to a mutation in both copies of a gene *CLN3*, so leading to accumulation of ceroid lipofuscin in neurons. A gene-disruption model in mice revealed altered expression of enzymes required for the synthesis of the neurotransmitter glutamate and circulating antibodies to brain proteins including GAD65. This prompted a search for anti-GAD65 in human Batten disease, with positive results (Chattopadhyay et al., 2002). As yet, the role (if any) of anti-GAD in the overall pathogenesis of Batten disease is uncertain.

Sandhoff disease is another metabolic autoimmune curiosity. It is a recessively inherited lysosomal storage disease of infancy in which neuronal cell death results from an enzyme deficiency that causes accumulation of gm2 gangliosides in lysosomes of brain cells. A murine equivalent has been created by knockout of the *hexb* gene that encodes the hexosaminidase enzyme. It is claimed that antiganglioside antibodies in Sandhoff disease accelerate premature neuronal death, perhaps via complexes of antibody and ganglioside that cause inflammatory activation of microglial cells. Similar events are postulated for the human counterpart (Yamaguchi et al., 2004).

## Movement Disorders

A miscellaneous group of movement disorders, observed particularly in children, and sharing the features of an antecedent streptococcal infection, are claimed to have in common the expression of autoantibodies to neurons of basal ganglia in the brain. Prototypic among these is Sydenham’s chorea, marked by frequent unintended jerky movements, and long known to occur occasionally in association with streptococcal-related rheumatic carditis.

Others include the Tourette syndrome of motor and vocal tics, and a pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections (Shulman, 1999). Speculative extensions have brought in other entities including obsessive-compulsive and attention-deficit disorders. Autoimmunity has been implicated, but on rather slender evidence: (1) the claimed antecedent streptococcal infections that provide a reasoning for the occurrence of autoimmunity similar to that proposed for the onset of rheumatic carditis (see Chapter 63: Rheumatic Fever and Rheumatic Heart Disease), (2) positive tests for antineuronal autoantibodies particularly to autoantigens of basal ganglia neurons, and (3) a claimed capacity of patients' sera to transfer disease passively after direct injection into the striatum of rats. However, the autoantibody studies are in earlier literature and have not been convincingly confirmed (reviewed by Dale, 2005), and the validity of the data on passive transfer to animals by serum is likewise questionable (Giovannoni, 2005).

## Narcolepsy

Narcolepsy is a sleep–wake disorder with onset during adolescence in which there is irresistible daytime sleepiness. It is now confidently attributed to deficient neurotransmission dependent on a neurotransmitter that sustains wakefulness, known according to the discoverers as either hypocretin or orexin. Deficiency of this transmitter, synthesized by neurons in the hypothalamus, is the underlying fault—in canines with narcolepsy there is a profound loss of hypocretin-secreting neurons in the hypothalamus. *Prima facie*, narcolepsy would seem hardly likely as an autoimmune disease, yet there is a long-known extreme and puzzling coassociation with the class II MHC allele, HLA DQB1\*0602. Inconveniently for theorists, an autoantibody relevant to narcolepsy against hypocretin/orexin, or the cognate receptor, has not been demonstrated by conventional assays. However, some evidence for a serum factor was obtained by a bioassay based on passive transfer to mice of IgG from narcolepsy patients, by a readout of increased contractile responses of detrusor muscle strips (Smith et al., 2004), but these preliminary bioassay data would seem to require further work. There is a published personal account of a narcolepsy sufferer annotating the curious symptoms, together with comments on the occurrence of narcolepsy in inbred Doberman Pinscher dogs (although this is attributed to a genetically faulty cell receptor, see below), the extreme immunogenetic HLA D locus bias (DQ6//DQB1\*0602 and/or DR2/DRB11501) and seasonal (springtime) peak incidences suggesting an antecedent infection (Nicholls, 2012). Suspected infections include either H1N1 influenza or streptococcal throat infection substantiated by raised levels in childhood narcolepsy of anti-streptolysin O, as implicated also in movement disorders of childhood described above.

