pregnancy or postpartum, the presence of other autoimmune conditions in the same patient (comorbidity) or family (familial aggregation), and a relatively rapid development of hypopituitarism, which is often disproportionate to the size of the pituitary mass. MRI remains the most powerful tool currently available to aid in the differential diagnosis and will be described in details below.

## PATHOLOGICAL FEATURES

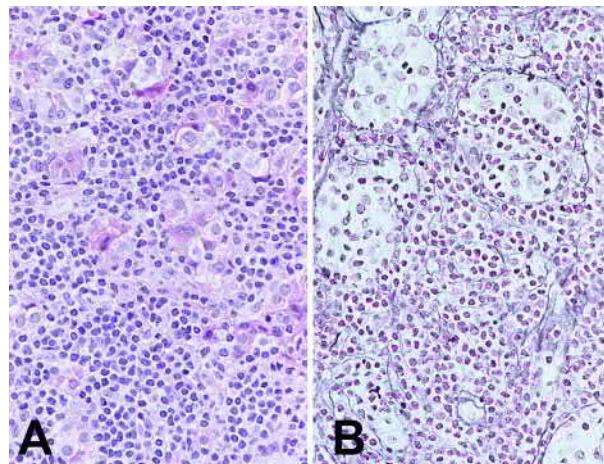

Primary hypophysitis comprises five pathological variants: lymphocytic, granulomatous, xanthomatous, IgG4 plasmacytic, and necrotizing (Table 43.1).

Lymphocytic hypophysitis, first reported by Goudie and Pinkerton in 1962, is the most common form of hypophysitis. It is characterized by the infiltration of the pituitary gland with lymphocytes (Fig. 43.4A), sometimes aggregating into lymphoid follicles with germinal centers. Immunohistochemistry reveals a mixture of T and B lymphocytes (Gutenberg et al., 2005), without a dominant subset, as is seen in other autoimmune diseases. The additional hematopoietic cell types that are found in the infiltrate include plasma cells, eosinophils, macrophages, histiocytes and neutrophils, and mast cells (Vidal et al., 2002). Fibrosis is common and often severe, explaining the toughness and adherence the surgeon finds upon entering the sella turcica. Necrosis is rare and usually of modest and focal nature. Little is known on the mechanisms by which the infiltrate causes the loss of function/destruction of the endocrine cells. Staining with reticulin usually shows that the delicate connective tissue framework is conserved (Fig. 43.4B), whereas in pituitary adenomas is destroyed.

Granulomatous hypophysitis was first described by Simmonds (1917). He analyzed 2000 pituitary glands at autopsy and found four cases not related to tuberculosis or syphilis, characterized by numerous, scattered multinucleated giant cells, histiocytes, and surrounding lymphocytes and plasma cells. The first antemortem patient was reported in 1980 (Taylor and Duff, 1980). The disease can occur together with lymphocytic hypophysitis (Madsen and Karluk, 2000; McKeel, 1983; Miyamoto et al., 1988) and has been reviewed most recently by Hunn et al. (2014). It is significantly more common in females (F:M ratio of 4:1) and has a mean ( $\pm$  SD) age at presentation of 44 ( $\pm$  15) years.

Xanthomatous hypophysitis, originally described by Folkerth et al. (1998), features an infiltration of the pituitary with foamy histiocytes and lymphocytes. The histiocytes, also called xanthoma cells, have a cytosol loaded with lipids, which confer the characteristic foamy appearance. Cystic areas can be observed in the pathological specimen and also on the MRI images. The pathogenesis of xanthomatous hypophysitis remains unknown, with autoimmune, infectious, and localized endothelial dysfunctions as postulated etiologies. Xanthomatous hypophysitis is more common in women (12 of the 17 cases reported thus far, 70%) and impairs more frequently the gonadal axis.

IgG4 plasmacytic hypophysitis is the form of most recent description. It was first reported on clinical grounds in 2004 in a 66-year-old woman with multiple pseudotumors of salivary glands, pancreas, and retroperitoneum

**FIGURE 43.4** Histopathology of primary lymphocytic hypophysitis. (A) Hematoxylin and eosin stain showing the infiltration of lymphocytes among the endocrine cells. (B) Reticulin stain showing the conservation of the connective tissue framework.

(van der Vliet and Perenboom, 2004) and then pathologically proven in 2007 in a 77-year-old man with blurred vision, hypogonadism, and a history of autoimmune pancreatitis and sclerosing cholangitis (Wong et al., 2007). This form is more common in men (13 of the 16 reported cases are men, 81%) and in advanced ages (mean age at presentation is  $69 \pm 6$  years). It is characterized pathologically by a mononuclear infiltrate of the pituitary gland that is rich in IgG4-producing plasma cells. We suggested a number of 10 or more IgG4-producing plasma cells in a high-power microscopic field for establishing this diagnosis (Leporati et al., 2011). The other diagnostic criteria are the increased levels of IgG4 in the serum ( $>140$  mg/dL) and the association with IgG4-positive lesions in other organs. The disease responds extremely well to glucocorticoids and therefore a correct preoperative diagnosis is crucial, since it can spare the patient an invasive pituitary surgery.

Necrotizing hypophysitis, first reported by Ahmed in 1993 (Ahmed et al., 1993), is the rarest form, with only five published cases, four biopsy-proven (Ahmed et al., 1993; Gutenberg et al., 2012; Nater et al., 2012), and one clinically suspected (Ogawa, 1995). Patients present suddenly with severe headache and develop a long-lasting hypopituitarism, features that, however, can also be seen with the other forms of hypophysitis, as well as with other nonhormone-secreting sellar masses. Histologically, the pituitary appears destroyed by diffuse necrosis with surrounding lymphocytes, plasma cells, and a few eosinophils. MRI shows the symmetric enlargement of the pituitary without signs of hemorrhage, and a thickened stalk, features that again are not specific enough to establish a diagnosis before surgery.

## AUTOIMMUNE FEATURES

That autoimmune hypophysitis is indeed an autoimmune disease that is indicated by the availability of animal models and circumstantial evidence (Rose and Bona, 1993). The latter include the association with other diseases of known autoimmune nature, such as Hashimoto's thyroiditis (7% of the patients) and autoimmune polyglandular syndrome type 2 (2%), the improvement of symptoms upon usage of immunosuppressive drugs such as glucocorticoids, and the induction of the disease by drugs that promote immune activation like ipilimumab.

The autoantigen(s) recognized by the autoimmune attack await identification. Kobayashi's laboratory first described sera from patients with pituitary disorders that, when reacted with pituitary cytosolic extracts, recognized a 22 kDa protein (Kikuchi et al., 2000; Yabe et al., 1995), later identified by Takao et al. (2001) as growth hormone. Crock's laboratory subsequently reported that 7 of 10 patients with biopsy-proven lymphocytic hypophysitis and 12 of 22 patients with suspected hypophysitis had a low titer antibody that recognized a 49 kDa cytosolic pituitary protein (Crock, 1998), later identified as alpha-enolase (O'Dwyer et al., 2002b). The authors concluded that alpha-enolase is the autoantigen targeted by the immune system in autoimmune hypophysitis and, considering its coexpression in the placenta, the basis to explain the strong association between autoimmune hypophysitis and pregnancy (O'Dwyer et al., 2002a). Antibodies recognizing alpha-enolase, however, have been reported in many other diseases, ranging from endometriosis to discoid lupus and Wegener's granulomatosis (Crock, 1998). In addition, Tanaka et al. (2003) have shown that the antibody is present in 7 of 17 patients (41%) with autoimmune hypophysitis, but similarly in 6 of 13 (46%) patients with nonfunctioning pituitary adenoma, and in 4 of 17 (24%) patients with other pituitary diseases, making the use of the alpha-enolase antibody not adequate as diagnostic marker of autoimmune hypophysitis. Finally, Nishiki et al. (2001) reported that 5 of 13 patients with LAH and 1 of 12 patients with LINH had antibodies that recognized 68, 49, and 43 kDa proteins in pituitary membrane extracts.

In addition to growth hormone and alpha-enolase, five candidate autoantigens have been reported in recent years: pituitary gland specific factor 1a and 2 (Tanaka et al., 2002), secretogranin 2 (Bensing et al., 2007), chorionic somatotrophic hormone (Lupi et al., 2008), TPIT (Smith et al., 2012), and PIT-1 (Yamamoto et al., 2011). None of them, however, has yet proven to be pathogenic in animal models, useful in clinical practice, or confirmed by independent investigators.

Antibodies to pituitary antigens have been measured occasionally in the published patients (98 of 857, 11%), mainly by indirect immunofluorescence (Bottazzo et al., 1975) or western blotting (Crock et al., 1993). They were found positive in a minority of patients, yielding an extremely poor sensitivity (37%) (Caturegli et al., 2005). They also seem to be not specific for autoimmune hypophysitis, since they have been described in type 1 diabetes (Mirakian et al., 1982), Hashimoto's thyroiditis (Kobayashi et al., 1988), Graves' disease (Hansen et al., 1989), and normal women during postpartum (Engelberth and Jezkova, 1965). This lack of sensitivity and specificity may have several explanations. For example, patients with autoimmune hypophysitis may come to medical attention long after the onset of disease, and it is known that antibodies against endocrine glands disappear over the years.

## GENETIC AND ENVIRONMENTAL INFLUENCES

Insufficient data are available to establish associations between the genes that are classically thought to influence autoimmunity such as the major histocompatibility complex (MHC) locus and CTLA-4, and autoimmune hypophysitis. Also, no environmental agent has been involved with primary hypophysitis, with the exception of four cases presenting after a viral infection of the meninges (Honegger et al., 1997; Matta et al., 2002; Sandler et al., 1998; Vanneste and Kamphorst, 1987).

## ANIMAL MODELS

The first animal model for autoimmune hypophysitis was published in 1964 by Beutner and Witebsky. The authors immunized 16 rabbits with rabbit anterior pituitary extracts, emulsified in complete Freund's adjuvant, and were able to induce specific antibody responses but no pituitary pathology (Beutner et al., 1964). Levine (1967) immunized rats with a single intracutaneous injection of rat pituitary tissue, emulsified in complete Freund's adjuvant, showing that 2–3 weeks after the injection, 6 of the 14 rats (43%) developed infiltration of the adenohypophysis with mononuclear cells, mainly lymphocytes, monocytes, and occasional epithelioid cells. A few posterior and intermediate lobes had minimal inflammation. Disease incidence could be increased to 75% (15 out of 20 rats) by addition of a second immunologic adjuvant, pertussis toxin. He subsequently showed that pituitary extracts from guinea pig were the most potent inducer of experimental autoimmune hypophysitis (six of six rat recipients), whereas human and cow extracts were poorly effective, and dog and rabbit extracts not effective at all (Levine, 1969). In 1970 Beck and Melvin induced experimental autoimmune hypophysitis in one rhesus monkey by injecting her multiple times, over the course of 3 years, with human placental extracts and human chorionic gonadotropin, both emulsified with Freund's adjuvant. Histology showed infiltration of the adenohypophysis with lymphocytes and scattered plasma cells; the neurohypophysis was normal.

In 1982 Klein induced lympho-plasmacytic infiltration of the anterior pituitary by injecting 12 rabbits (seven cases and five controls) 3 times, at 2-week interval, with rabbit pituitary tissue, emulsified in complete Freund's adjuvant. Eight weeks (10 rabbits) or 16 weeks (two rabbits) after the first injection, five of the seven experimental rabbits showed focal infiltration of the adenohypophysis with lymphocytes, some plasma cells, and a few eosinophils and fibrosis. None of the five controls showed histological abnormalities. In 1992 Yoon et al. immunized over 100 hamsters by injecting intradermally 3 times, at 1-week interval, recombinant rubella virus E1 and E2 glycoproteins. Three weeks after the first injection, specific antibodies against the adenohypophysis were found in 95% of the hamsters. Eleven weeks after the first injection, a diffuse lymphocytic infiltration throughout the adenohypophysis was seen. None of the hamsters that had received the control protein (nonglycosylated rubella nucleoprotein C) developed such lesions. The disease could be prevented by neonatal thymectomy and could not be produced by passive transfer of the auto-antibodies, thus indicating that T cells are critical for disease induction and that antibodies are more important as markers of disease rather than as a pathogenic player (Yoon et al., 1992). Finally, Watanabe et al. in 2001 immunized 12 Lewis rats twice, at 1-week interval, with rat pituitary extract emulsified in complete Freund's adjuvant. Three ( $N = 6$ ) or 6 weeks ( $N = 6$ ) after the first immunization, rats showed minimal lymphocytic infiltration in the adenohypophysis and developed antibodies directed against the growth hormone, thyroid-stimulating hormone, and luteinizing hormone (Watanabe et al., 2001). It is unclear, however, whether these hormones represent the initiating autoantigens is rather the natural response of the immune system to the injection of hormone rich pituitary extracts.

A somewhat different experimental approach was taken by Stockinger's laboratory (De Jersey et al., 2002, 2004). The authors have made a transgenic mouse that expresses specifically in the anterior pituitary (because under the transcriptional control of the growth hormone promoter) a nucleoprotein from the influenza virus, thus a foreign antigen. This influenza nucleoprotein contains a peptide that binds to the  $D^b$  allele of the mouse MHC locus and is recognized by specific CD8 T cells. When the authors crossed the nucleoprotein transgenic mice to T cell receptor (TCR) transgenic mice that have CD8 T cells specific for that nucleoprotein, they observe the growth hormone defect due to destruction of the growth hormone cells expressing the viral antigen. Although informative about accessibility and homing of CD8 T lymphocytes to the pituitary, this transgenic model is likely remote from the human disease where CD8 T lymphocytes are rarely seen in the infiltrate, and somatotrophs are usually spared by the autoimmune attack.

In 2008 we published a comprehensive model of autoimmune hypophysitis. It is induced in SJL female mice by immunization with pituitary proteins emulsified in complete Freund's adjuvant (Tzou et al., 2008). The model

mimics closely the human counterpart, featuring a female bias, a diffuse infiltration of the anterior lobe with a mixture of T and B lymphocytes, and panhypopituitarism. The model has provided useful insights into the human disease. It has shown that hypophysitis is characterized initially by an expansion of the pituitary gland but that later evolves into an atrophic structure that reflect the human empty sella condition (Lupi et al., 2011b). The model is being used to identify novel pituitary autoantigens with the intent of translating the findings to the human disease.

## DIAGNOSIS

As indicated above, hypophysitis is a relatively rare condition, but it enters in the differential diagnosis of other more common lesions, such as the pituitary adenomas and other masses arising in the sella turcica (classified in Table 43.3). All sellar masses share similar clinical and radiological findings so that a diagnosis of certainty can only be achieved by examining under the microscope the pituitary tissue obtained from pituitary surgery. Clinical and immunological markers have, at the moment, low predictive values in establishing a differential diagnosis without pathology. Currently, the most powerful tool to differentiate autoimmune hypophysitis from other sellar mass is MRI. We have reviewed systematically the MRI features of the published patients with the primary hypophysitis and identified a set of seven features that can orient the clinician toward a diagnosis of hypophysitis: pituitary volume, symmetry of the sellar mass, stalk diameter, status of the normal posterior pituitary bright spot, status of the mucosa lining the sphenoidal sinus, intensity of the signal after contrast, and heterogeneity of the signal after contrast (Gutenberg et al., 2009). Hypophysitis induces initially an enlargement of the pituitary gland, thus a measurable increased volume by MRI. This volume increase, however, rarely surpasses 6 mm<sup>3</sup>, as is instead more commonly seen in nonsecreting pituitary adenomas. The increase in volume is also typically symmetric in hypophysitis, with the gland assuming a sort of pear-shaped appearance, whereas in adenomas the mass typically displaces the normal (nontumorous) pituitary tissue. The stalk (or infundibulum) is composed of the median eminence of the hypothalamus, the infundibular stem that arises from it, and the pars tuberalis of the anterior hypophysis that surrounds the stem. The normal stalk has an average anteroposterior diameter (sagittal sections) of 3.25 mm at the level of the optic chiasm and 2.32 mm at the pituitary insertion (Satogami et al., 2009). In hypophysitis the stalk thickens above 4 mm, because the inflammation either involves directly the posterior pituitary or extends to it from the involved anterior pituitary. In coronal sections the normal stalk has a transverse diameter of 3.35 mm at the optic chiasm level and 2.16 mm at the pituitary insertion and a uniform cylindrical appearance. In hypophysitis instead the thickened stalk assumes a V-shaped or round appearance (Turcu et al., 2013). The stalk is of normal size and shape in pituitary adenoma. On precontrast images the anterior pituitary has a signal intensity that is approximately identical to that of the gray matter whereas the stalk is hyperintense. This hyperintensity, commonly known as posterior pituitary bright spot, is believed to reflect the high phospholipid content of the anti-diuretic hormone (ADH) and oxytocin neurosecretory granules. In hypophysitis the normal posterior pituitary bright spot is lost, whereas in adenomas is conserved. After injection of the contrast a pituitary gland affected by hypophysitis enhances the signal strongly (similar to the intensity of the cavernous sinus) and homogeneously, whereas in adenomas the enhancement is less intense and more heterogeneous. Finally, the mucosa lining the sphenoidal sinus is typically normal in hypophysitis whereas is swollen with pituitary adenomas. None of these signs is individually specific enough to diagnose with certainty hypophysitis, but in aggregate the signs classified correctly 97% of the patients, with a sensitivity of 92% and a specificity of 99% (Gutenberg et al., 2009).

More recently, Nakata et al. (2010) described an additional MRI feature that was considered characteristic of hypophysitis and capable of distinguishing hypophysitis from adenoma with certainty: the presence in hypophysitis of a dark signal intensity area around the pituitary and in the cavernous sinus on T2-weighted images.

## TREATMENT

The treatment of autoimmune hypophysitis is, at the moment, only symptomatic and aimed at reducing the size of the pituitary mass and replacing the defective hormones.

Mass reduction treatment comprises lympholytic drugs (mainly glucocorticoids), surgery, and radiotherapy. The first line of the treatment is typically the use of glucocorticoids to reduce the pituitary inflammation (reviewed in Lupi et al., 2011a). They are typically given in the form of high-dose prednisone or prednisolone

that is then tapered over a period of weeks to months, depending on the clinical response. Some patients, however, do not respond to glucocorticoids or experience relapses after an initial improvement. In these instances the other immunosuppressive medications such as cyclosporine (Ward et al., 1999), methotrexate (Tubridy et al., 2001), azathioprine (Lecube et al., 2003), and rituximab (Schreckinger et al., 2012) have been reported with success.

Surgery has historically been the most used way to reduce the pituitary mass in patients with primary hypophysitis. It also has the advantage of providing a tissue sample for pathological examination, which establishes a diagnosis of certainty and also expands our understanding of the disease. Nowadays, surgery is recommended for those patients who have significant and progressive visual loss, for those who do not respond to the various options of medical treatment outlined above, and for those with intractable symptoms. Modern pituitary surgery is typically done through the endoscopic transsphenoidal approach, an approach that is relatively safe and effective. The goal of the surgery is to debulk the pituitary mass as to relieve the compression of the cranial nerves or relieve the pressure responsible for headache. The excision of one-third to half of the pituitary mass is typically sufficient, and there is no need to perform a total excision (Iuliano and Laws, 2011).

Stereotactic radiotherapy (Selch et al., 2003) and gamma knife radiosurgery (Ray et al., 2010) have been employed effectively in a few patients who failed medical and surgical treatments and experienced a disease recurrence.