A possible disease pathway can now be specified based on the interaction of hypocretin/orexin and the cognate receptor. The first hints in the 1990s came from the identification of hitherto unknown hormone-like agents in the brain of rats and mice, hypocretins/orexins, and one group further identified the structure of the orexin receptors (Sakurai et al., 1998), although these authors directed their attention to the role of the orexin system in energy balance and eating behavior rather than sleep patterns. However, it was evident from other investigations that the hypothalamic cells that secrete hypocretin/orexin hormones provide also send “stay awake” messages to other cells in the CNS via the orexin-receptor pathway. Reliable detection of antibody or T cell reactivity to hypocretin/orexin or to the cognate receptor is still awaited. Meanwhile further immunogenetic and immunological anomalies have come to light (reviewed by Faraco and Mignot, 2011) and include polymorphism of the alpha chain of the T cell antigen receptor (Hallmayer et al., 2009), with three single-nucleotide polymorphisms within the TCRA locus showing significant association with narcolepsy syndromes across various ethnic groups; another susceptibility locus is the gene for the P2RY11 purinergic receptor. There is an autoantibody association too, depending on the tribbles2 homolog (trib2) protein, in 14%–26% of DQB1 (cataplexy-associated) cases, but trib2 is a ubiquitously expressed protein, and there are no indications that antibodies to it are related to narcolepsy. One wonders how the story will eventually pan out!

## Osteoarthritis

Osteoarthritis (OA) is prototypically a “degenerative” articular disease with usually a late-in-life onset and a relationship to articular stresses and previous trauma, but there can be an early inflammatory phase with an obviously acute onset. In tests for specificity of serological reactants used for the diagnosis of rheumatic diseases, that is, autoantibodies to citrullinated peptides or native collagen type II (CII) (nCII), a degree of reactivity is usually observed. In regard to anti-nCII, Xiang et al. (2004) reported that sera from patients with OA reacted more with denatured than with native CII, and Burkhardt et al. (2002) found that OA sera were reactive but, in contrast to RA, sera engaged different antibody epitopes of nCII, notably CII-F4 located at the C-terminal region of nCII,

rather than the characteristic RA-related epitopes, CII-C1 and CII-M2139. Interestingly, a murine anti-CII-F4 monoclonal antibody (mAb), in contrast to other mAbs reactive with specific epitopes of nCII, is not pathogenic on passive transfer in mice but actually inhibits the adverse effects (matrix disruption) of mAbs that do react with nCII epitopes other than F4 (Burkhardt et al., 2002). Xiang et al. (2004) further found that those OA sera, as well as reacting with CII-F4, reacted with an antigen of different provenance, triose phosphate isomerase. In regard to pathogenicity, the capacity of autoantibodies to nCII to perpetrate articular damage remains an open question.

T lymphocytes have not been neglected in OA, according to a recent review by Sakkas and Platsoukas (2007). T-cell infiltrates are demonstrable in the affected articular cartilage, and particularly in the synovial membrane, appearing as nodular aggregates suggestive of an antigen-driven process, although a provocative cartilaginous autoantigen has not so far been identified, despite much search and speculation. Curiously, erosive effects of cartilage/synovial inflammation associated with activated T lymphocytes infiltrating subchondral bone, as seen in RA, are not evident in OA. The T cells demonstrable in synovial membrane in OA are of the Th1 subtype and their activated phenotype is revealed by transcripts for cytokines such as IL-12, detectable in synovial fluid. Sakkas and Platsoukas (2007) discuss the utility of future procedures to assess the degree of clonality of T-cell infiltrates in joints in OA. However, while few of the conventional markers (particularly reactivity with an “accepted” autoantigenic structure) are fulfilled, it remains difficult to ascribe OA to an adaptive autoimmune response. In addition, results of a large (and latest) genome-wide association study (GWAS) that included stratified cases of OA defined some eight candidate loci for association with OA, although none could be aligned with those often associated with autoimmune disease (arcOGEN Consortium and arcOGEN Collaborators, 2012).

Hence it is of interest to consider a new slant on the immunological contribution to OA, namely an inflammatory association with an anomaly of the complement cascade. Wang et al. (2011) found in mice that injury to articular cartilage in the setting of dysregulation of complement gene expression in joint tissues led to formation of the membrane attack complex on chondrocytes, with either killing or production of matrix degrading enzymes, so linking OA to such age-related diseases as macular degeneration and Alzheimer’s disease. Possible applications of this concept to define subsets of human OA are awaited. This theme was developed in a recent review in which various components of innate immunity were implicated, without recourse to an adaptive response (Haseeb and Haqqi, 2013). So perhaps OA may be better placed in the category of autoinflammatory diseases.

## Parathyroid Disease

An autoimmune basis for hypoparathyroidism was proposed by Solomon and Blizzard (1963), and then by Seemann (1967), whose histological study revealed lymphocyte-plasma cell infiltrates—hence “lymphocytic parathyroiditis.” In our first edition of this text, Maclarens and Blizzard (1985) described autoimmune polyendocrine syndrome (APS) types 1 and 2. For type 1, the three major components appeared usually in a uniform sequential order: candidiasis, hypoparathyroidism, and Addison’s disease. Autoimmune hypoparathyroidism, despite being a characteristic feature of APS type 1, did not occur in any of 224 cases of APS type 2. However, serological reactivity with parathyroid tissue was insufficiently convincing to generate clinical laboratory assays, although accompanying autoantibodies were reported to bind to the cell surface of human parathyroid cells and to inhibit parathyroid cell secretion. Perhaps these autoantibodies were related to those revealed by a mAb raised by immunizing mice with parathyroid tissue and shown to react with a parathyroid cell surface antigen called parathyroid antigen (PTA) (Cance et al., 1986). An autoimmune basis was strengthened when Li et al. (1996) demonstrated, in both APS type 1–associated and sporadic cases of hypothyroidism, serological reactivity with the ubiquitous calcium-sensing receptor (Ca-SR) on the parathyroid cell surface; an immunoprecipitation assay showed that the extracellular domain of the Ca-SR contained the reactive epitopes. This autoimmune reactivity, anti-Ca-SR, was demonstrable in 56% of 25 cases and was far more frequent among females than males. Also, cases were recognized wherein antibodies to the parathyroid Ca-SR had an inactivating effect, so rendering the glands insensitive to ambient calcium, such that the ensuing oversecretion of parathyroid hormone had effects like those seen with parathyroid adenomas, causing hypocalciuric hypercalcemia (Pallais et al., 2004). These antibodies were functionally active but nondestructive were of the IgG4 subclass, and in one case were associated with autoimmune pancreatitis, perhaps illustrating another facet of “IgG4 disease” (see Chapter 64: Myocarditis and Dilated Cardiomyopathy). Thus the clinical expressions of autoimmune parathyroiditis with anti-Ca-SR reactivity may be either hypoparathyroidism if the antibodies are nonblocking as pertains when the glands are subject to lymphocytic-mediated destruction, or hyperparathyroidism if the antibodies are blocking and the glands retain functional activity.

In 2008 a novel autoimmune reactant was discovered by screening a cDNA expression library with serum samples from cases of APS type 1, identified as the NACHT leucine-rich-repeat protein 5 (NALP5) (Alimohammadi et al., 2008). These authors, in their Introduction, negated the role of other described autoantigens in parathyroiditis, although anti-Ca-SR reactivity in parathyroiditis had been well established in earlier studies (see Gavalas et al., 2007). The authors of the NALP5 study decisively showed that autoantibody was limited to cases of APS type 1 hypoparathyroidism with AIRE mutations, was not demonstrable in "isolated" (sporadic) hypoparathyroidism, and was detectable as a subcellular autoantigen only in the chief and not the oxyphilic cells of the parathyroid gland. Still to come are studies on patterns of T-cell reactivity to NALP5, and the relative contributions of defective thymic deletional tolerance versus Treg-mediated suppressive tolerance to this putative parathyroid autoantigen.

## Polychondritis, Relapsing

Relapsing polychondritis (RP) was so named by Pearson et al. (1960) to designate recurring inflammatory damage to, and degradation of, (mainly) type II collagenous cartilage throughout the body (Michet et al., 1986). More particularly vulnerable is cartilage of nasal, auricular, tracheobronchial, and audiovestibular sites than is articular cartilage. However, there is a very wide distribution of lesions to noncartilaginous sites, such as ocular sclera, heart valves, skin, and others, and therefore RP is called "an autoimmune disease with many faces" (Lahmer et al., 2010). There is clustering in some 30% of cases with one or another systemic autoimmune rheumatic disease, notably RA and SLE. Lymphoid cell accumulation is prominent at affected sites. There is a weak association with the MHC class II allele HLA DR4, and clear benefit accrues from prednisolone (McAdam et al., 1976). Thus polychondritis has most of the hallmarks of an autoimmune process.