The replacement of the defective pituitary hormones is the main form of long-term therapy in patients with hypophysitis. It is carried out similarly to the replacement performed for the other causes of hypopituitarism. The hormones most commonly replaced are hydrocortisone for a defective corticotroph axis, thyroxine for the thyrotroph axis, desmopressin for the defective adreno-corticotrophic hormone (ACTH) secretion, and testosterone or estradiol for a defective gonadotroph axis. The growth hormone axis, as indicated above, is not assessed systematically in patients with hypophysitis. However, a few adult patients have also been replaced with recombinant growth hormone (Gachoud et al., 2002; Hindocha et al., 2013; Leung et al., 2004). Prolactin deficiency, if diagnosed and clinically significant, can be corrected with administration of recombinant prolactin (Powe et al., 2010).

## OUTCOME

After a diagnosis of hypophysitis is made, either by pathology or on clinical grounds, there are five main outcomes. The majority of patients (68%) improve after the initial mass reductive treatment but the pituitary hormone deficiencies remain and require prolonged replacement. In some of these patients a detailed imaging follow-up has shown that the pituitary gland becomes atrophic with time, yielding on the MRI the appearance of an empty sella (Karaca et al., 2009). In about a fifth of the patients (18%), the disease improves markedly after the initial mass reductive treatment and no further therapy is necessary. In a few patients (2%) the disease regresses spontaneously without any treatment. In a significant minority of patients (6%), the disease progresses and recurs despite medical and surgical attempts to contain it. In the remaining 6%, hypophysitis kills the patient, likely through the development of an irreversible adrenal insufficiency. These autopsy cases have been published sporadically but consistently throughout the years, the most recent one in 2009 (Gonzalez-Cuyar et al., 2009), reminding us that autoimmune hypophysitis can be fatal if unrecognized.

## HYPOPHYSITIS SECONDARY TO CYTOTOXIC T LYMPHOCYTE ANTIGEN 4 BLOCKADE

The introduction in the early 2000s of cancer drugs that act by blocking proteins expressed on immune cells (so-called immune checkpoint inhibitors) has changed dramatically the significance of hypophysitis: from being a rarity, it has now become a disease that most clinicians and practitioners involved in immunotherapy are familiar with. As of September 2018, immune checkpoint inhibitors approved by the FDA for clinical use include the following: monoclonal antibody blocking CTLA-4: ipilimumab (an IgG1, Yervoy, Bristol-Myers Squibb), monoclonal antibodies blocking PD-1: nivolumab (an IgG4, Opdivo, Bristol-Myers Squibb and Ono Pharmaceutical) and pembrolizumab (an IgG4, Keytruda, Merck), monoclonal antibodies against PD-L1: atezolizumab (an IgG1, Tecentriq, Genentech), avelumab (an IgG1, Bavencio, EMD Serono and Pfizer), durvalumab (an IgG1, Imfinzi, Medimmune and AstraZeneca). The highest incidence of hypophysitis has been reported in clinical trials using

ipilimumab alone (up to 17%), combination of ipilimumab and cancer vaccine GVAX (up to 25%) (van den Eertwegh et al., 2012), or combination of ipilimumab and nivolumab (Prete and Salvatori, 2000).

Ipilimumab binds to CTLA-4, a protein expressed mainly by T cells, found primarily in intracellular granules. Within 2–4 hours of the activation of conventional effector T cells, CTLA-4 is transported to the cell surface where it remains for about 48 hours (Jago et al., 2004; Valk et al., 2008). CTLA-4 is expressed constitutively on the surface of CD4 + Foxp3 + regulatory T cells and is required for maintenance of immune tolerance, as conditional CTLA-4 knockout in Tregs leads to fatal autoimmune reactions (Wing et al., 2008). Recent reports show that CTLA-4 expression is not only limited to lymphoid cells but also found on various tumor cells (Contardi et al., 2005; Laurent et al., 2013). CTLA-4 binds to B7 molecules on antigen-presenting cells, initiating a negative cascade that ultimately results in T-cell inhibition. Ipilimumab blocks the physiological binding of CTLA-4 to B7 and therefore prolongs T-cell activation, inducing unrestrained immune responses not only against tumor cells but also against normal self-antigens. Ipilimumab was approved in 2011 by the FDA and the European Medicines Agency for the treatment of metastatic or unresectable melanoma and is currently tested in several other types of cancer, including renal cell carcinoma, pancreatic cancer, prostate cancer, non–small cell lung cancer, and liver cancer. Patients undergo an induction course of ipilimumab consisting of one intravenous infusion every 3 weeks for a total of four infusions (Culver et al., 2011). The dose is usually 3 mg/kg and the price set by Bristol-Myers Squibb is \$30,000 per injection, which translate to a cost of \$120,000 for a course of therapy.

Patients treated with ipilimumab experience an array of autoimmune reactions collectively referred to as immune-related adverse events. As properly stated by Voskens et al. (2013), these adverse events represent “the price of tumor control”. They occur in about 75% of the patients and are clinically significant (grade 3 or 4) in about 15% (Culver et al., 2011). The most common adverse events are dermatitis, enterocolitis, hepatitis, and hypophysitis, thus differing from adverse events typically reported with chemotherapy. It is unclear why hypophysitis, traditionally considered a rare autoimmune disease, is seen at increased frequency in cancer patients treated with ipilimumab. Approximately 66 clinical trials using CTLA-4 blocking antibodies (ipilimumab or tremelimumab, as monotherapy or in combination with anti-PD-1 blocking antibody, chemotherapy or cancer vaccine) have been published between 2003 and 2018 (Chang et al., 2019). Of them, 25 reported hypophysitis as an adverse event. These 25 trials included 2417 patients with advanced cancer, 116 of whom developed hypophysitis, for an average incidence of about 7% (0.4%–25%). Additional patients developing hypophysitis after the treatment with immune checkpoint inhibitors have been published as individual case reports.

The clinical presentation of hypophysitis secondary to the administration of immune checkpoint inhibitors, such as CTAL-4 blocking antibodies, originates mainly from pituitary gland enlargement and multiple hormonal deficiencies. Headache and fatigue are the most common presenting symptoms, occurring in 60%–80% of the patients treated with CTLA-4 blockade (Caturegli et al., 2016; Faje et al., 2018; Wang et al., 2017). In contrast to primary hypophysitis, visual disturbances are usually rare, likely due to the mild degree of pituitary gland enlargement in ipilimumab-treated patients (Bertrand et al., 2015). Corticotroph, thyrotroph, and gonadotroph axes are commonly affected, occurring in more than 80% of patients. Central adrenal insufficiency may be life-threatening if prompt treatment with corticosteroid is not initiated. Few cases of isolated adrenocorticotropin deficiency due to nivolumab-induced hypophysitis have been reported (Ohara et al., 2018). As for the primary hypophysitis, growth hormone deficiency is less frequently reported. The growth hormone/IGF-1 axis is less systematically assessed because the growth hormone replacement therapy is contraindicated in the setting of active malignancies. Prolactin deficiency is common (Chang and Yialamas, 2018), whereas hyperprolactinemia due to stalk-effect is uncommon. Diabetes insipidus is extremely rare in ipilimumab-treated patients (less than 1%) (Caturegli et al., 2016). The other symptoms, such as nausea, weakness, anorexia, weight loss, decreased libido, confusions, dizziness, and hallucinations, have been reported (Chang and Yialamas, 2018). However, these symptoms are nonspecific and may be related to both cancer disease process and nonendocrine-related adverse events.

The recommended treatment for grade 3 or 4 secondary hypophysitis is a course of high-dose glucocorticoids (i.e., prednisone 50–60 mg/day), gradually tapered over a month to a physiological replacement dose (hydrocortisone 15–20 mg/day). It is unclear whether initial high doses are truly needed or if instead the patients could be started on physiological doses from the time of diagnosis. Thyroid hormone and sex steroids are then added as needed. No information about the growth hormone replacement is available. It is now considered not necessary to discontinue ipilimumab for the treatment of CTLA4-induced hypophysitis, although initial cases did. Pituitary deficits seem to persist after glucocorticoid treatment, and long-term hormonal replacement has to be anticipated for most patients.

## CONCLUDING REMARKS—FUTURE PERSPECTIVES

Autoimmune hypophysitis is a rare but increasingly recognized disease that has exploded on the medical arena due to its association with cancer immunotherapies. Its spectrum continues to expand and increase in complexity. The field will advance when a reliable serological test that identifies the autoimmune nature of hypophysitis becomes available.

### Acknowledgments

We dedicate this chapter to the memory of Breanna, a patient with primary autoimmune hypophysitis who, after delivery of her daughter, developed the inability to lactate and adrenal insufficiency that went unrecognized. Several months later, she developed an acute adrenal crisis and died on June 18, 2010.

Pathogenesis and Complications of Autoimmune Gastritis	840	Further Reading	847

Pernicious anemia is the result of advanced autoimmune gastritis, which in its initial stages is an asymptomatic autoimmune disease. First reported by Addison in 1849, the link between the anemia and gastric degeneration was realized by Flint in 1860 and histologic evidence of the gastric atrophy was provided by Fenwick in 1870. In 1871, a fatal anemia was termed perniciosa by Biermer. Subacute combined degeneration was later applied to the posterolateral spinal cord lesions that can be associated with the anemia (Pearce, 2008). In 1926, Minot and Murphy discovered that feeding patients large meals of cooked liver led to a reticulocyte response and reversal of anemia, which earned them a Nobel Prize in 1934. At first, the causal connection between pernicious anemia and chronic gastritis was incomprehensible. Castle (1953) showed that the anemia was a result of a combined deficiency of an “extrinsic factor” subsequently identified as vitamin B12 and present in the liver (Smith, 1948; Rickes et al., 1948), and an “intrinsic factor” (IF) in gastric juice (Highley et al., 1967). Oral treatment with extracts of hog stomach (Sharp, 1929; Sturgis and Isaacs, 1929; Renshaw, 1930) resulted in remission for several years (Wilkinson, 1949). However, relapses tended to occur and some cases became refractory to increasing amounts of the extract (Berlin et al., 1958a,b). This refractory state was due to a serum factor that inhibited the effectiveness of IF (Schwartz, 1958). Subsequently, sera from patients with pernicious anemia were shown to contain autoantibodies to IF (Jeffries et al., 1962; Jacob and Schilling, 1966) and to gastric parietal cells (Irvine et al., 1962; Jeffries et al., 1962; Markson and Moore, 1962). However, little progress was made in understanding the pathology of the gastric lesion until a flexible biopsy tube was designed that permitted the taking of samples of the gastric mucosa for histologic examination (Wood et al., 1949).

Pernicious anemia was observed to cluster in families (McIntyre et al., 1959; Whittingham et al., 1969) and to coexist with autoimmune thyroid diseases (Tudhope and Wilson, 1960). These observations suggested a genetic component to the disorder, a suggestion further strengthened by an association with another endocrine autoimmune disease, type 1 diabetes mellitus (Ungar et al., 1968). The suggestion by Taylor (Taylor, 1959; Taylor and

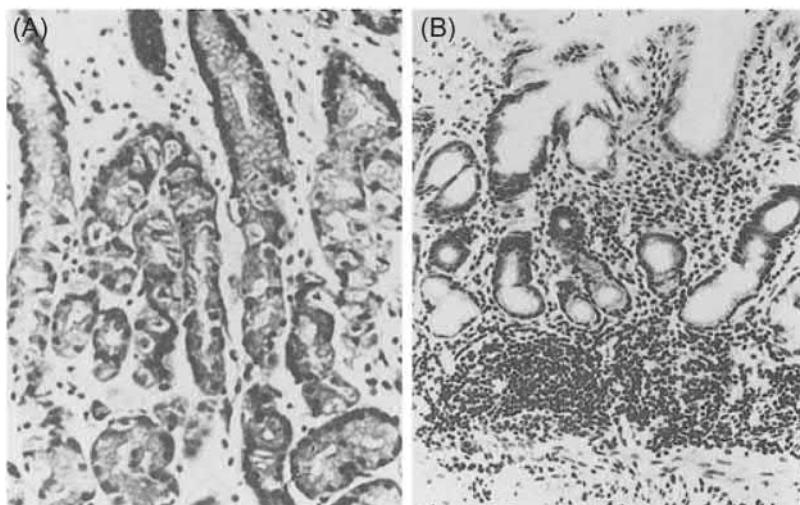

Morton, 1959) that the inhibitory substance to gastric IF in the serum of patients with pernicious anemia was antibody and possibly autoantibody and the recognition that pernicious anemia fulfilled the markers of autoimmune disease put forward by Mackay and Burnet (1963) led to its acceptance as an autoimmune disease of the stomach. The historical antecedents of pernicious anemia have recently been recapitulated as the “dawn of molecular medicine” (Bunn, 2014).

## CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Autoimmune gastritis in the early stages is asymptomatic and demonstrable only by the serologic detection of antibodies to gastric parietal cells. Pernicious anemia only manifests when stores of vitamin B12 are depleted and only 10%–15% of the patients with autoimmune gastritis develop pernicious anemia (Strickland and Mackay, 1973; Irvine et al., 1974) after a latent period of 20–30 years (Toh et al., 1997). Nonetheless, at an estimated prevalence of about 2% in Western adult populations at or over the age of 60 years, pernicious anemia represents the most common cause of vitamin B12 deficiency (Carmel, 1996). Although “silent” until the end stage, the gastric lesion can be predicted years before clinical presentation by immunologic markers specific for gastric autoimmunity. Terminally, the gastritis results in the deficiency of IF, a protein that binds avidly to dietary vitamin B12 (Glass, 1963) and promotes its transport to the terminal ileum for absorption (Donaldson et al., 1967) by ileal cubilin receptors, a multifunctional endocytic receptor (Lindblom et al., 1999). Consequently, the gastritis is expressed clinically as vitamin B12 deficiency associated with megaloblastic anemia arising as a consequence of the requirement of the vitamin for DNA synthesis. The megaloblastic anemia is demonstrated by examination of the blood and bone marrow (Chanarin, 1979) and is now readily controlled by vitamin B12 treatment (Carmel, 2008). Pernicious anemia usually results in low serum pepsinogen I levels, a low serum pepsinogen I/II ratio, and increased serum gastrin levels, which also can be diagnostically useful (Varis et al., 1979; Samloff et al., 1982; Carmel, 1988).

Pernicious anemia is uncommon before the age of 30. Reportedly more common in individuals of northern European decent, the disease has been reported in Blacks and in Latin Americans (Carmel and Johnson, 1978). Patients with advanced pernicious anemia are usually women of late middle age, who appear pale, tired, and depressed and may complain of a sore tongue and abdominal discomfort. Vitamin B12 deficiency can lead to neuropsychiatric syndromes, such as sensory impairment, abnormal reflexes, motor impairment, and spastic paraparesis, and possibly mental or psychiatric disturbances (Savage and Lindenbaum, 1995). Patients with pernicious anemia have also been reported to have a 3–5-fold higher risk of developing gastric cancer and a 13-fold increased risk of developing gastric carcinoids (Hsing et al., 1993; Fuchs and Mayer, 1995; Kokkola et al., 1998).

Strickland and Mackay (1973) proposed a classification of gastritis based on histologic findings of the gastric mucosa, the presence of gastric parietal cell antibody, and serum levels of gastrin. Type A gastritis, the “pernicious anemia type,” is restricted to the fundus and body of the stomach. Early lesions are characterized by chronic inflammation in the submucosa that extends into the lamina propria of the mucosa between gastric glands with accompanying loss of gastric and zymogenic cells (Fig. 44.1). In advanced disease, gastric atrophy is

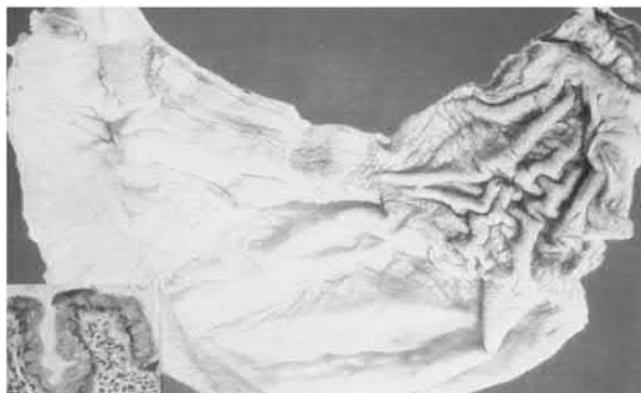

**FIGURE 44.1** The early lesion of autoimmune gastritis. (A) The normal mucosa of the body of the stomach showing gastric glands and the absence of a chronic inflammatory infiltrate in the lamina propria. (B) An early lesion of autoimmune gastritis showing a dense chronic inflammatory infiltrate in the gastric submucosa that extends into the lamina propria with the accompanying loss of gastric parietal and zymogenic cells.

readily recognized macroscopically and microscopically (Figs. 44.2 and 44.3). The wall of the fundus and body of the stomach becomes paper-thin because the gastric glands are markedly reduced or absent. In particular, parietal cells and zymogenic (chief) cells are absent from the gastric mucosa and replaced by mucus containing cells resembling those of the intestine (intestinal metaplasia) (Fig. 44.3).

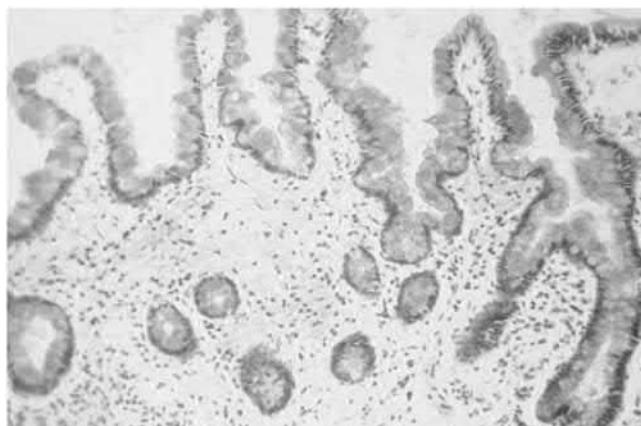

Type A gastritis is characterized by circulating antibodies to gastric parietal cells (Fig. 44.4) that have subsequently been shown to be directed to the gastric H<sup>+</sup>/K<sup>+</sup> ATPase (Burman et al., 1989; Goldkorn et al., 1989; Toh et al., 1990, 1997), achlorhydria, and high levels of serum gastrin secreted by the intact antral glands. Strickland and Mackay observed that 5 out of 30 patients with type A gastritis (16%) developed overt or latent pernicious anemia during a follow-up period of 3–24 years. Type A gastritis is also the gastritis characteristic of families in whom pernicious anemia predominates (Varis, 1981; Kekki et al., 1983).

Type B gastritis, the nonpernicious anemia type, involves the antrum initially but can extend to the fundus and body of the stomach and shows incomplete failure of acid secretion and low levels of serum gastrin because of the antral gastritis. Type B gastritis is usually associated with *Helicobacter pylori* infection; type A is not (Fong et al., 1991).

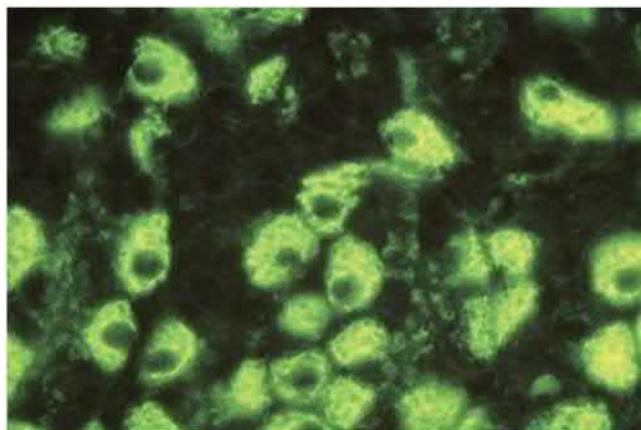

Pernicious anemia in patients with the common variable type of immunodeficiency associated with low levels of serum immunoglobulins can be distinguished from classic pernicious anemia on the basis of this classification. This former type of pernicious anemia usually occurs in a younger age group, is histologically type B, is associated with a negative test for antibodies to gastric parietal cells and IF, and shows a low level of serum gastrin (Twomey et al., 1969; Hughes et al., 1972; Cowling et al., 1974). Pernicious anemia in childhood is not associated with gastritis or achlorhydria and is the result of inadequate IF production.

**FIGURE 44.2** Macroscopic appearance of advanced autoimmune gastritis in a patient with pernicious anemia showing the extreme atrophy of the mucosa of the fundus and body of the stomach with loss of rugal folds contrasted with the healthy mucosa of the gastric antrum. Inset is the microscopic appearance of the mucosa.

**FIGURE 44.3** Microscopic appearance of the gastric mucosa of advanced autoimmune gastritis showing a chronic inflammatory infiltrate in the gastric mucosa and the loss of parietal and zymogenic cells and replacement with mucus containing cells.

**FIGURE 44.4** Indirect immunofluorescent staining of gastric parietal cells in a mouse stomach reactive with serum from a patient with autoimmune gastritis.

The evolution of gastric atrophy in most cases of pernicious anemia probably spans 20–30 years but this is difficult to assess in individual cases. The presence of gastric parietal cell antibody in the serum is predictive of autoimmune gastritis (Irvine et al., 1965; Serafini et al., 1970). Conversely, gastric parietal cell antibody is not observed when gastritis is due to diseases affecting the body of the stomach that are not autoimmune.

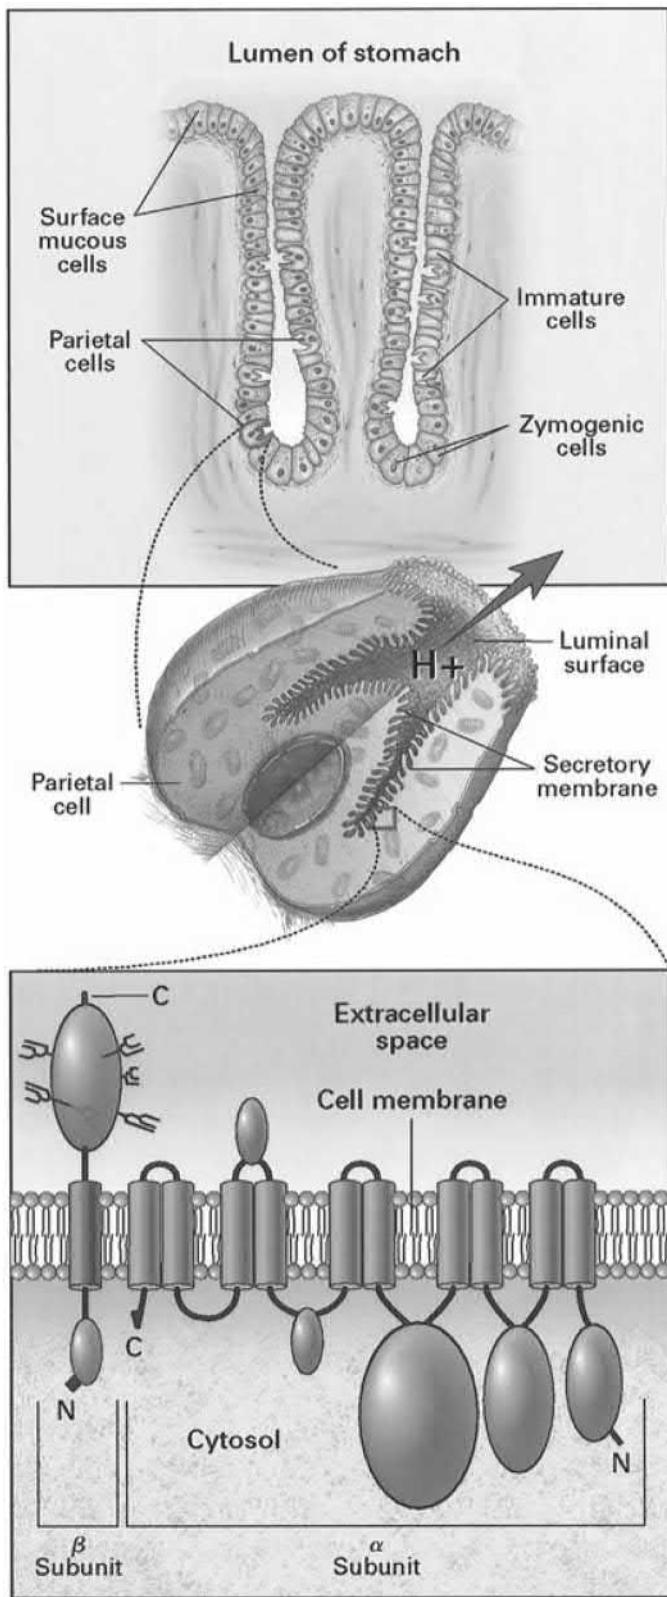

There are many reports of regeneration of gastric parietal cells, improvement in gastric function, and hematologic remission after treatment with corticosteroids (Doig et al., 1957; Gordin 1959; Ardeman and Chanarin, 1965; Jeffries et al., 1966; Rodbro et al., 1967; Strickland, 1969) or azathioprine (Jorge and Sanchez, 1973). This suggests that the gastric mucosa is the direct target of an autoimmune process that can be checked by immunosuppressive drugs. The observations also suggest that precursor stem cells capable of differentiating into parietal cells and zymogenic cells are present in stomachs of patients with autoimmune gastritis and that these are responsible for the regeneration of the differentiated cells when the destructive autoimmune process is controlled. The suggestion is supported by observations in experimental models of autoimmune gastritis where there is evidence of the persistence, and even expansion, of these precursor stem cells in gastritis stomachs (see below). It is also of interest and relevance that reversal of recovery with degeneration of the gastric mucosa recurred once immunosuppressive treatment was halted (Wall et al., 1968). This highlights the persistence of autoreactive T cells that cause this disease, even in the face of immunosuppression.

Pernicious anemia associates predominantly with the autoimmune endocrinopathies and the antireceptor autoimmune diseases. The associated diseases include Hashimoto's thyroiditis, insulin-dependent type 1 diabetes mellitus, primary Addison's disease, primary ovarian failure, primary hypoparathyroidism, premature graying of the hair, vitiligo, thyrotoxicosis, myasthenia gravis, and the Lambert–Eaton syndrome. These organ-specific “thyrogastric” autoimmune diseases may occur in the same patient with pernicious anemia but aggregate in “pernicious anemia families” (Ardeman et al., 1966; Wangel et al., 1968a; Whittingham et al., 1969).

## AUTOIMMUNE FEATURES

### Autoantibodies

Autoimmune gastritis is associated with autoantibodies to gastric parietal cells and to their secreted product, IF. Like most autoantibodies, these autoantibodies are polyclonal but are predominantly of the IgG isotype (Serafini et al., 1970). IgA antibodies to gastric IF have been demonstrated in gastric juice (Goldberg and Bluestone, 1970). Autoantibodies to gastric parietal cells are routinely detected by immunofluorescence (see Fig. 44.4). These autoantibodies are directed toward both the catalytic 100 kDa  $\alpha$  subunit and the 60–90 kDa glycoprotein  $\beta$ -subunit of the gastric  $H^+/K^+$  ATPase (Fig. 44.5) (Karlsson et al., 1988; Burman et al., 1989; Toh et al., 1990; Callaghan et al., 1993; Ma et al., 1994). The gastric  $H^+/K^+$  ATPase is the enzyme responsible for acidification of gastric luminal contents (Forte et al., 1989; Rabon and Reuben, 1990; Prinz et al., 1992). It belongs to a family of ion-motive P-type ATPases and is most closely related to the ubiquitous  $Na^+/K^+$  ATPase. The gastric  $H^+/K^+$  ATPase is located on specialized secretory membranes of gastric parietal cells (DiBona et al., 1979;

**FIGURE 44.5** Gastric parietal cell H<sup>+</sup>/K<sup>+</sup> ATPase as the target in autoimmune gastritis associated with pernicious anemia. Top panel represents a gastric gland showing location of parietal cells in relation to zymogenic cells, immature cells, and surface mucus cells. Middle panel represents a stimulated gastric parietal cell showing the lining membrane of the secretory canalculus on which gastric H<sup>+</sup>/K<sup>+</sup> ATPase is located. Bottom panel represents the catalytic  $\alpha$  and the glycoprotein  $\beta$  subunits of the gastric H/K ATPase showing their orientation in the membrane of the secretory canalculus of the parietal cells. N denotes the N-terminal of protein and C the C-terminal of protein. The role of the gastric H/K ATPase in the initiation of autoimmune gastritis is supported by the development of the gastritis following immunization with the gastric H/K ATPase (Scarff et al., 1997). Callaghan et al., 1990; Toh et al., 1990; Pettitt et al., 1995). Parietal cell antibodies have been shown to deplete H<sup>+</sup>/K<sup>+</sup> ATPase activity from parietal cell membranes in vitro (Burman et al., 1989). Antibody reactivity with the  $\alpha$  subunit of the H<sup>+</sup>/K<sup>+</sup> ATPase includes an epitope on the cytosolic side of the secretory membrane

(Song et al., 1994). The H<sup>+</sup>/K<sup>+</sup> ATPase β subunit extracellular domain has three disulfide bonds and is highly glycosylated and these structural features are required for binding of autoantibodies (Goldkorn et al., 1989; Callaghan et al., 1993). These observations have led to the development of diagnostic ELISAs to gastric H/K ATPase that is more sensitive than the immunofluorescence test for parietal cell antibody (Toh et al., 2012b).

Human IF is a glycoprotein with a molecular mass of 44,000. Each molecule of IF has the capacity to bind to one molecule of vitamin B12 (Chanarin, 1979). Two distinct antibody activities are detected by radioimmunoassay; one reacts with the binding site for vitamin B12 and blocks subsequent binding of IF with free vitamin, and the other reacts with an antigenic determinant remote from this site (Samloff et al., 1968; Rothenberg et al., 1971).

## T-Cell Immunity

Studies of animal models suggest that CD4<sup>+</sup> T cells mediate the gastric lesion (see below). In humans, a significant increase in CD4<sup>+</sup> and CD8<sup>+</sup> T cells and a sixfold increase in non-T cells (probably B cells) have been observed in the cellular infiltrate of stomachs of patients with pernicious anemia (Irvine et al., 1965; Kaye et al., 1983). Electron microscopy has shown that lymphocytes line up against the membranes of gastric parietal cells and zymogenic cells in the gastric mucosa. Phenotypic analysis of the peripheral blood T cells from patients with pernicious anemia have not shown any significant differences compared to age matched controls (Vargas et al., 1995); although, in humans, no studies have been made on the gastric lymph nodes, which are the sites appropriate for such studies.

A number of early studies suggested a T cell response to IF and gastric extracts (Fisher et al., 1965, 1966; Tai and McGuigan, 1969; Rose et al., 1970; Fixa et al., 1972; Goldstone et al., 1973; MacCuish et al., 1974; Whittingham et al., 1975). However, the identification of the gastric H<sup>+</sup>/K<sup>+</sup> ATPase as the major gastric autoantigen that was targeted by antibodies in humans and mice and T cells in mice led to the isolation of human H<sup>+</sup>/K<sup>+</sup> ATPase-specific CD4<sup>+</sup> T cell clones from the gastric mucosa of patients with autoimmune gastritis. The clones were shown to recognize a number of epitopes in the H<sup>+</sup>/K<sup>+</sup> ATPase α and β subunits (Bergman et al., 2003) and were biased toward the production of IFN-γ and TNF-α although some also produced IL-4 and stimulated immunoglobulin production by B cells (D'elios et al., 2001). Most clones also displayed cytotoxic activity that was either perforin or FAS-dependent.

Studies in mice have shown that a T cell immune response to the gastric H<sup>+</sup>/K<sup>+</sup> ATPase is essential for the initiation and development of autoimmune gastritis. These observations include the resistance to autoimmune gastritis in mice expressing the H<sup>+</sup>/K<sup>+</sup> ATPase β subunit in the thymus and mice deficient in the gastric H<sup>+</sup>/K<sup>+</sup> ATPase, a high incidence of disease in mice with repertoires enriched in H<sup>+</sup>/K<sup>+</sup> ATPase reactive T cells, and mice immunized with purified H<sup>+</sup>/K<sup>+</sup> ATPase. Initial findings suggested that the H<sup>+</sup>/K<sup>+</sup> ATPase β subunit may be the primary initiating autoantigen (Alderuccio et al., 1993). However, subsequent studies indicated that both subunits are targeted in this disease and that the expression of the H<sup>+</sup>/K<sup>+</sup> ATPase β subunit is required for presentation of the α subunit to CD4<sup>+</sup> T cells, which explained earlier findings on antigenic hierarchy (Allen et al., 2005).

The pathways that lead to immunological tolerance to the gastric H<sup>+</sup>/K<sup>+</sup> ATPase have been extensively investigated. High avidity H<sup>+</sup>/K<sup>+</sup> ATPase-specific T cells exit the thymus and the H<sup>+</sup>/K<sup>+</sup> ATPase-specific T cells in the periphery represent the residue of a T cell repertoire that has been subjected to partial extrathymic deletion (Read et al., 2007). This depletion occurs following antigen-specific activation of H<sup>+</sup>/K<sup>+</sup> ATPase-specific CD4<sup>+</sup> T cells in the stomach draining paragastric lymph node. Additional mechanisms of peripheral tolerance, mediated by dendritic cells and Foxp3<sup>+</sup> regulatory T cells (Tregs), play important roles in influencing the activation of self-reactive T cells that remain after clonal deletion (Scheinecker et al., 2002; Zwar et al., 2006; Dipaolo et al., 2007; Read et al., 2007; Hogan et al., 2008; Stummvoll et al., 2008). Therefore, protection from gastritis is mediated almost exclusively by tolerogenic mechanisms in the local tissue environment.

## GENETIC FEATURES

Predisposition to pernicious anemia appears to be genetically determined, at least in part. Evidence for genetic factors influencing the expression of pernicious anemia includes clustering of this disease in families and with other autoimmune diseases as well as a racial predilection for northern Europeans. Pernicious anemia is rare

among southern Europeans and earlier reports suggest that it is almost nonexistent among Black and Asian people (Jayaratnam et al., 1967; Irvine et al., 1969). In keeping with ethnic differences, pernicious anemia is associated with phenotypic markers that are absent or occur with low frequency in these racial groups. These markers include blue eyes, fair skin, and blood group A (Callender et al., 1957). However, a more recent study by Carmel (1992) reported a higher prevalence in Black people, particularly among Black women.

There have been reports of a number of Caucasian families with a high frequency of pernicious anemia over several generations (Callender et al., 1957; Callender and Denborough, 1957; McIntyre et al., 1959; Doniach et al., 1965; Ardeman et al., 1966; Wangel et al., 1968a,b; Whittingham et al., 1969). A higher but not absolute concordance of pernicious anemia has been observed in monozygotic twins (Delva et al., 1965; Balcerzak et al., 1968). While associations with susceptibility to pernicious anemia and HLA molecules have been reported (Ungar et al., 1977), such findings were not substantiated in other studies (Whittingham et al., 1991). NALP1, a component of the inflammasome (Faustin et al., 2007), has been reported to be associated with vitiligo and multiple autoimmune diseases including pernicious anemia.

Studies in mice have also substantiated the role of specific genes in predisposing to autoimmune gastritis. BALB/c mouse strains are highly susceptible to autoimmune gastritis whereas C57BL/6 mice are very resistant (Kojima and Prehn, 1981; Silveira et al., 1999). To identify genes conferring susceptibility to the disease, linkage analysis was performed on (BALB/cCrSlc × C57BL/6)F2 mice. Two major genes on chromosome 4 that confer susceptibility to autoimmune gastritis, termed Gasa1 and Gasa2, were identified (Silveira et al., 1999). Further analysis found Gasa3 on chromosome 6, coincident with the MHC locus, and Gasa4 on chromosome 17 as minor gastritis susceptibility genes (Silveira et al., 2001). Experimental evidence for the Gasa1 and Gasa2 loci was obtained using congenic mouse strains that also proved that Gasa1 and Gasa2 can act independently to cause full expression of susceptibility to autoimmune disease (Ang et al., 2007).

## IN VIVO AND IN VITRO MODELS

Mice can readily develop high incidence of autoimmune gastritis, either spontaneously or after manipulation. Mouse models have proven to be a very reliable and robust model of autoimmune gastritis that shares key features with human disease including antigen and epitope commonality, cytokine secretion, and pathogenic mechanisms. As a result, mouse autoimmune gastritis has been used extensively to investigate basic mechanisms of immune tolerance and the cellular and molecular basis for autoimmune disease.

Spontaneous gastritis has been reported in C3H/He mice with an incidence of about 20% (Alderuccio and Toh, 1998). A variety of organ-specific autoimmune diseases can be induced by lymphopenic conditions and the particular organ affected is determined by the genetic background of the mouse strain. BALB/c mice are the most susceptible mouse strain to lymphopenia induced autoimmune gastritis whereas C57BL/6 mice are resistant to the induction of disease (Ahmed and Penhale, 1981; Kojima and Prehn, 1981). Thymectomy induced autoimmune gastritis is historically one of the most commonly used gastritis models. BALB/c mice thymectomized at approximately day 3 after birth develop autoimmune gastritis at 30%–90%. Adult mice did not develop autoimmune gastritis followed by thymectomy unless the mice were treated with cyclophosphamide or irradiation (Ahmed and Penhale, 1981; Barrett et al., 1995). It was previously believed that induction of autoimmune gastritis by neonatal thymectomy was the result of a block in Tregs being seeded into the periphery from the thymus; thus gastritogenic T cells were not suppressed (Asano et al., 1996). However, this proposal was not supported by findings that Tregs are able to repopulate in the periphery after neonatal thymectomy and these Tregs are fully suppressive in vivo (Asano et al., 1996; Dujardin et al., 2004; Ang et al., 2007; Samy et al., 2008).

Comparatively recently, it has been demonstrated that neonatal thymectomy results in a lymphopenic environment that promotes homeostatic proliferation of effector T cells, including expansion of gastritogenic T cell clones (Monteiro et al., 2008). Therefore, autoimmune gastritis induced by neonatal thymectomy is probably the result of a reduced Treg: effector T-cell ratio that does not favor suppression by Treg, rather than the depletion of Tregs per se or intrinsic defects of Tregs.

Murine autoimmune gastritis can also be induced by immunization of adult BALB/c mice with purified gastric H<sup>+</sup>/K<sup>+</sup> ATPase in complete Freund's adjuvant (Scarff et al., 1997). However, the disease induced is transient and is reversible after cessation of immunization, perhaps due to regeneration of parietal cells and zymogenic cells from the expanded stem cell population.