Specific antibodies to cartilage were detected using IIF and cartilage substrate from mouse leg, or from human costochondral and tracheal cartilage, after preincubation with hyaluronidase to remove masking proteoglycan (Dolan et al., 1976; Foidart et al., 1978). Autoantibodies were more readily detected in the acute stages, were of IgG class and noncomplement-binding, and levels correlated with disease severity. Absorption exclusively with CII removed reactivity with cartilage from serum. Using a direct immunofluorescence procedure, and serum from in a single case, Bergfeld (1978) detected deposits in vivo of IgG, IgA, and C3 in affected cartilage. In a subsequent study positive results were reported in six of nine patients for antibodies to cartilage, and there was association with organ (thyroid)-specific autoantibodies as well (Ebringer et al., 1981). Assays for T cell-mediated immune responses to cartilage proved indecisive (Foidart et al., 1978; Ebringer et al., 1981).

Reactivity of serum with CII has been investigated in polychondritis. This was rather low by ELISA among Japanese patients, 202 with RA, 26 with polychondritis, and 92 with other rheumatic diseases, positivity being only 42%, 11%, and 0.3%, respectively (Terato et al., 1990). In tests using peptides derived by cyanogen bromide (CB) digestion of CII, polychondritis sera reacted preferentially with the CB 9.7 kDa peptide, unlike the anti-CII reactivity of sera from other diseases, and the species of anti-CII antibody detectable in polychondritis lacked the epitope specificity of sera from patients with erosive articular inflammation (Burkhardt et al., 2002). However, subsequent studies have indicated that the primary reactant in polychondritis might not be CII, since reactivity of serum antibodies and T cells was greater with collagens IX and XII (Yang et al., 1993). Moreover, in NOD mice carrying a human HLA DQ1 transgene and immunized with CII, there developed an auricular chondritis that simulated the abnormality seen in human polychondritis, and sera reacted to CIX as well as CII (Taneja et al., 2003). Perhaps, then, in polychondritis, anti-CII occurs secondarily by epitope spreading.

The cartilage protein matrilin is another suggested autoantigen in polychondritis (Hansson et al., 2004). Matrilin is a cartilage-specific protein abundant at sites affected in polychondritis (trachea, ears) but sparse in sites that are spared (joints). A model of polychondritis induced in mice by active immunization with matrilin I showed that functional B cells and complement factor V were required for disease expression and that passive transfer could be accomplished by a mAb to matrilin I suggesting that polychondritis, in this model at least, is essentially an antibody-mediated autoimmune disease (Hansson et al., 2004).

The disease itself, and in particular expressions of it, limits survival, for example, after 10 years to 55%. Therapists have relied mainly upon corticosteroid drugs that are of variable efficacy, supplemented with the conventional immunosuppressives. Successful use of TNF antagonists is reported but in very limited case studies (Lahmer et al., 2010) and a recent review on the utility of biological therapies identified some benefits with the authors deplored the limitations of the data available (Kempta Lekpa et al., 2012).

## Prostatitis

Aging men become afflicted by the urinary obstructive effects of benign prostatic hyperplasia due to prostatic cell proliferation. Often a component of inflammation is demonstrable histologically despite no evident infection. The question thus has arisen whether BPH is an “immune inflammatory disease” (Kremer et al., 2007), or even whether autoimmunity is implicated. From the earlier days, prostate-specific autoantigens were demonstrable by immunization of rabbits with a saline extract of prostate tissue that provoked an autoantibody response (Shulman et al., 1965) but histological data were not provided.

However, interest waned, as judged by a lapse in citations on inflammatory prostatitis even until the post-2000 era, according to Penna et al. (2009). These authors implicated stromal cells in the prostate as having the properties of immune accessory cells, that is, antigen-presenting cells (APCs), that induced expression of MHC class II molecules, costimulatory molecules, and demonstrability of high levels of the two interrelated cytokines, IL-12p75 and IL-23p40, as well as other cytokines and chemokines characteristic of immunoinflammatory reactivity (see Chapter 15: Cytokines, Their Receptors and Signals). Penna et al. (2009) also cited publications on the detection in semen from cases of chronic prostatitis of proinflammatory cytokines IL-6, IL-8, IL-1beta, and TNF-alpha, together with other data suggesting that products of immunoreactive cells in the prostate foster chronic inflammation and prostate cell growth. A credible sequence for an autoimmune prostatitis would require a candidate prostate-specific autoantigen; among those cited is the controversial cancer marker, prostate-specific antigen. There is clearly more work needed, but considerations such as the high frequency of prostatitis among aging males and its dependency on hormonal influences leave open the idea of an autoimmune component to prostate disease in men.

## Sarcoidosis

An early suspicion that sarcoidosis could have an autoimmune connection (Mackay and Burnet, 1963) proved not sustainable, although few other more credible pathogeneses have emerged. Epidemiological data implicate an environmental influence, with possible person-to-person transmission, or a shared response to a provocative transmissible agent (Newman et al., 1997).