Autoimmune gastritis may occur as the result of the immune system being dominated by self-reactive T cells. T-cell receptor (TCR) transgenic mouse lines that constitutively express H<sup>+</sup>/K<sup>+</sup> ATPase-specific TCR on their T cells have been generated. A23 TCR transgenic mice contain CD4<sup>+</sup> T cells that target residues 630–641 of the H<sup>+</sup>/K<sup>+</sup> ATPase  $\alpha$  subunit and display a Th1 phenotype (McHugh et al., 2001), whereas A51 TCR transgenic mice contain CD4<sup>+</sup> T cells that target residues 889–899 of the H<sup>+</sup>/K<sup>+</sup> ATPase  $\alpha$  subunit and reveal a Th2 phenotype (Candon et al., 2004). Both A23 and A51 T cell clones were isolated from the paragastric lymph node of mice that developed autoimmune gastritis following neonatal thymectomy (Suri-Payer et al., 1999). A23 mice develop more severe autoimmune gastritis spontaneously with higher penetrance than in A51 mice due to difference in the availability of their respective autoantigenic epitopes (Levin et al., 2008). IE4 TCR transgenic mice were created using TCR genes isolated from a T cell hybridoma, which was derived by immunization of a BALB/c mouse with residues 253–277 of the H<sup>+</sup>/K<sup>+</sup> ATPase  $\beta$  subunit (Alderuccio et al., 2000; De Silva et al., 2001). Autoimmune gastritis only occurred in 20% of the mice, even though transgenic T cells in the periphery responded well to the antigenic peptide in vitro.

Constitutive expression of the cytokine granulocyte macrophage colony stimulating factor in the stomach induces autoimmune gastritis with very similar antigenic and pathological features to those of other models (Biondo et al., 2001). It is not clear which of the proinflammatory activities of granulocyte macrophage colony stimulating factor are responsible for the disease initiation.

T cells from mice deficient in gastric H<sup>+</sup>/K<sup>+</sup> ATPase autoantigens can induce autoimmune gastritis in sublethally irradiated mice, presumably due to the preponderance of H<sup>+</sup>/K<sup>+</sup> ATPase-specific T cells that result from a lack of autoantigen-specific tolerance (Tu et al., 2011). This recent model is attractive for the study of many aspects of organ-specific autoimmunity because of a high degree of consistency of disease severity, the use of polyclonal T cells, and a specific T cell response to a bona fide autoantigen (Fig. 44.6). The cardinal features of mouse autoimmune gastritis are illustrated in this disease. The gastric mucosa becomes heavily infiltrated by mononuclear cells, parietal and zymogenic cells are severely depleted, and there is overgrowth by immature cell types resulting in gastric hypertrophy visible at both microscopic and macroscopic levels (Fig. 44.6A–D). The depletion of parietal cells leads to an increase in gastric pH (Fig. 44.6E). High titer anti-H<sup>+</sup>/K<sup>+</sup> ATPase autoantibodies develop within 4–6 weeks (Fig. 44.6F and G).

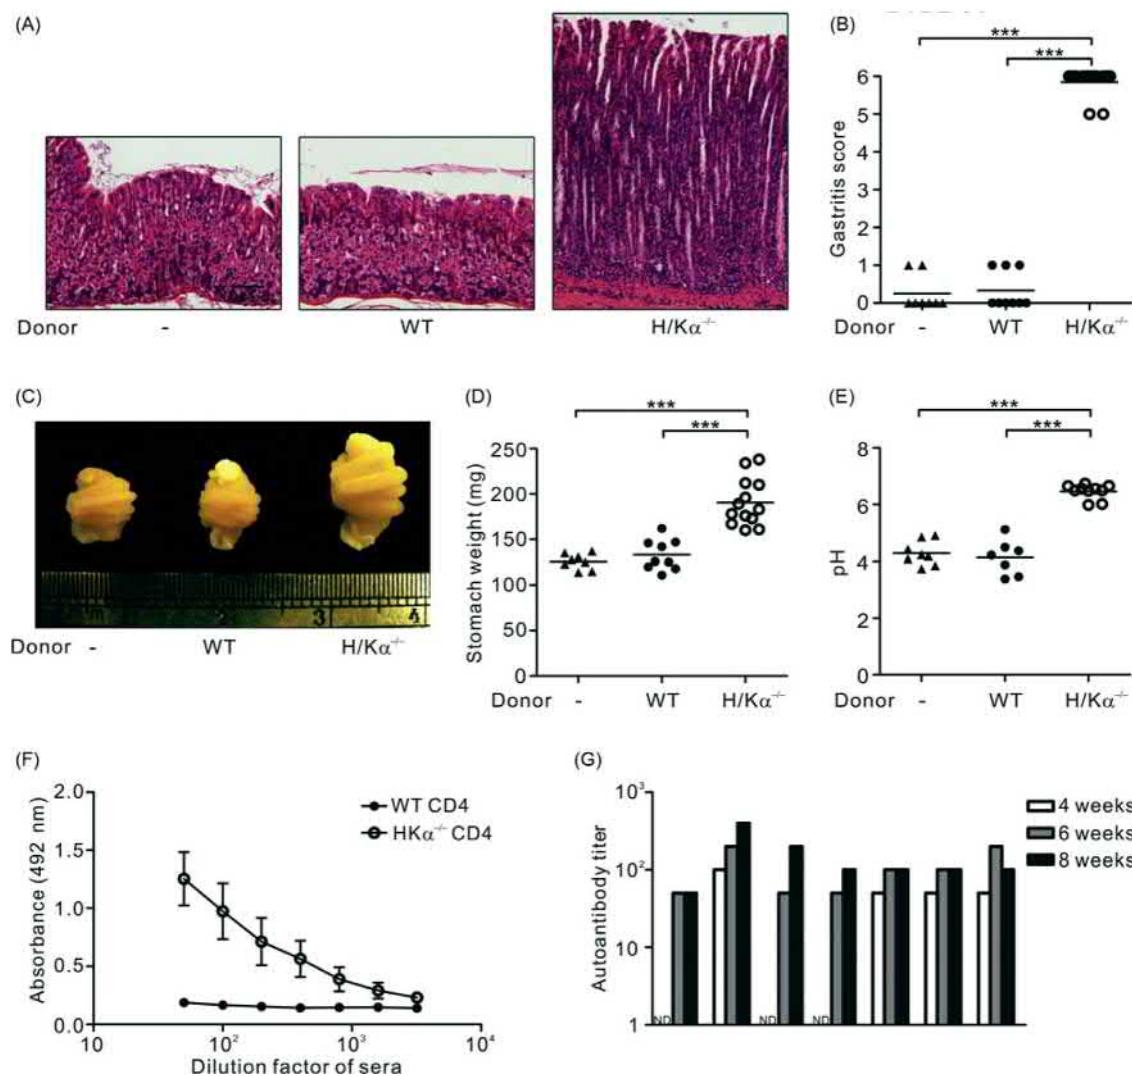

## PATHOGENESIS AND COMPLICATIONS OF AUTOIMMUNE GASTRITIS

### Pathologic Effector Mechanisms

Studies in mice have clearly indicated that autoimmune gastritis is initiated by CD4<sup>+</sup> T cells. First, gastritis can be transferred to immunocompromised hosts by CD4<sup>+</sup> T lymphocytes but not by sera from animals with autoimmune gastritis (van Driel et al., 1984, 2005; Gleeson et al., 1996; Toh et al., 1997; van Driel and Ang, 2008). In addition, histopathologic features of gastritis occur in mice before the appearance of autoantibodies. The early gastric lesion is composed predominantly of CD4<sup>+</sup> T cells and macrophages with production of a mix of Th1- and Th2-type cytokines but not interleukin-4, suggesting a key role for these cells and their cytokines in initiation of the disease (Martinelli et al., 1996; Katakai et al., 1998). Interferon- $\gamma$ , probably produced by the Th1 cells, appears to be crucial for the induction of gastric lesion, as a single injection of antibodies to interferon- $\gamma$  immediately following neonatal thymectomy prevents autoimmune gastritis (Barrett et al., 1996) and T cells from mice deficient in interferon- $\gamma$  or interleukin-12 have a reduced pathogenicity in causing autoimmune gastritis (Suri-Payer and Cantor, 2001). CD81 T cells do not seem to have a role in this disease since depletion of this T cell population by treatment with anti-CD8 antibody did not reduce the capacity of the remaining T cells to transfer disease (De Silva et al., 1998). Recent data suggest that interleukin-17 may play a role in assisting the development of severe late stage autoimmune gastritis. B lymphocytes tend to accumulate in gastric lesions and aggregate in follicular-like structures and it is not known if they play a functional role at these sites (Martinelli et al., 1996) (Fig. 44.7).

There is evidence for various mechanisms whereby T cells could cause the lesion in the gastric mucosa including direct cytotoxicity and cytokine mediated disruption of developmental pathways in the stomach (Judd et al., 1999; Marshall et al., 2002; Kang et al., 2005).

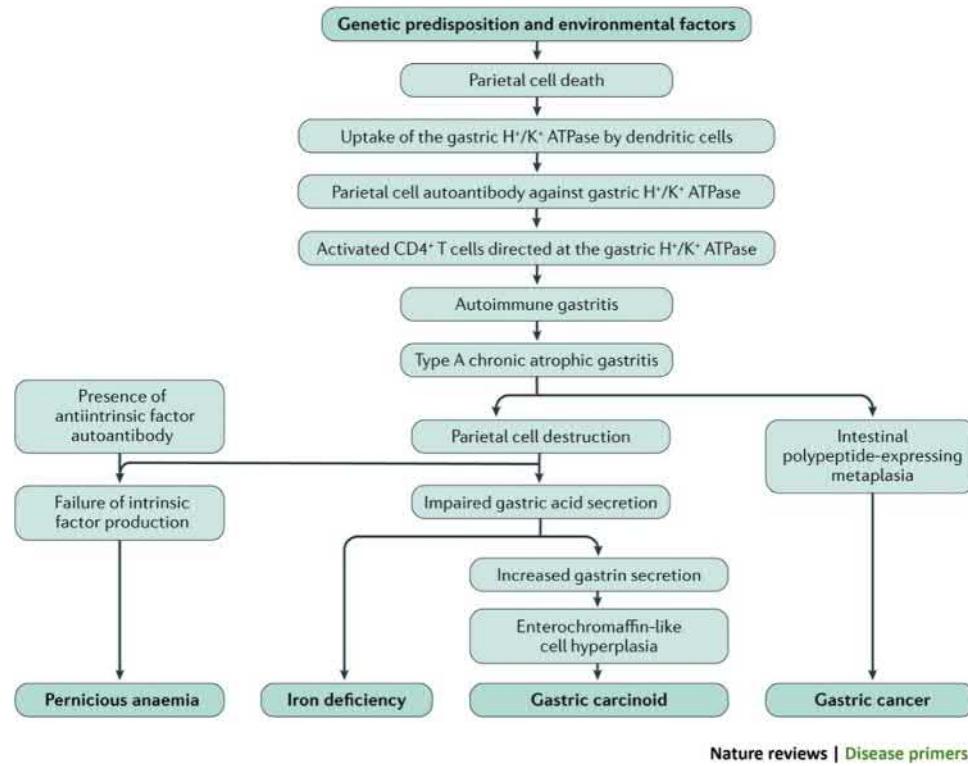

As described above, CD4<sup>+</sup> T cell clones specific for the gastric H<sup>+</sup>/K<sup>+</sup> ATPase and with activities that support a pathogenic role have also been isolated from patients with pernicious anemia (D'elios et al., 2001).

**FIGURE 44.6** A mouse model of autoimmune gastritis. Irradiated wild-type mice that received  $5 \times 10^7$  CD4 $^+$  T cells from either wild-type (WT) or H $^+$ /K $^+$  ATPase  $\alpha$  subunit-deficient mice (H/K $\alpha^{-/-}$ ), were killed 8 weeks after transfer and compared to nonmanipulated mice (−). (A) Hematoxylin and eosin stained sections of stomachs. (B) Gastritis scores. (C) Macroscopic views of stomachs. (D) Stomach weights after stomach contents were removed. (E) Gastric pH. Mice were starved overnight and their stomachs were rinsed in 1 mL saline which were then collected and measured by a pH meter. (F) H $^+$ /K $^+$  ATPase-specific autoantibodies in serum were detected by ELISA using serial twofold dilutions of mouse sera, with a starting dilution factor of 50. (G) Gastric H $^+$ /K $^+$  ATPase autoantibody levels in mice at various times after cell transfer. Serum samples were collected at the indicated time points from each mouse after transfer of CD4 $^+$  T cells from H/K $\alpha^{-/-}$  mice. Autoantibody titer was represented by the maximum dilution factor that had an absorbance reading above 50% maximum. ND = not detectable. Data pooled from four independent experiments. In (B), (D), and (E), each circle represents the data from one mouse. Mann–Whitney U test was used; bars, median, and \*\*\*, P < .001.

## AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Autoimmune gastritis and pernicious anemia are typically associated with autoantibodies to parietal cells, directed to gastric H $^+$ /K $^+$  ATPase and to IF. For the diagnosis of pernicious anemia, IF antibodies have a much higher disease specificity (> 95%), albeit lower sensitivity (50%–70%), than antibodies to gastric parietal cells. A recent study suggests that assaying autoantibodies to both IF and the H $^+$ /K $^+$  ATPase results in an increased specificity and sensitivity and would aid in the selection of patients for follow-up gastroscopic procedures (Lahner et al., 2009; Toh et al., 2012b). Since the Schilling test is no longer available as a diagnostic procedure, there has been increased dependence on IF antibodies for diagnosis. Antibodies to the vitamin B12 binding site of IF are demonstrable in serum of ~70% of the patients and to a second site in ~50%. These frequencies are

**FIGURE 44.7** Pathogenesis and complications of autoimmune gastritis. Autoimmune gastritis and type A chronic atrophic gastritis can develop in genetically predisposed individuals. Environmental risk factors (such as *Helicobacter pylori* infection) might also have a role. Apoptosis of parietal cells might result in the release of gastric H<sup>+</sup>/K<sup>+</sup> ATPase constituents, which are taken up by gastric dendritic cells that then migrate to the draining gastric lymph nodes to activate naïve CD4<sup>+</sup> T cells. The gastric H<sup>+</sup>/K<sup>+</sup> ATPase-activated CD4<sup>+</sup> T cells then migrate to the gastric mucosa to initiate tissue damage by binding to MHC class II molecules and by activating FAS-dependent mechanisms. Gastritis is marked by the presence of autoantibodies to the gastric H<sup>+</sup>/K<sup>+</sup> ATPase. Impaired acid secretion leads to iron deficiency anemia that can precede the onset of pernicious anemia by up to 20 years (Hershko et al., 2006). Chronic atrophic gastritis also represents a risk factor for gastric cancer arising from polypeptide expressing intestinal metaplasia, as well as enterochromaffin-like cell hyperplasia arising from gastrin hypersecretion by antral G cells predisposing to gastric carcinoid. Pernicious anemia arises from intrinsic factor deficiency as a result of loss of intrinsic factor producing gastric parietal cells and the presence of intrinsic factor autoantibodies (Green et al., 2017; Toh, 2017).

greater if gastric juice is assayed. There may be coexisting autoantibodies specific for the various other autoimmune diseases in the thyrogastriac cluster. The incidence of these antibodies rises with increasing duration of disease, almost doubling after 10 years (Ungar et al., 1967).

Parietal cell antibodies to gastric H<sup>+</sup>/K<sup>+</sup> ATPase are diagnostic of the underlying pathologic lesion of autoimmune gastritis, as gastric biopsies carried out in asymptomatic patients have revealed the presence of type A gastritis (Uibo et al., 1984). These antibodies are routinely detected by indirect immunofluorescence or, to gastric H<sup>+</sup>/K<sup>+</sup>ATPase, by ELISA (Chuang et al., 1992; Lahner et al., 2009). Antibodies to gastric parietal cells can be demonstrated by serum reactivity with the cytoplasm of gastric parietal cells in unfixed, air-dried, and frozen sections of mouse stomach (see Fig. 44.4). Mouse stomach is preferable to rat stomach because of a lower frequency of heterophile reactions (Muller et al., 1971) that could be misinterpreted as antibody to parietal cells. The antibodies are detected by immunofluorescence in 90% of the patients with pernicious anemia, with a prevalence of 2%–5% in the general population, and in 30% of the patients with other thyrogastriac autoimmune diseases, including type 1 diabetes mellitus (De Block et al., 2000, 2001a,b). Diagnostic ELISAs to gastric H/K ATPase are more sensitive than the immunofluorescence test for parietal cell antibody and can be used instead of the immunofluorescence test (Toh et al., 2012b). The prevalence of gastric autoantibodies increases with age and correlate with rising serum gastrin levels (Jassel et al., 1999; De Block et al., 2001a). Parietal cell mass and hence the availability of autoantigens decreases as autoimmune gastritis progresses to pernicious anemia and this may explain the observation that the prevalence of autoantibodies decreases with progression (Davidson et al., 1989) and may also explain the lower antibody prevalence in one study of pernicious anemia (Carmel, 1992).

## LABORATORY DIAGNOSIS

Laboratory diagnosis of autoimmune gastritis rests on serum biomarkers of antibody to parietal cell H/K ATPase and IF and corpus atrophy identified by serum biomarkers of gastrin and pepsinogen levels. Subjects with asymptomatic parietal cell antibody should be regularly assessed for serum biomarkers for progression to corpus atrophy, development of iron and B12 deficiency anemia, and for associated autoimmune thyroiditis and type 1 diabetes mellitus (Toh, 2014).

## CONCLUDING REMARKS—FUTURE PROSPECTS

As one of the most common autoimmune diseases, autoimmune gastritis has been intensively investigated and a great deal has been discovered concerning its immunological pathogenesis. The availability of excellent animal models has meant that the identity of the gastric autoantigens is well defined, and the pathway that leads to immunological tolerance in normal individuals is well understood. On the other hand, in common with most other autoimmune diseases, the reason why the immune system begins to react to gastric autoantigens to the detriment of patients is still not clear. While we know some level of detail of the genetics of autoimmune gastritis in mice, such data have not as yet been translated into the human setting. Environmental triggers for autoimmune gastritis are also unclear. While some data suggest a role for *Helicobacter* infection, this hypothesis is not supported by other epidemiological information and the question of its role remains open (Toh et al., 2012a).

From a clinical standpoint, pernicious anemia is now routinely treatable to reverse hematologic manifestations and to prevent neurological complications of the disease by vitamin B12 replacement. High-dose oral vitamin B12 tablets (1000–2000 µg) taken daily are as effective as intramuscular monthly injections in correcting blood and neurologic abnormalities (Stabler, 2013). However, this therapy does not cure the underlying cause of the disease, namely the decimation of the gastric mucosa by the autoimmune response, which increases the risk of gastric cancer. In mice, ectopic expression of the gastric autoantigen (Murphy et al., 2003) and treatment with Tregs (Nguyen et al., 2011) lead to long-term reversal of gastric lesions. Whether such treatments will become feasible or practical in humans remains to be seen. The challenge is to restore antigen-specific T cell tolerance to the gastric H/K ATPase (Anderson and Jabri, 2013).

## GENERAL INTRODUCTION

Celiac disease (also termed gluten-sensitive enteropathy) was early on considered a food hypersensitivity disorder as it precipitates in genetically susceptible individuals by the ingestion of cereal gluten proteins. This perception of the etiology of the disorder has changed as the disease has several autoimmune features of which the highly disease-specific antibodies to the enzyme transglutaminase 2 (TG2) are particularly striking. There is also tissue-specific destruction of enterocytes in the small bowel—not very different from the destruction of islet cells in the pancreas of subjects affected with type 1 diabetes. The combination of the disease driving antigen being identified, the relatively easy access to the target organ by gastroduodenoscopy, and an unusually clear

association to certain human leukocyte antigen (HLA) allotypes has led to a detailed understanding of the pathogenic mechanisms. Hence, among the chronic inflammatory disorders with autoimmune components, celiac disease stands out as a particularly instructive model. Insight into the pathogenesis of this disorder is relevant for the diseases for which the genetic and environmental components are yet poorly characterized.

## HISTORICAL ASPECTS

Celiac disease was probably first described in the 2nd century A.D. by Aretaeus of Cappadocia. However, the important discovery of the Dutch pediatrician Willem Karel Dicke that this is a condition dependent on oral gluten exposure is fairly recent. Apparently, Dicke's suspicion was alerted by a young mother who reported that her child's rash improved by removal of bread from the diet, and he began experimenting with gluten-free diet treatment in the mid-1930s (van Berge-Henegouwen and Mulder, 1993). His first publication on the dietary treatment of the condition was in Dutch in 1941 (Dicke, 1941). Dicke (1950) defended his thesis entitled "Coeliac disease investigations of the harmful effects of certain types of cereal on patients suffering from coeliac disease" at the University of Utrecht. Elimination and provocation diets played a central role in the early diagnostic workup schemes reflecting upon the fact that celiac disease was considered a food intolerance disorder (Meeuwisse, 1970). Now, celiac disease is equally considered to be much an autoimmune condition where the diagnosis in the recent guidelines for pediatric disease is diagnosed essentially on detection of high levels of autoantibodies (Husby et al. 2012). Gluten-free diets are popular today and staying gluten free is adopted by many more people than those affected with celiac disease. Some of the people staying gluten free suffer from nonceliac gluten sensitivity. The diagnostic criteria of this condition are solely based on symptoms and an exclusion of celiac disease, and its etiology, which while still being unknown, may as well not involve immunological mechanisms. In Box 45.1, some key historical findings which have led to our current understanding of the pathogenesis and the clinical handling of celiac disease are listed.

### BOX 45.1

#### IMPORTANT HISTORICAL ACHIEVEMENTS IN THE STUDY OF CELIAC DISEASE.

- First description of a condition resembling celiac disease by Aretaeus of Cappadocia (2nd century A.D.)
- First precise description of the disorder (Gee, 1888)
- Suggestion that banana diet can cure the disease (Haas, 1932)
- Wheat gluten identified as a causative agent (Dicke, 1950)
- Villous atrophy and crypt hyperplasia found to be pathognomonic for the disease (Paulley, 1954)
- Celiac disease of childhood and adult nontropical sprue share the same pathogenesis (Rubin et al., 1960)
- Familial clustering of biopsy proven disease (MacDonald et al., 1965)
- First diagnostic criteria of pediatric celiac disease from ESPGAN (Meeuwisse, 1970)
- Existence of autoantibodies to reticulin detected (Alp and Wright, 1971; Seah et al., 1971)
- Celiac disease found to be an HLA associated disorder (Falchuk et al., 1972; Stokes et al., 1972)
- Cell-mediated immunity to gliadin in celiac disease intestinal biopsy specimens (Ferguson et al., 1975)
- HLA-DQ2 heterodimer ( $DQA1^*05/DQB1^*02$ ) identified as the primary HLA susceptibility factor (Sollid et al., 1989)
- Isolation of gliadin-specific, HLA-DQ2 restricted T cells from intestinal biopsies (Lundin et al., 1993)
- Celiac disease autoantigen identified as transglutaminase 2 (Dieterich et al., 1997)
- Diagnosis in children can be done without a gut biopsy examination (Husby et al., 2012)

## EPIDEMIOLOGY

Celiac disease was previously considered to be a disease primarily of Caucasians but new observations suggest that the disease has an almost worldwide distribution. For instance, a study from China based on serology indicated that the prevalence in the Shandong province in north China, where wheat is a staple in the diet, is 0.76% (Yuan et al., 2017). In Europe and the United States the prevalence is around 1% (Choung et al., 2017; Mustalahti et al., 2010). There are unexplained differences in prevalence between European countries with adult prevalence figures varying from 2.4% in Finland to 0.3% in Germany (Mustalahti et al., 2010). Similarly, there is a striking difference in prevalence between Finnish and Russian Karelia, which should be genetically homogenous, as the region was divided after the Second World War (Kondrashova et al., 2008). The strong regional differences in the prevalence speak of the involvement of environmental factors in the etiology of the disease.

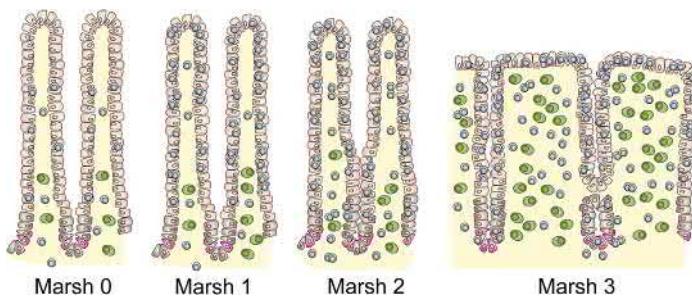

More than half of the cases of celiac disease are now diagnosed in adult life, and some patients are diagnosed after the age of 60 years (Holmes and Muirhead, 2017; Rubio-Tapia et al., 2012). Many patients may have had undetected disease since childhood whereas in others, the disease has started later (Catassi et al., 2010). The natural history and the timing for conversion to seropositive and/or mucosal inflammation are not fully understood. Studies have reported that some children have transient positive serology that normalizes without dietary manipulation (Mäki et al., 2003; Simell et al., 2007). These events suggest that at least certain aspects of celiac disease may be transient.

Between 1985 and 1995, there was an epidemic of celiac disease in Sweden among children below 2 years of age with a threefold increase in incidence (Namatovu et al., 2014). The sharp rise and subsequent abrupt decrease in incidence was investigated and explained by changes in infant feeding habits, including an increase in amount of gluten given, the age at introduction of gluten to the diet, and whether breastfeeding was ongoing or not when gluten was introduced. These observations fueled hope that it should be possible to prevent celiac disease by introducing small amounts of gluten at 4–6 months of age. This approach was tested in a multicenter, randomized, double-blind, placebo-controlled dietary intervention study (Vriezinga et al., 2014). Disappointingly, no preventive effect by this intervention was observed in children at the age of 3 years. Neither did a parallel intervention study that awaited gluten introduction to after 1 year of age demonstrate a preventive effect (Lionetti et al., 2014). Thus prevention of celiac disease by dietary intervention is not possible today.

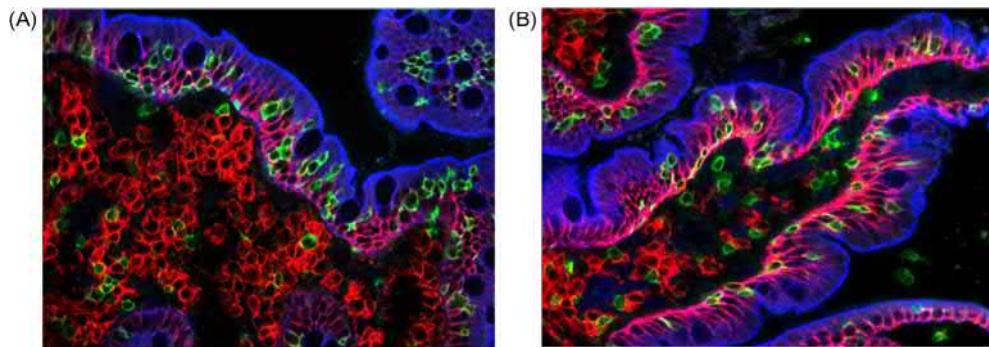

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

Celiac disease may present in early childhood soon after the introduction of gluten containing food. A dramatic and even fatal clinical picture with diarrhea, anorexia, failure to thrive, abdominal distension, and growth retardation was once regarded as typical. This is now rare, and most patients, both children and adults, present with less and milder symptoms (Lebwohl et al., 2017). Many of the symptoms associated with the milder disease form, such as chronic fatigue, joint pain, and headache do not directly point to a small intestinal disorder. Neither do complications, such as osteoporosis, reduced fertility, peripheral neuropathy, ataxia, epilepsy with cerebral calcifications, or dermatitis herpetiformis (Ciacci et al., 1995; Collin and Reunala, 2003; Hadjivassiliou et al., 2003; Sanders et al., 2003). The coexistence of autoimmune diseases is striking; in particular, there is an overrepresentation of type 1 diabetes (Cronin et al., 1997; Green et al., 1962; Koletzko et al., 1988), Sjögren's syndrome (Collin et al., 1994), autoimmune thyroid disorders (Collin et al., 1994; Counsell et al., 1994), connective tissue disease (Collin et al., 1994), and IgA deficiency (Cataldo et al., 1997; Mawhinney and Tomkin, 1971; Wang et al., 2011). It has been debated whether gluten consumption in undiagnosed celiac disease can induce other autoimmune diseases; however, the available evidence supporting this notion is weak (Lundin and Wijmenga, 2015). Like many autoimmune disorders, pediatric and adult celiac disease show a gender bias with a female to male ratio of approximately 2:1 (Ciacci et al., 1995; Ivarsson et al., 2003b).

Recently, there has been much interest in the clinical entity of nonceliac gluten sensitivity. Such patients may have symptoms resembling celiac disease but the enteropathy, serology, and HLA association typical of celiac disease are lacking as are clear diagnostic criteria (Ludvigsson et al., 2013).

**FIGURE 45.1** Schematic representation of the stages of the intestinal lesion in celiac disease according to Marsh. These stages are dynamically related. The normal state is Marsh type 0. In Marsh type 1, there is increased number of intraepithelial lymphocytes. Marsh type 2 has increased number of intraepithelial lymphocytes and enlarged, hyperplastic crypts. Marsh type 3 has, in addition to increased number of intraepithelial lymphocytes and crypt hyperplasia, partial to complete blunting of the villous structures also. The number of leukocytes in the lamina propria, such as plasma cells and T cells, are increased in the full-blown celiac disease lesion but their presence is not included as a parameter for the Marsh staging. Source: Courtesy of A.-C.R. Beitnes and Jorunn Stamnaes.

**FIGURE 45.2** The celiac lesion is characterized by the increased infiltration of T cells and plasma cells. Immunohistochemical staining of T cells (CD3, green), plasma cells (CD138, red), and epithelial cells (cytokeratin, blue) in the biopsy sections of (A) a patient with untreated celiac disease and (B) a normal subject. ## PATHOLOGICAL FEATURES

The intestinal lesion in celiac disease can be classified into three dynamically connected stages as suggested by Marsh—the infiltrative, hyperplastic, and destructive lesion (Marsh, 1992) (Fig. 45.1). In the infiltrative lesion (Marsh 1), the mucosal architecture is normal but there is an increased infiltration of intraepithelial lymphocytes (IELs) in the villous epithelium. The hyperplastic lesion (Marsh 2) is similar to the infiltrate lesion but in addition, has enlarged hyperplastic crypts. The last stage is the destructive lesion which can be subgrouped into partial, subtotal, or total villous atrophy (Marsh 3A-C) (Oberhuber et al., 1999). The latter is corresponding to the classic flat lesion, which in addition to the increased IELs, is characterized by swelling and infiltration of plasma cells, CD4 +  $\alpha\beta$  T cells, macrophages/dendritic cells, mast cells, and neutrophils in the lamina propria (Fig. 45.2).

## AUTOIMMUNE FEATURES

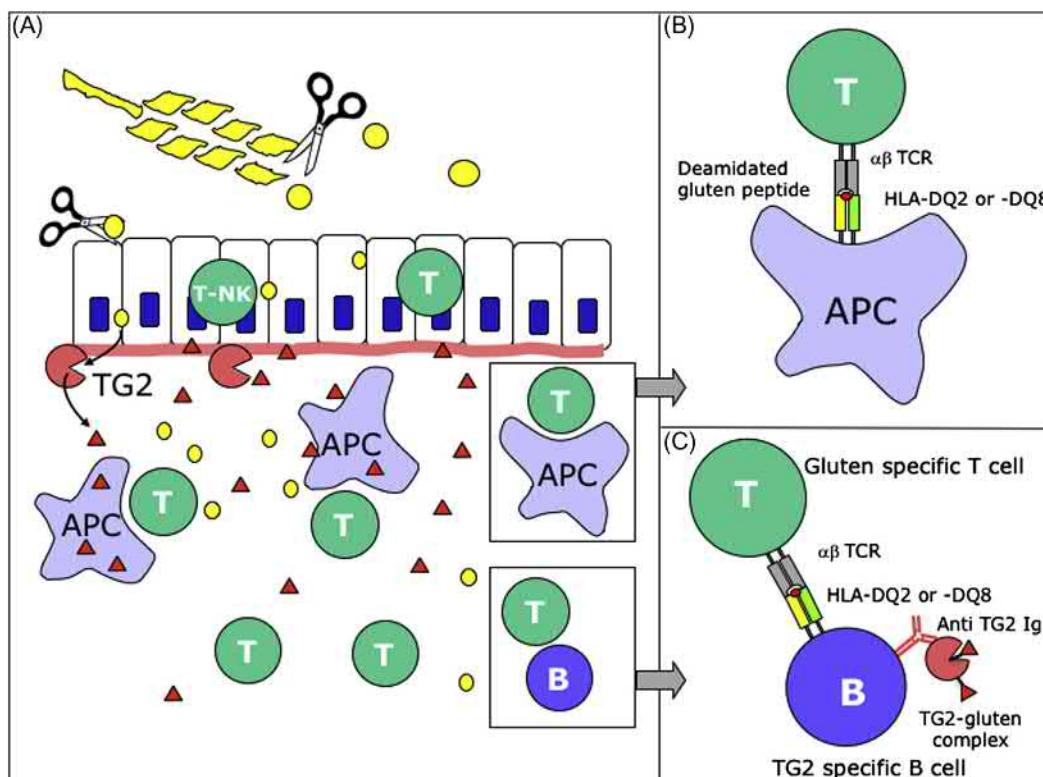

### Autoantibodies

Untreated celiac disease patients (on a regular diet) usually have increased levels of antibodies against gluten, other food antigens, and autoantigens. Initially, autoantibodies in celiac disease were detected as antireticulin antibodies by staining of various rat tissues (Alp and Wright, 1971; Seah et al., 1971). Later IgA antiendomysium antibodies (EMA), either as detected by staining of monkey esophagus (Chorzelski et al., 1984) or human umbilical cord (Ladinser et al., 1994), were described. The enzyme TG2 was identified as the target antigen of

both antireticulin antibodies and EMA (Dieterich et al., 1997), although antibodies to calreticulin and actin are also found in the serum of some patients (Clemente et al., 2000; Sanchez et al., 2000). The antibodies to TG2 are both of the IgA and IgG isotypes but the IgA antibodies are most closely linked with celiac disease and are the best predictor of disease (Rostom et al., 2005).

Anti-TG2 antibodies only occur in individuals who are HLA-DQ2 or HLA-DQ8 (Bjorck et al., 2010). Moreover, the production of the IgA anti-TG2 antibodies is dependent on dietary gluten exposure (Dieterich et al., 1998; Sulkkanen et al., 1998). These two observations indicate that gluten-specific T cells are implicated in the generation of the antibodies. A model where gluten-specific T cells may provide help to TG2-specific B cells by means of haptene-carrier-like gluten-TG2 complexes can explain the gluten and HLA dependence of the anti-TG2 antibody production (Solidi et al., 1997) (Fig. 45.3C). The same T cells should also be able to provide T-cell help to the B cells specific for the deamidated gluten peptides.

The production of anti-TG2 antibodies is vigorous in the active celiac lesion. On an average, 10% of the plasma cells in the lesion produce anti-TG2 antibodies and the IgA isotype dominates the response (Di Niro et al., 2012). The TG2-specific plasma cells have a responsive population dynamics and a wide seeding in the duodenal lamina propria (Di Niro et al., 2016). On commencement of a gluten-free diet, the frequency of the cells in the lesion drops dramatically within 6 months, yet some cells remain. The anti-TG2 antibodies have a unique repertoire with a biased usage of certain heavy chain genes, such as *IGHV5-51* and *IGHV3-48*.

**FIGURE 45.3** The celiac small intestinal lesion. (A) Depiction of the intestinal mucosa with emphasis on the factors taking part in the development and control of celiac disease. The parts of the gluten proteins that are resistant to processing by the luminal and brush border enzymes will survive digestion and can be transported across the epithelial barrier as polypeptides. Gluten peptides are deamidated by TG2, which, in the intestinal mucosa, is mainly located extracellularly in the subepithelial region but is also found in the brush border. TG2 may also be expressed by APC like macrophages and dendritic cells. CD4+ T cells in the lamina propria recognize predominantly deamidated gluten peptides, presented by HLA-DQ2 or HLA-DQ8 molecules on the cell surface of the APC. (B) DQ2 and DQ8 molecules have preference for binding peptides with negatively charged amino acids and thereby bind gluten peptides deamidated by TG2 with increased affinities. (C) Model of how gluten-specific T cells control the formation of anti-TG2 antibodies. Covalent complexes of gluten peptides and TG2 (involving glutamine residues of peptide either by isopeptide bond linkage to TG2's cell surface lysine residues or by thiolester linkage to TG2's active site cysteine) can be taken up by TG2-specific B cells via cell surface immunoglobulin. In endosomes, deamidated gluten peptides can be loaded onto DQ2 or DQ8 molecules. After transport to the cell surface of the HLA molecules with bound peptides, gluten-specific T cells can recognize the deamidated gluten peptides and thereby provide T-cell help to the TG2-specific B cells. *T*, T cell; *T-NK*, T cell with natural killer cell receptors; *B*, B cell; *APC*, antigen presenting cell; *TG2*, transglutaminase 2.

(Di Niro et al., 2012; Marzari et al., 2001) and light chain genes, such as *IGKV1-39p* and *IGKV5-1* (Roy et al., 2017). Further, the antibodies have few mutations despite being part of a chronic inflammatory response (Di Niro et al., 2012; Roy et al., 2017). Albeit few, displacement mutations dominate over silent mutations, thus speaking of the involvement of T cells in the antibody response (Di Niro et al., 2012; Marzari et al., 2001). Further, there is a reduction in the binding affinity of the antibodies by reversion to presumed germline sequence indicating that affinity maturation takes place in the generation of the antibodies (Di Niro et al., 2012). The plasma cells specific for the deamidated gluten peptides are less frequent in the celiac lesion than the TG2-specific plasma cells, but these cells, as the anti-TG2 plasma cells, have restricted the VH/VL usage and limited degree of mutations (Steinsbo et al., 2014). Interesting information on the generation of the celiac disease-relevant antibodies was obtained by the comparative analysis of the immunoglobulin protein sequences of serum and biopsy explants with the gene sequences of the gut plasma cells (Iversen et al., 2017). Serum IgA specific for either TG2 or a deamidated gluten peptide has the V-gene usage that match with those of the gut plasma cells. Further, the CDR-H3 sequences of the gut plasma cells are abundant in serum IgA and also detectable in serum IgG. As the serum IgA antibodies were found to be mostly monomeric and the gut IgA antibodies mostly dimeric, the observations indicate that the same B cell clones give rise to gut plasma cells and contribute to the serum antibody pool, but that there are distinct plasma cell origins of the immunoglobulins.