The disease expressions depend on noncaseating granulomatous lesions in multiple sites—skin, lymph nodes, lung, liver or CNS, and pathogenicity depends either on inflammatory fibrosis as in the lungs, or pressure effects of lesions as in the CNS. The immune system is clearly implicated as judged by the Th1-directed granulomatous histopathology. Also, there is solid evidence from a comparative population study in Italy of coassociation with other autoimmune diseases, notably autoimmune thyroiditis, although the strength of this association is questionable (Antonelli et al., 2006).

Ho et al. (2005) drew on the known Th1-biased CD4<sup>+</sup> T-cell response in sarcoidosis, together with possible involvement of the natural killer T (NKT) cell system. NKT cells are activated by glycolipid antigens presented by CD1 molecules on APCs (Chapter 11: Dendritic Cells in Autoimmune Disease). There is a particular class of CD1 (CD1d) that, after interaction with NKT cells with an invariant receptor (Va24/JaQ, paired with Vb11), can exert regulatory effects. Also, in mice at least, the CD1-restricted repertoire includes autoreactive T cells (Park et al., 2001). Ho et al. (2005) ascertained in sarcoidosis a deficiency (for unknown reasons) of Va24 NKT cells, with ensuing loss of their normal regulatory effect on CD1d-dependent reactivity. However, for sarcoidosis to be confidently ascribed to autoimmunity, depletion of Va24 NKT cells would need to be associated with persistent stimulation of the Th1 T-cell pathway by some endogenous autoantigen, for which the evidence is meagre, at best.

## A

- A20-deficient mice, 540–541
- Abatacept, 536–539, 686, 724, 1416t, 1427–1428
- Aberrant antibodies, 9–10
- Aberrant SUMOylation, 437
- Abnormal liver tests, 1119–1120
- Absent in melanoma 2 (AIM2), 202
- Acanthamoeba castellanii*-induced EAE, 366
- Accelerated atherosclerosis, 1074
- Acetylation
  - of histones, 338
  - marks in rheumatoid arthritis immune cells, 435
- Acetylation of lysine 27 of H3 (H3K27ac), 432–433
- Acetylcholine (ACh), 1012–1013
- Acetylcholine receptor (AChR), 270, 1013–1014
  - antibodies, 1018–1019
  - pathogenicity, 1018
  - cellular immunology of AChR MG, 1022
- Acquired aplastic anemia, 923
- Acquired FVII deficiency, 942
- Acquired FX deficiency, 946
- Acquired hemophilia A (AHA), 943
- Acquired vWD (avWD), 948
- ACTH test, 798–799, 799t
- Activated B-cell type (ABC), 641
  - of PBC, 1152–1153
- Activated partial thromboplastin time (aPTT), 939
- Activated phosphoinositide-3-kinase δ syndrome (APDS), 518
- Activated protein C (APC), 623
- Activated prothrombin complex concentrate (aPCC), 941
- Activated thromboplastin time (aPTT), 621
- Activation-induced cell death (AICD), 77, 541
- Activation-induced cytidine deaminase (AID), 175, 516–517
- Active demethylation, 431
- Active immunization, 1042, 1054
- Acute adrenal failure, 806
- Acute anterior uveitis (AAU), 1044
- Acute disseminated encephalomyelitis, 965–966
- Acute hepatic episodes, 1119
- Acute human hantavirus infection, 237
- Acute inflammatory demyelinating polyradiculoneuropathy (AIDP), 988–989

- Acute inflammatory neuropathies, 987, 997
- Acute interstitial nephritis (AIN), 1360
- Acute kidney injury model (AKI model), 1355, 1358–1359
- Acute malar rash, 562
- Acute motor and sensory axonal neuropathy (AMAN), 988
- Acute motor and sensory neuropathy, 989
- Acute motor axonal neuropathy (AMAN), 988–989, 990f
- Acute neuropathies, 988–997
- Acute respiratory distress syndrome (ARDS), 613–614, 1336
- Adalimumab, 686, 886, 1045, 1059, 1416t, 1425
- Adaptive immune responses, 51–59
  - antibodies, 56–57, 56t
  - antigen receptors, diversity of, 52f
  - B-cell development and functions, 55–56
  - functional activities of T cells, 53–55
  - secondary lymphoid tissues, 57–59
  - T-cell development, 51–53
- Adaptive immune system, 558–559, 1052
  - cells, 19–20