The high disease sensitivity and specificity of the antibodies to TG2 and the deamidated gluten peptides suggest that the antibodies somehow are involved in the pathogenesis of celiac disease. This could be at the level of the soluble antibodies, but not mutually exclusive, it could also be at the level of the antigen receptor of the B cells (i.e., cell surface immunoglobulin). The B cell receptor mediated capture of either TG2 decorated with deamidated gluten peptides and capture of the deamidated gluten peptides would both lead to the increased presentation of the gluten antigen to T cells, and as such, an amplification of the anti-gluten T cell response. Notably, a higher prevalence of celiac disease among patients with IgA deficiency (Wang et al., 2011) argues against the involvement of the IgA antibodies per se in the pathogenesis.

The autoantibodies may well be implicated in the extraintestinal manifestations of celiac disease. In dermatitis herpetiformis, which could be considered as celiac disease with additional skin lesions, the IgA autoantibodies are prime suspects. These patients, in addition to the anti-TG2 antibodies, have the antibodies that target the transglutaminase 3 (TG3) and these IgA anti-TG3 antibodies are more closely associated with the disease than the IgA anti-TG2 antibodies (Sardy et al., 2002). TG3, being closely related to TG2, can also use the gluten peptides as the substrates (Stamnaes et al., 2010). It is expressed in the epidermis but not in the dermal papillae, where the granular IgA deposits in dermatitis herpetiformis are located.

## Autoreactive Intraepithelial Lymphocytes

Untreated celiac disease is characterized by an increased density of proliferating  $\text{TCR}\alpha\beta + \text{CD8} + \text{CD4} -$  and  $\text{TCR}\gamma\delta + \text{CD8} + \text{CD4} -$  cells within the epithelium (Fig. 45.3A). In contrast to the  $\text{TCR}\alpha\beta + \text{CD8} +$  IELs that return to normal when gluten is removed from the diet, the  $\text{TCR}\gamma\delta +$  IELs remain at an elevated level (Kutlu et al., 1993). This may suggest that these two types of T cells play different roles in the pathogenesis. Many of the IELs co-express the innate (NK cell) receptors recognizing the nonclassical HLA molecules, such as MIC molecules and HLA-E. In celiac disease, there is a decrease in IELs expressing the inhibitory receptor CD94-NKG2A (Meresse et al., 2006) and an increase of the cells expressing the activating receptors NKG2D (Hüe et al., 2004; Meresse et al., 2004) and CD94/NKG2C (Meresse et al., 2006) (Fig. 45.3A). The activated IELs can kill the enterocytes by use of the NK cell receptors without any involvement of the T-cell receptor (Hüe et al., 2004; Meresse et al., 2004).

## GENETICS

A high prevalence (10%) among the first-degree relatives of celiac disease patients indicates that the susceptibility to develop celiac disease is strongly influenced by the inherited factors (Ellis, 1981). The familial clustering is stronger in celiac disease than in most other chronic inflammatory diseases with multifactorial etiology (Risch, 1987). The strong genetic influence in celiac disease is further supported by a high concordance

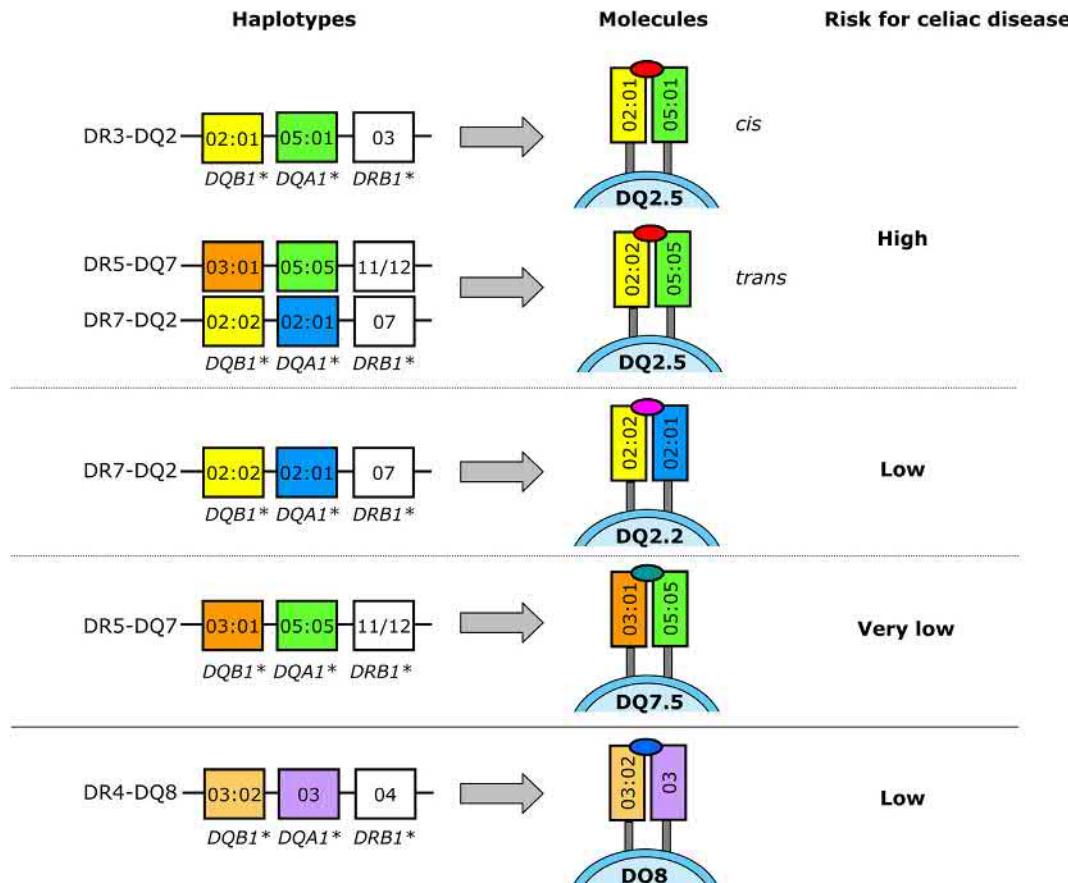

rate (approximately 75%) in monozygotic twins (Nistico et al., 2006). Both HLA and non-HLA genes contribute to the genetic predisposition.

## HLA Genes

The strongest HLA association in celiac disease is with a variant of DQ2 that is often termed DQ2.5 (Fig. 45.4). This HLA molecule is usually carried by 90% or more of celiac disease patients. The DQ2.5 molecule is in individuals who carry the DR3-DQ2 haplotype encoded by *DQA1* and *DQB1* alleles (*DQA1*\*05:01 and *DQB1*\*02:01), which are located on the same chromosome (*cis* position). Alternatively, it can be expressed by the individuals who are DR5DQ7/DR7DQ2 heterozygous and then the alleles (*DQA1*\*05:05 and *DQB1*\*02:02) are located on the opposite chromosomes (*trans* position) (Sollid et al., 1989). About half of the remaining celiac patients carry HLA-DQ8 encoded by the *DQA1*\*03 and *DQB1*\*03:02 alleles. The rest of the patients are either DQ2.2 or DQ7.5 (Karell et al., 2003); thus they carry either the genes for the  $\alpha$ -chain or the  $\beta$ -chain of the DQ2.5 molecule. Only a small fraction of the individuals with celiac disease associated DQ allotypes develop celiac disease. HLA can thus be considered a necessary, but not sufficient, genetic factor for disease development.

## Non-HLA Genes

The genome wide association studies (GWAS) have advanced the knowledge of the non-HLA genes in celiac disease. So far, 42 loci outside of HLA have been identified to harbor one or more genes predisposing to or protecting against celiac disease (Trynka et al., 2011; Withoff et al., 2016). Each of these non-HLA genes

**FIGURE 45.4** HLA association in celiac disease. The majority of celiac disease patients carry the DQ2.5 molecule, which can be encoded in *cis* or in *trans* positions. Most of the remaining patients express DQ8 whereas the rest of celiac disease patients express DQ2.2 or DQ7.5. The polypeptides encoded by *DQA1*\*05:01 and *DQA1*\*05:05 differ by one residue in the leader peptide whereas those encoded by *DQB1*\*02:01 and *DQB1*\*02:02 differ by one residue in the membrane proximal domain. It is unlikely that these substitutions have functional consequences.

contributes little to the genetic risk. It has been estimated that the 42 non-HLA loci account for 15% of the genetic variance whereas HLA in comparison accounts for about 25%–40% (Withoff et al., 2016). Evidence suggests the existence of many additional non-HLA genes with even smaller effect sizes than those identified to date.

Most of the 42 non-HLA loci contain genes of immunological function. Many of these genes are related to the function of the T cells. Thus the pathogenesis model established by the studies of immune cells of celiac disease patients is confirmed by the findings of the GWAS. Most celiac disease associated risk variants in the 42 non-HLA loci are not located in protein coding regions but rather in the regions implicated in gene regulation (Withoff et al., 2016). This suggests that the differences in gene expression play an important role in the pathogenesis of celiac disease. Finally, celiac disease and other immune mediated diseases, in particular type 1 diabetes (Smyth et al., 2008), share the risk gene variants that speak of the sharing of the critical pathways in the development of the various diseases. New therapeutics for the treatment of the autoimmune diseases, including the biologicals, may thus find a rational basis for the testing in celiac disease as well.

## ENVIRONMENTAL FACTORS

### Gluten Proteins

Gluten is the cohesive mass that remains when the dough is washed to remove the starch. Gluten was originally used to denote the wheat proteins only but it is now increasingly used as a term for the proline- and glutamine-rich proteins of wheat, barley, and rye (and oat, see later). In wheat, gluten consists of the gliadin and glutenin subcomponents. The gliadin proteins can be subdivided into the  $\alpha$ -,  $\gamma$ -, and  $\omega$ -gliadins while the glutenin proteins can be subdivided into high molecular weight and low molecular weight subunits (Shewry et al., 2003). The number of unique gluten proteins in common bread wheat is enormous due to a hexaploid genome, multiple encoding loci, and allelic variation. Thus, in a single wheat variety, there are several hundred different gluten proteins, many of which only differ by a few amino acids. The high content of proline residues makes the gluten proteins particularly resistant to gastrointestinal digestion (Shan et al., 2002). This has important implications for their immunogenicity for the T cells.

The gluten proteins of barley are termed hordeins, those of rye secalins and those of oat avenins. The gluten proteins of barley and rye are also harmful to celiac disease patients (Anand et al., 1978) and the T-cell epitopes of barley and rye have been defined (see below). In general, the feeding studies have indicated that oat is safe for celiac disease patients (Hoffenberg et al., 2000; Janatuinen et al., 2002). Occasional oat-intolerant celiac patients exist (Arentz-Hansen et al., 2004; Lundin et al., 2003). The lesions of these rare patients harbor the T cells specific for the oat avenin peptides that closely resemble the gliadin T-cell epitopes, but which are present in low amounts (Arentz-Hansen et al., 2004).

### Other Environmental Factors

Infections may play a role in the development of celiac disease. Perhaps the best epidemiological evidence comes from the studies of Sweden. In the children below the age of 2 years, a positive correlation was found between celiac disease risk and being born during the summer (Ivarsson et al., 2003a). The children born in the summer are first exposed to the dietary gluten during the winter when these infections are more prevalent. Moreover, the same population case control studies indicated that the celiac subjects had experienced three or more infection episodes more frequently than the referents. The evidence for the involvement of rotavirus in the pathogenesis was provided by a prospective multinational study (the TEDDY study), which showed that the rotavirus vaccination reduced the risk of celiac disease in the children vaccinated against rotavirus and introduced to gluten before the age of 6 months (Kempainen et al., 2017). Further, reovirus was proposed as the candidate agent as a certain strain of reovirus in mice was able to trigger an inflammatory response in the gut to the orally administered antigens (Bouziat et al., 2017). It was demonstrated that the virus, via action on the dendritic cells, suppressed peripheral regulatory T cell conversion and promoted the immunity to the dietary antigen dominated by the interferon- $\gamma$  production. The same study found some serological evidence that reovirus is involved in the human celiac disease but failed to find any similar evidence for rotavirus. Clearly, more studies are required to understand which environmental factors can trigger celiac disease.

---

## IN VIVO AND IN VITRO DISEASE MODELS

---

### Animal Models

The attempts to establish good animal models for celiac disease have been troublesome. The gluten-sensitive conditions in macaques (Bethune et al., 2008) and horses (van der Kolk et al., 2012) have been described, but whether these faithfully represent celiac disease is unclear. Until recently, all attempts to establish a mouse model have been unsuccessful. The gluten-sensitive enteropathy could not be induced in mice made transgenic for HLA-DQ2.5 (Chen et al., 2003; Chen et al., 2002) or HLA-DQ8 (Black et al., 2002). Not even HLA-DQ2.5 transgenic mice made transgenic for T-cell receptors specific for the celiac disease-relevant gluten epitopes developed enteropathy (de Kauwe et al., 2009; du Pré et al., 2011). Dermatitis herpetiformis, such as skin lesions occurred in a fraction of the HLA-DQ8 transgenic mice on a NOD background after systemic immunization with gluten but the mice did not have enteropathy (Marietta et al., 2004). A model with overexpression of IL-15 is more promising (Abadie et al., 2017). Mice made triply transgenic, expressing HLA-DQ8 and IL-15 both in the lamina propria and epithelium, have a gluten-dependent phenotype with the gut villous atrophy, intraepithelial lymphocytosis, and antibodies to the deamidated gluten peptides. Importantly, the disease phenotype is dependent on the involvement of the CD4+ T cells.

### Organ Culture Assays

The culturing of the small intestinal biopsies ex vivo has frequently been used to dissect the pathogenic events in celiac disease. This assay for instance has been used to examine the innate effects of gluten (Maiuri et al., 2000) and to show that the gluten challenge induces a stress response with the upregulation of the IL-15, MICA, and heat shock proteins (Hüe et al., 2004). Although the ex vivo culture system has been very important in clarifying the pathogenic mechanisms of celiac disease (Lindfors et al., 2012), this result should be carefully interpreted. One of the problems with the ex vivo organ culture system may relate to the uneven distribution of the inflammatory cells in the mucosa (our unpublished results).

---

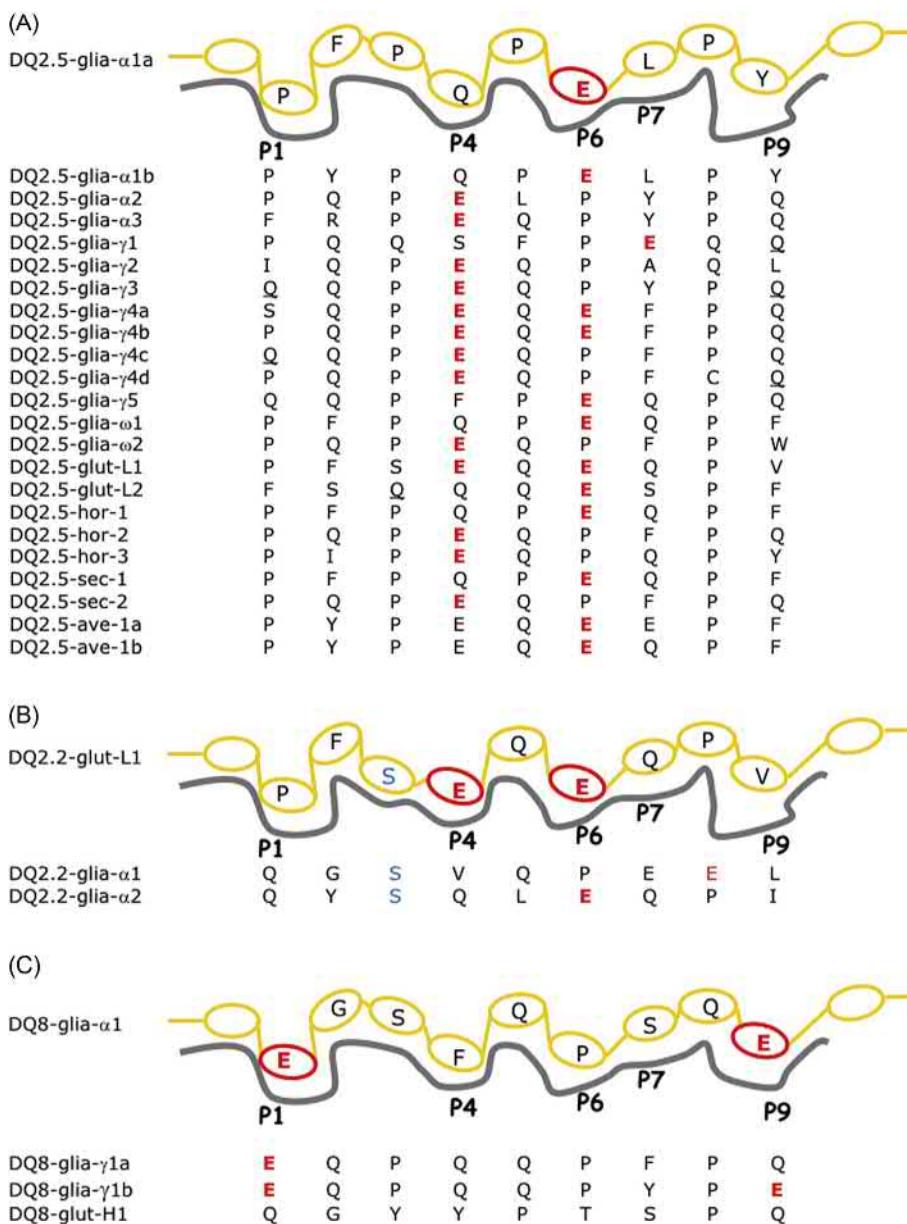

## PATHOGENIC MECHANISMS

---

The strong HLA association in celiac disease and overrepresentation of non-HLA susceptibility genes related to the T-cell function implicate the T cells in the pathogenesis of celiac disease.

### Gluten-Specific CD4+ T Cells

CD4+ T cells specific for the gluten proteins can be isolated from the small intestinal biopsies of the majority of celiac disease patients (Lundin et al., 1993; van de Wal et al., 1998b) but not from the biopsies obtained of disease controls (Molberg et al., 1997). By contrast, both the patients and many control subjects have gluten-specific T cells in their peripheral blood. These T cells use many different HLA molecules for peptide presentation (DR, DQ, and DP) (Gjertsen et al., 1994) and their reactivity is not enhanced by the deamidation of the gluten antigen (Molberg et al., 1998). This implies that the subjects can be immunologically sensitized to gluten without developing any small intestinal pathology. The gluten-specific T cells derived from the intestinal celiac lesions display a remarkable feature in that these invariably recognize the epitopes restricted by the disease associated HLA-DQ molecules, DQ2.5, DQ8, and DQ2.2 (Bodd et al., 2012; Lundin et al., 1994; Lundin et al., 1993) (Fig. 45.3B). Many distinct gluten T-cell epitopes that are derived from a variety of different classes of the gluten proteins exist (Solid et al., 2012). In general, there are unique sets of epitopes presented by the DQ2.5, DQ2.2, and DQ8 molecules reflecting distinct peptide binding motifs of the different HLA molecules (see later) (Fig. 45.5). For each HLA:peptide complex, the patients use a variety of receptors for T-cell recognition. Notwithstanding, there is a selection of the preferred T-cell receptors and this biased usage is observed across the patients, thereby representing the public type of responses. Such public responses are more pronounced for the recognition of certain HLA:peptide complexes. For instance, the pair TRAV26-1/TRBV7-2 is preferred by the T cells recognizing the HLA-DQ2.5:DQ2.5-glia- $\alpha$ 2 complex (Qiao et al., 2014; Qiao et al., 2011). These T cells also use a certain CRD3 $\beta$  motif with a nongermline encoded arginine residue (Qiao et al., 2014) that serves as the lynchpin in the interaction with the HLA:peptide complex (Petersen et al., 2014).

**FIGURE 45.5** The T-cell epitopes of gluten presented by HLA-DQ molecules and recognized by CD4+ T cells of celiac disease patients. Epitopes presented by DQ2.5 are shown in (A), epitopes presented by DQ2.2 are shown in (B), and epitopes presented by DQ8 are shown in (C). The 9-mer core regions of the epitopes are given with one letter amino acid codes in the register with which they bind to the HLA molecules. The T-cell receptors recognizing the epitopes are often sensitive to the residues outside the 9-mer core region. Glutamate residues (E, in red) formed by TG2-mediated deamidation, which are important for recognition by the T cells, are shown. Additional glutamine residues (Q, also targeted by TG2, are underlined. Epitopes presented by DQ2.2 have commonly serine (S, in blue) at position P3 hence complying with the binding motif of this HLA molecule. Of note is the abundance of proline (P) residues within the epitopes. Further information about epitopes and epitope nomenclature can be found elsewhere (Sollid et al., 2012).

The gluten-specific T cells can be detected with the HLA-DQ:gluten tetramers (Quarsten et al., 2001). In these reagents, the biotinylated HLA:DQ molecules are tethered with the gluten epitopes and multimerized onto a fluorescently labeled streptavidin thereby obtaining sufficient avidity of the reagent to stain the antigen-specific T cells. Although around 1% of the CD4+ T cells in the intestinal lamina propria of the untreated patients bind the HLA-DQ:gluten tetramers (Bodd et al., 2013), such cells are rare in blood, ranging 1–100 cells per million CD4+ T cells of the untreated patients and even 5-fold less in the treated patients (Christophersen et al., 2014). Of note, maybe only half of all the celiac disease-relevant and gluten-specific T cells will be captured by the HLA-DQ:gluten tetramers used in these studies. The majority of the HLA-DQ:gluten tetramer staining cells in the celiac patients are the effector memory T cells (Christophersen et al., 2014). Such cells are almost completely absent in the nonceliac DQ2.5 controls and thus HLA-DQ:gluten tetramer staining has a potential as a diagnostic marker. The gluten-specific T cells increase substantially in frequency in blood on day six after the short-term oral gluten challenge either as detected by ELISPOT (Anderson et al., 2000) or by HLA tetramer staining (Brottveit et al., 2011; Ráki et al., 2007). Along with the surge of the gluten-specific CD4+ T cells in blood on day six after the gluten challenge, there is also a surge of the activated CD8+ T cells and  $\gamma\delta$  T cells (Han et al., 2013). The specificities of these cells are unknown.

## Transglutaminase 2

The enzyme TG2 is not only the target of the autoantibodies in celiac disease because it is also involved in the creation of the T-cell epitopes for being recognized by the HLA-DQ restricted CD4+ T cells (Molberg et al., 1998; van de Wal et al., 1998a). This dual role of TG2 is hardly coincidental. TG2 catalyzes a posttranslational transamidation or deamidation of specific glutamine residues within substrate proteins (Folk, 1983; Lorand and Graham, 2003). In the transamidation reaction, the glutamine becomes cross-linked to a protein-bound lysine or polyamine whereas the deamidation reaction results in the conversion of glutamine to the glutamic acid. The enzyme displays regional selectivity for the glutamine residues in the gliadin peptides, and QXP is a particularly good target sequence (Fleckenstein et al., 2002; Piper et al., 2002; Vader et al., 2002). It is the deamidation reaction that is critical for the creation of the T-cell epitopes and there is mounting evidence that the enzyme is centrally involved in the selection of the HLA-DQ restricted T-cell epitopes in celiac disease (see later). Exactly where in the body TG2 is creating the T-cell epitopes is not known, but there is the indication of increased activity in the celiac lesion; assessing enzymatic activity in the lysates of gut biopsies revealed higher activity in the untreated celiac disease patients compared to controls (Bruce et al., 1985).

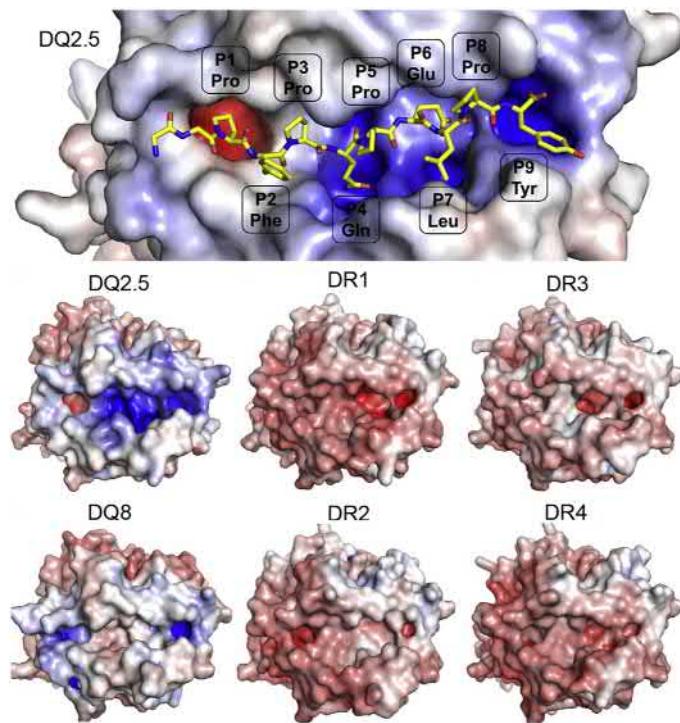

## Gluten Antigen Presentation by Disease Associated HLA-DQ Molecules

The MHC class II molecules bind the antigenic peptides in a groove in their membrane distal part. In this groove, there are pockets that accommodate the side chains of amino acids of the peptide, the so-called anchor residues. In the MHC class II peptides, the anchor residues are usually found at the positions P1, P4, P6, P7, and P9. All DQ2.5, DQ2.2, and DQ8, which are associated with celiac disease, have a fairly unique preference for binding peptides with multiple negatively charged residues. Both DQ2.5 and DQ2.2 have preference for the negatively charged anchor residues at the positions P4, P6, and P7 (Kim et al., 2004; Tollefse et al., 2006) whereas DQ8 has preference for the negatively charged anchor residues at the positions P1 and P9 (Henderson et al., 2007; Tollefse et al., 2006) (Fig. 45.6). The binding motif of DQ2.2 is similar to that of DQ2.5 but in addition, the DQ2.2 molecule has a preference for binding the serine or threonine residues at the P3 position (Bergseng et al., 2015; van de Wal et al., 1997). Overall, the HLA association in celiac disease can be explained by a superior ability of the disease associated HLA-DQ molecules to bind the biased repertoire of the proline-rich gluten peptides that have survived the gastrointestinal digestion and which have been deamidated by TG2.

There is a hierarchy among the gluten T-cell epitopes both in terms of how many T cells of a single patient respond to each, and in terms of the responder frequency among different patients (Marti et al., 2005; Tye-Din et al., 2010). The same epitopes dominate in each of these settings, likely reflecting variation in immunogenicity between the epitopes. In  $\alpha$ -gliadin of wheat, there are two immunodominant epitopes (i.e., DQ2.5-glia- $\alpha$ 1a/b and DQ2.5-glia- $\alpha$ 2) (Arentz-Hansen et al., 2000). In some  $\alpha$ -gliadin proteins, these epitopes are expressed in altogether 6 copies within a 33-mer fragment. This potent antigen is resistant to degradation by the gastric, pancreatic, and intestinal brush border membrane proteases (Shan et al., 2002). Other immunodominant epitopes are the DQ2.5-glia- $\omega$ 2 epitope that derives from  $\omega$ -gliadin of wheat and a shared 9 amino acid sequence-stretch found in the proteins of wheat, rye, and barley (termed DQ2.5-glia- $\omega$ 1, DQ2.5-hor-1, and DQ2-sec-1) (Tye-Din et al., 2010). A similar hierarchy probably exists for the HLA-DQ8 restricted epitopes. Celiac disease patients who express DQ2.2 but not DQ2.5 or DQ8 have T cells that do respond to the common DQ2.5 restricted epitopes but often respond to the immunodominant DQ2.2 restricted epitope (DQ2.2-glut-L1) that has a serine residue at the P3 position (Bodd et al., 2012). The common DQ2.5 restricted epitopes bind stably to DQ2.5 but unstably to DQ2.2 (Fallang et al., 2009) while the immunodominant DQ2.2 epitope binds stably to DQ2.2 but not to DQ2.5 (Bodd et al., 2012).

The stable binding of a gluten peptide to the MHC molecule appears to be important for a successful T-cell priming (Fallang et al., 2009). Notably, deamidation of the gluten peptides decreases the off-rate for binding to DQ2.5 (Xia et al., 2005) and hence, one effect of deamidation can be that more gluten-DQ complexes are generated resulting in better T-cell priming.

Only a few sequences in the huge gluten proteome are recognized by the CD4+ T cells of celiac disease patients. This suggests that there are strong guidance factors in the selection of the T-cell epitopes. Three factors have been identified as being particularly important—protease resistance, MHC binding, and TG2 efficiency. The clustering of epitopes to regions of gluten proteins that have high contents of proline residues and that are proteolytically stable suggests that proteolytic stability is critical (Arentz-Hansen et al., 2002; Shan et al., 2002). Antigen concentration is important for T-cell stimulation and fragments that are resistant to breakdown will survive at higher concentrations. The selection by MHC would relate to the selection of peptides with the correct binding

**FIGURE 45.6** Three-dimensional structures of the binding sites of HLA class II molecules. (A) HLA-DQ2.5 complexed with the deamidated gluten epitope DQ2.5-glia- $\alpha$ 1 (PDB 1S9V). The peptide is shown with a stick representation (carbon = yellow, nitrogen = blue, oxygen = red; amino acid residues in the positions P1–P9 are labeled). (B) The electrostatic potential surface of the HLA molecules at pH7.0 (red, negative; blue, positive). HLA-DQ2.5 (PDB 5KSU), HLA-DR1 (3PDO), HLA-DR3 (PDB 1A6A), HLA-DQ8 (PDB 2NNA), HLA-DR2 (PDB 1H15), and HLA-DR4 (PDB 2SEB) are depicted. Note the unique distribution of positively charged binding pockets in the peptide binding groove of DQ2.5 (P4, P6, P7) and DQ8 (P1, P9). Source: Figure in panel (A) has been prepared with help from Chu-Young Kim and figure in panel (B) is adapted from reference (Nguyen, T.B., Jayaraman, P., Bergseng, E., Madhusudhan, M.S., Kim, C.Y., Sollid, L.M. 2017. Unraveling the structural basis for the unusually rich association of human leukocyte antigen DQ2.5 with class-II-associated invariant chain peptides. *J. Biol. Chem.* 292, 9218–9228; Nguyen et al., 2017).

motif as well as the selection of peptides that form stable MHC complexes. The observation that the DQ2.5 and DQ8 molecules in general select discrete epitopes of the gluten proteome underscores the importance of HLA allotype selection (Tollefson et al., 2006). Finally, TG2 specificity appears to be vital. There is a correlation between how frequently the T-cell epitopes are recognized by celiac disease patients and their propensity to be targeted as substrates for TG2 (Dørum et al., 2009). Moreover, using TG2 to select its best substrates from a proteolytic digest of gluten consisting of several thousand different peptides, the majority of about 30 peptides selected contained celiac disease related T-cell epitopes (Dørum et al., 2010). This suggests that TG2 specificity is a major force in the T-cell epitope selection process.

## Macrophages and Dendritic Cells

Several types of HLA-DQ positive cells can serve as antigen presenting cells (APC) in the small intestinal mucosa (Beitnes et al., 2012; Ráki et al., 2006). There are CD163 + CD11c – macrophages and CD11c + dendritic cells which express either CD163 or CD103 and CD1c. The CD163 + CD11c + dendritic cells likely derive from circulating monocytes as these co-express CD14 and CCR2. The CD11c + dendritic cells expressing CD103 + or CD1c + do not express CD163 or CD14, suggesting the existence of separate functional lineages. In the active celiac disease lesion, there is an increase of CD163 + CD11c + dendritic cells whereas the CD163 + CD11c – macrophages and CD103 + and CD1c + dendritic cells are all decreased (Beitnes et al., 2011). Based on the studies in mice (Schulz et al., 2009), it is tempting to speculate that the CD11c + CD103 + dendritic cells function to transport antigen to the mesenteric lymph nodes for presentation to the naïve or central memory T cells, whereas the CD163 + CD11c – macrophages and CD163 + CD11c + dendritic cells serve to present antigen locally to the effector T cells.

## Plasma Cells

The density of IgA and IgM plasma cells in the lesion of active celiac disease patient increase 2.4 and 4.6 fold, respectively (Baklien et al., 1977). Strikingly, these plasma cells express surface immunoglobulin as a functional B-cell receptor (Di Niro et al., 2010; Pinto et al., 2013) raising the question whether they might sense antigen. The sensing could either only involve the B-cell receptor but conceivably if the cells have sufficient MHC class II molecules, they could also serve as the antigen-presenting cells for T cells. If so, this could have consequences for the function of the plasma cells themselves but also for the T cells in the lamina propria.

## Effector Mechanisms Leading to Mucosal Alterations

Despite the lack of detailed knowledge of effector mechanisms involved in the creation of the celiac lesion, evidence suggests that inflammatory cytokines, particularly interferon- $\gamma$  and IL-15, are involved. The messenger RNA for interferon- $\gamma$  is abundant in the biopsies taken from untreated patients and is rapidly induced when biopsies from the treated patients are challenged ex vivo with gluten (Nilsen et al., 1998). Interferon- $\gamma$  is also produced by the intestinal, gluten-specific CD4+ T cells (Nilsen et al., 1995) and by IELs (Forsberg et al., 2002; Olaussen et al., 2002). The gluten-specific CD4+ T cells also produce IL-21 (Bodd et al., 2010). Importantly, IL-21, together with IL-2 and tumor necrosis factor, induce proliferation and expansion of IELs (Kooy-Winkelaar et al., 2017). The same effect on IELs is mediated by the enterocyte bound IL-15 (Mention et al., 2003). In active celiac disease, there is increased expression of IL-15, both in the lamina propria (Maiuri et al., 2000) and in the epithelium (Mention et al., 2003). The expression of IL-15 increases following in vitro gluten challenge of the celiac biopsies and certain gluten peptides appear to cause innate immune activation and IL-15 production (Maiuri et al., 2003). IL-15 is a key factor for reprogramming IELs in celiac disease, where the cells downregulate inhibitory and upregulate activating NK cell receptors (Meresse et al., 2006) (Fig. 45.3A). The activated IELs kill the stressed enterocytes and this appears to be an important component in creating the celiac lesion (Jabri and Sollid, 2009).

Taken together, currently available data places the activation of CD4+ T cells recognizing gluten peptides presented by DQ2 or DQ8 molecules as the central key gateway for the control of celiac disease development. The activation of naïve T cells probably takes place in the mesenteric lymph nodes and effector cells then seed to the lamina propria in the small intestine where these are reactivated upon challenge with gluten. This model would explain the dominant genetic role of HLA. The products of the other predisposing genes likely feed into the processes that lead to T-cell activation or tissue destruction but as each of the non-HLA susceptibility genes have small effects, this indicates a lack of critical checkpoints or redundancy in pathways.

While regulatory T cells are frequently described in the gut and breakage of oral tolerance to gluten conceivably could be the underlying cause of celiac disease, there is still meager evidence for the existence of such cells (Sollid, 2017). In addition, there is no evidence of a protective effect of HLA allotypes in celiac disease that one could expect if the regulatory T cells were using certain HLA allotypes for recognition of their antigenic peptides.

## AUTOANTIBODIES AS IMMUNOLOGIC MARKERS

In adults, the examination of gut biopsy is still considered mandatory in the diagnostic workup although serology has become an increasingly important diagnostic adjunct. To state definite diagnosis of CD, villous atrophy is required (Bai and Ciacci, 2017; Ludvigsson et al., 2014). In children, gut histology examination is no more deemed necessary in many cases. Updated European guidelines for the pediatric celiac disease recommend that the diagnosis can be made without the assessment of intestinal histology by using a combination of strongly positive serology ( $>10 \times$  upper limit of normal of IgA anti-TG2), positive IgA EMA in independent blood sample, HLA typing, and clinical criteria (Husby et al., 2012). Two large prospective multicenter studies assessing the diligence of the new diagnostic scheme concluded that children can be accurately diagnosed with celiac disease without biopsy analysis resulting in more than half the children with celiac disease avoiding the risks and costs of endoscopy (Werkstetter et al., 2017; Wolf et al., 2017). Detection of autoantibodies is the single most important diagnostic factor of the new scheme. It is striking that celiac disease that previously was diagnosed as a food intolerance based on elimination and provocation diets, is now essentially diagnosed as an autoimmune disease by detection of autoantibodies.

## Serology

More than 95% of the untreated celiac disease patients (at least in selected patient cohorts) have high titers of serum IgA antibodies reactive with TG2 (Dieterich et al., 1998; Sulkkanen et al., 1998). Most tests are ELISA based with human recombinant TG2 as the antigen. In the recent European guidelines for pediatric celiac disease (Husby et al., 2012), the EMA test is included in the diagnostic algorithm because this test was judged to outperform the anti-TG2 ELISA for prediction of celiac disease (Giersiepen et al., 2012). This may relate to the fact that the celiac anti-TG2 antibodies are reactive with conformational epitopes and that the TG2 antigen in some commercial kits is suboptimally refolded. IgG anti-TG2 antibodies can be useful to evaluate in the patients with selective IgA deficiency but should otherwise not be tested for (Murray, 1999).

The patients with untreated celiac disease also have increased levels of IgA and IgG anti-gluten antibodies. Monitoring of such antibodies, in particular anti-gliadin antibodies, was used for many years in the clinical workup of celiac disease. However, the IgA EMA and anti-TG2 tests gradually took over in clinical practice due to better performance. A fraction of the anti-gluten antibodies are directed against deamidated epitopes (Osman et al., 2000) and tests based on reactivity to deamidated gliadin peptides are performed at the level of anti-TG2 tests (Lewis and Scott, 2010).

Some celiac disease patients present with negative serology (Dahele et al., 2001; Kaukinen et al., 2002) and an intestinal biopsy should therefore be examined irrespective of serology when there is high clinical suspicion of celiac disease (Ludvigsson et al., 2014). Notably, false positive anti-TG2 tests do also occur, particularly in patients with inflammatory bowel disease (Carroccio et al., 2002; Dahele et al., 2001).

## Staining of Immune Complexes

In patients with active celiac disease, there are deposits of IgA in the small intestine corresponding to the distribution of fibronectin bound extracellular TG2, typically as a band beneath the epithelium (Korponay-Szabo et al., 2004). Such deposits of specific IgA complexed with TG2 can be found in the intestinal mucosa even in those patients where serum autoantibodies are undetectable (Salmi et al., 2006b). In IgA deficient patients, these deposits are made up of IgM (Borrelli et al., 2010). Case reports have described autoantibody deposits years before any intestinal damage was observed and the production of TG2-specific autoantibodies is therefore considered an early marker for developing celiac disease (Salmi et al., 2006a). Because detection of IgA deposits can only be done with frozen tissue sections, this method has not reached widespread usage.

## TREATMENT AND OUTCOME

### Current Treatment

The current treatment of celiac disease is a lifelong gluten exclusion diet. This disease is largely a benign disorder and particularly so in patients detected by screening (West et al., 2003). Although celiac patients overall have an increased relative risk for nonHodgkin's lymphoma of the gastrointestinal tract, the absolute risk is low and lower than previously anticipated (Askling et al., 2002; Catassi et al., 2002). In an Italian study, it was found that the overall mortality rate in celiac disease was two times greater than in the controls (Corrao et al., 2001). This increased mortality was accounted for by the increased death rates in the first 3 years after diagnosis. The gluten-free diet has been considered to be protective against the development of malignancy but this notion was not supported by a study from the United States (Green et al., 2003). Persistent mucosal inflammation (compatible with either lack of compliance or other autoimmune phenomena) is of particular concern (Ludvigsson et al., 2009).

The most frequent reason for absent or incomplete clinical improvement is poor diet compliance (Ciacci et al., 2002), but it is clear that some patients have refractory disease that do not respond to an adequate diet. Refractory celiac disease is classified into type 1 and type 2 (Rishi et al., 2016). Type 2 patients, in contrast to type 1 patients, have monoclonal expansions of IELs that can progress to become overt enteropathy associated T-cell lymphoma (Cellier et al., 2000). While the clinical management of type 2 is more difficult than that of type 1, the treatment of enteropathy associated T-cell lymphoma is particularly difficult with poor outcome for the patients (Rishi et al., 2016). Recent insight into the mechanism of malignant transformation may give clues for better treatments (Ettersperger et al., 2016). The cells that undergo malignant transformation are IL-15 dependent T cell-like innate IELs and they do so by acquiring gain-of-function mutations in Janus kinase 1 (JAK1) or signal transducer and activator of transcription 3 (STAT3).

## Novel Treatments

Many patients cope with the gluten-free diet easily. Others find that the dietary restrictions are laborious and negatively impacting their quality of life. Suboptimal and even poor compliance is frequent. Better alternatives are thus called for. It is hence promising that the insight into the molecular mechanisms involved in the intestinal T-cell reactivity to gluten has uncovered novel targets for therapy. Several avenues are being pursued. One possibility, which is basically an extension of today's treatment with a gluten-free diet, is to produce cereals with bread-making properties that are devoid of the T-cell epitopes, either by breeding programs or transgenic technology including RNAi or CRISPR/Cas9 technologies (Gil-Humane et al., 2010; Sánchez-León et al., 2018). Another possibility is enzyme supplementation with the aim of either to destroy the T-cell epitopes directly or to facilitate their gastrointestinal proteolysis (Gass et al., 2007; Hausch et al., 2002; Mitea et al., 2008). Prolyl endopeptidases are particularly attractive enzymes as they will target the proline-rich regions of gluten that harbor the T-cell epitopes. In a recent phase 2 trial testing of patients with symptomatic celiac disease and with histologic evidence of duodenal mucosal injury, the protease drug did no better than placebo, which is likely due to a trial effect as the placebo group also showed improvement (Murray et al., 2017). TG2 appears as a target for intervention because of its critical role in generating the gluten T-cell epitopes. A series of TG2 inhibitors have been developed (Keillor and Apperley, 2016) that potentially may be useful in the therapy of celiac disease. A problem with this approach could be unacceptable side effects as TG2 is involved in many different physiological processes (Lorand and Graham, 2003). Another strategy would be to aim directly at the gluten-specific T cells. This can possibly be achieved by peptide vaccination (Goel et al., 2017) or by removal of the antigen-specific T cells by eradication of the activated T cells after the oral gluten challenge. Yet another possible target would be to block the presentation of gluten peptides by DQ2 and DQ8, and thereby the activation of gluten-specific T cells. The approach does not appear to be very efficient in preclinical testing. Whatever new therapeutic modality is introduced in uncomplicated celiac disease, it will have to prove to be as good as or even better than the current gluten-free diet regime with regard to its long-term safety and outcome. For complicated celiac disease, in particular refractory celiac disease type 2 and enteropathy associated T-cell lymphoma, better treatment alternatives are urgently needed. The next years will tell whether targeting of IL-15, JAK1, or STAT3 will be effective treatment modalities.

## PERSPECTIVES

It has become clear that gluten serves as the driver of autoimmune reactions in celiac disease (Sollid and Jabri, 2013). Considerable progress has been made in recent years on the understanding of the molecular basis for celiac disease, but several new questions have emerged. Many of these relate to the autoimmune aspects of the disease. What is the trigger event that transforms the mucosal immune system from gluten-tolerant to gluten-intolerant? To what extent are the autoimmune components of celiac disease involved in the disease development? How relevant are the findings of T-cell recognition of posttranslationally modified peptides and autoantibody formation driven by an exogenous food antigen for other autoimmune disorders? Can it be that the other autoimmune disorders are driven by immune responses to foreign, not yet identified, antigens? Celiac disease, this fascinating condition in the gray zone between food intolerance and autoimmunity, continues to give us food for thought.

## Acknowledgments

Studies in the authors' laboratory are supported by grants from Stiftelsen Kristian Gerhard Jebsen (project number SKGJ-MED-017), the Research Council of Norway through the Centre of Excellence funding scheme (project number 179573/V40), and the South-Eastern Norway Regional Health Authority. We thank Ann-Christin R. Beitnes, Jorunn Stamnaes, and Chu-Young Kim for help in preparation of figures.

## GENERAL INTRODUCTION

Inflammatory bowel disease (IBD) traditionally is divided into two related subgroups called Crohn's disease (CD) and ulcerative colitis (UC) that often differ in location of bowel involved, pathological features, and surgical outcomes. They were thought to be distinct entities. It now appears more likely that both CD and UC are various conditions with somewhat overlapping clinical and pathological features. They are the manifestations of intestinal mucosal immune dysregulation in which the host immunologically overresponds to substances in the natural intestinal stream. IBD presently is not considered a classic autoimmune disease in which host T cells and antibodies inappropriately recognize and attack host tissue. Yet, the microbiota and molecular components of our inner intestinal lumen may be considered a functional "organ" essential for our health. In this sense, IBD could be considered an autoimmune disease in which a poorly regulated mucosal immune response to luminal contents leads to severe collateral damage to the intestinal lining. Advances in genomics have detected gene variants that, to a limited degree, predispose some people to these diseases. However, poorly defined environmental factors were

the major cause for the rapid growth of IBD in industrial societies in the latter half of the 20th century and are the primary drive for the precipitous spread of IBD worldwide in the 21st century. Advances in therapy are coming with increasing speed because of exciting new discoveries providing insight into the immune regulatory pathways that drive and limit intestinal inflammation as well as from the enhanced appreciation of the importance of the intestinal microbiota. This also comes with the sobering realization that there is a continual increase in both the prevalence and severity of these diseases, which will increasingly challenge healthcare systems and the quality of life of people everywhere.

## HISTORICAL ASPECTS

Both UC and CD were recognized in the 19th century. It is likely that the high prevalence of enteric mycobacterial infections, partly due to drinking unpasteurized milk, and other enteric infections masked the recognition of many cases.

With regard to CD, various case reports described patients with chronic inflammatory diseases of the small bowel and colon that did not appear to have enteric infection (Baron, 2000). With refinements in microscopy, small case series emerged documenting patients with inflammation and strictures of the ileocecal region without any evidence of malignancy or tuberculosis.

Doctors Burrill B. Crohn, Leon Ginzburg, and Gordon D. Oppenheimer practicing at Mount Sinai Hospital in New York published the seminal paper in 1932 entitled "Regional Ileitis: A Pathologic and Clinical Entity" (Crohn et al., 1932). The paper described 14 patients requiring surgery, performed by Dr. A. A. Berg, for idiopathic granulomatous inflammation of the terminal ileum. The condition was called regional ileitis because Dr. Crohn believed the disease only involved the terminal ileum (Wells, 1952) despite evidence presented by Ginzburg, Oppenheimer (Ginzburg and Oppenheimer, 1932), and others of cases with inflammation involvement in the colon and small bowel. Crohn's name was attached to the disease because the authors listed their names alphabetically on the paper and the surgeon, Dr. Berg, humbly declined to be included as an author (Baron, 2000).

Samuel Wilks (Wilks, 1859) receives credit for the discovery of UC as a distinct entity, which he called "idiopathic colitis." Hale-White (1888) coined the term "ulcerative colitis." However, his patients may have had irritable bowel syndrome rather than UC (Baron, 2000). The development of the electric sigmoidoscope allowed Sir William Hurst (Hurst, 1909) and Lockhart-Mummery (Mummery, 1907) to help clarify the appearance of the colon in UC.

## EPIDEMIOLOGY

The highest prevalence of IBD is in wealthy industrialized nations of North America and Europe (Molodecky et al., 2012). It is particularly common in the Northern regions of these geographical areas. These diseases were rare in the middle of the 20th century. Population-based, epidemiologic studies substantiated the rise in disease prevalence over time (Cosnes et al., 2011). It is estimated that perhaps 0.3% of the population in these Western regions now has UC or CD (Molodecky et al., 2012; Kaplan and Ng, 2017).

IBD was rare in less developed countries, but this is no longer the case. IBD presently is spreading around the world as nations undergo the process of industrialization (Molodecky et al., 2012). Although the incidence of IBD is lower in Eastern Europe, Africa, and Asia compared to North America and Western Europe, there are well-documented increases in disease prevalence in countries such as South Korea, India, China, Japan, and the nations of the Middle East (Goh and Xiao, 2009). IBD are diseases that usually begin in the second-to-third decade of life. The disease in less developed countries tends to be milder and come on at a later age, a situation similar to that seen in the United States during the early years of the IBD epidemic. Cohort studies suggest that children acquire an increased risk of developing IBD if they were born to immigrants who moved from regions with a low IBD incidence to areas of high incidence (Benchimol et al., 2015).

These observations strongly suggest that environmental factors greatly affect the prevalence of IBD. The "IBD Hygiene Hypothesis," which is now supported by substantial experimental and clinical data, suggests that an important cause is unintentional alterations in the composition of the various organisms residing within the intestines (Elliott et al., 2000). Another important factor could be a shift in the nature and composition of diets (Owczarek et al., 2016). However, data supporting this idea remain sparse.

Smoking affects the frequency of IBD (Rubin and Hanauer, 2000). People who smoke double their risk for CD. Also, the disease is more virulent and resistant to therapy in people who smoke. However, smoking lowers the risk for UC. Tobacco smoke is a complex molecular mix. Not yet identified are the factors in smoke responsible for these observations.

Another substantiated observation is the effect of appendectomy on IBD. Appendectomy, below the age of 20, for the confirmed diagnosis of appendicitis decreases the risk for UC.

Industrialization causes may alter lifestyle and environment that correlate with the increase in IBD incidence, but these are mostly irrelevant. Other proposed risk factors include use of antibiotics, failure to breastfeed, use of oral contraceptives, insufficient vitamin D intake, living in an urban versus a rural environment, and lack of exposure to farm animals to name a few. Evidence supporting causation remains weak for most of these associations.

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS (TABLE 46.1)

**TABLE 46.1** Findings That Help Differentiate Crohn's Disease (CD) From Ulcerative Colitis (UC)

	Crohn's disease	Ulcerative colitis
Symptoms and physical findings	Right lower abdominal pain, crampy periumbilical pain, perianal pain with defecation  Soreness in the right lower abdomen ± palpable mass  Anal fissure or perianal fistula	Tenesmus  Bloody diarrhea
Area and pattern of mucosal involvement	Small bowel involvement  Rectal sparing  "Skip lesions"  Strictures  Fistulas or fissures	Rectal involvement with confluent proximal disease of variable extension
Histologic features	Transmural inflammation  T lymphocyte and macrophage predominant infiltration  Noncaseating granulomas	Inflammation limited to mucosal epithelium  Lymphocytic with variable inclusion of eosinophils and mast cells, and neutrophils near the crypts
Common extraintestinal manifestations	Aphthous ulcers of the mouth	Primary sclerosing cholangitis  Pyoderma gangrenosum

### Crohn's Disease

CD can involve any part of the gastrointestinal tract from mouth to anus. Among all patients, about 50% have disease in the small bowel and colon, 30% have isolated small bowel disease, and 20% have disease just in the colon. The terminal ileum is the most commonly affected segment of bowel. A few patients have involvement of the more proximal small bowel and/or stomach. Rare sites of disease include the mouth, esophagus, and skin in the perineal area. When CD involves the colon, it usually spares the rectum.

The areas of inflamed mucosa can be confluent or discontinuous ("skip lesions"). In a subset of patients, the inflammation stimulates extensive fibrosis that can lead to intestinal strictures and bowel obstruction. Early mucosal lesions of CD are 1–2 mm superficial ulcers with surrounding erythema (aphthous ulcers) that can expand into larger and deeper ulcers (Fig. 46.1). These lesions, in turn, can grow into longitudinally oriented, "linear ulcers."

About 30% of patients develop fistulas (Schwartz et al., 2002). This is the consequence of the transmural nature of the inflammation, which erodes deeply into the intestinal wall. The most common site for fistulas is the

**FIGURE 46.1** (A) Moderately severe ulcerative colitis in the rectum showing diffuse inflammation, edema, and superficial ulceration. (B) Early CD in the terminal ileum showing a 1 cm ulcer and a 1 mm “aphthous” ulcer with surrounding inflammation (arrows). CD, Crohn’s disease.

perianal region followed by the terminal ileum. These abnormal channels extend from the intestines to either the skin or some internal structure conveying stool and pus. Perianal fistulas usually extend to the skin surrounding the anus. Those entering the bladder or vagina are the most difficult to treat. Ileal fistulas have the propensity to cause regional intrabdominal abscesses, enter other nearby segments of bowel creating enteral shunts or extend to the abdominal wall.

Patients often develop anal fissures. These are longitudinal tears in the mucosa of the anal canal. Patients with fissures experience pain with defecation and see fresh blood on the stool or toilet paper. Chronic fissures and fistulas can be the first manifestation of CD.

The clinical presentation depends on the location of mucosal inflammation and the presence or absence of strictures or fistulae. CD most commonly leads to inflammation in the terminal ileum and colon. CD typically presents as diarrhea with or without blood, crampy lower abdominal pain, abdominal soreness particularly in the right lower abdomen and fatigue. The presence of an anal fissure or fistula can result in rectal pain and perhaps fever secondary to perianal abscess. Common associated laboratory findings are iron and vitamin B12 deficiency with associated anemia. Partial small bowel obstruction presents as intermittent, crescendo-decrescendo perumbilical pain often associated with eating high-fiber foods. CD can produce additional symptoms if it involves the mouth, esophagus, stomach, and proximal small bowel.

### Ulcerative Colitis

The chronic inflammation in UC is isolated to the colon with occasional involvement of the distal terminal ileum (“backwash ileitis”). Unlike CD, UC is characterized by confluent inflammation with no skip lesions. It involves the rectum and more proximal colonic mucosa to a variable extent. The disease can present as inflammation localized to the rectum (“proctitis”) or involve the entire colon (“pan-colitis”). About 10% of patients with left-sided colonic disease also have an additional “patch” of inflammation around the appendix, which is on the right side of the colon. Unlike CD, the inflammation in active UC does not extend beyond the inner mucosal and submucosal lining and has a more variable cellular content ranging from lymphocytic to mixed eosinophilic and neutrophilic infiltration. Mild disease may present just as thickening of the mucosa with edema. More serious disease displays superficial ulcerations, areas covered with purulent exudate and a friable mucosa that tends to bleed upon scope contact (“friability”) (Fig. 46.1). The worst disease could present with nearly total loss of the epithelial lining.

Patients typically present with diarrhea (bloody or nonbloody), fecal urgency, nighttime symptoms, tenesmus (repeating urge to defecate with no result), and crampy lower abdominal pain. Fistulas do not develop, and colonic strictures are rare.

In severe pan-colitis, the colon can dilate presenting as “toxic megacolon” and threaten perforation. Associated findings may include tachycardia, diffuse abdominal tenderness, reduced frequency of defecation due to loss of colonic motility, fever, and leukocytosis. This is a dangerous condition requiring immediate intense medical therapy or colectomy if patients do not respond quickly to medical treatment (Autenrieth and Baumgart, 2012).

## Extraintestinal Manifestations Common to Ulcerative Colitis and Crohn's Disease (Brown and Coviello, 2015; Vavricka et al., 2015)

IBD is associated with several extraintestinal manifestations (EIM), one or more of which develop in 50% of patients. About 25% of the patients have EIM before developing the clinical symptoms of IBD. EIM commonly involve the skin, joints, eyes, mouth, and, less frequently, the hepatobiliary tree.

### **Skin**

IBD is associated with several skin diseases. Erythema nodosum (EN) presents as tender, raised erythematous nodules on extensor surfaces and develops in up to 15% of patients. EN appears in many immunologic diseases and some chronic infections (i.e., sarcoidosis, tuberculosis) and is not specific to IBD. Pyoderma gangrenosum (PG) is less common than EN and manifests as quickly developing, nontender purulent necrotic ulcers mostly on the lower extremities but can develop elsewhere. Unlike EN, 50% of patients with PG have IBD. Sweet's syndrome is a rare dermatologic condition characterized by diffusely distributed tender nodules. Sweet's syndrome can develop on its own or associates with underlying malignancy or infection. IBD is one of the more common associated conditions.

### **Joints**

Joint pain is the most common EIM manifestation in IBD, which occurs in 20%–30% of the patients (Bernstein et al., 2005). There are several forms of joint involvement. Patients can develop nondestructive arthropathy of the extremities characterized by morning stiffness and the lack of swelling and erythema in the involved joints. Some patients present with asymmetrical, large joint involvement. Others have bilateral involvement of the proximal small joints of the hands and perhaps feet. Still others get sacroileitis. Patients who are HLA B27 positive are prone to ankylosing spondylitis, and 50% of the patients with ankylosing spondylitis have IBD that can be quite mild.

### **Eyes**

IBD is associated with several ophthalmologic conditions, notably uveitis, episcleritis, and scleritis. Uveitis is most common. It may present with sudden onset of blurry vision, photophobia, and localized eye pain. Most patients have minimal symptoms that are easy to overlook. Patients should have routine eye examinations by an ophthalmologist to avoid glaucoma and the other complications associated with this condition.

### **Mouth**

Aphthous ulcers are lesions that periodically develop in the mouth. These painful ulcers appear most commonly on the side of the tongue or buccal mucosal along the bite zone. They are a common manifestation of IBD, especially CD, which frequently flare during IBD exacerbation. Most people who get aphthous ulcers have no known associated disease. They need to be distinguished from CD of the mouth. Mouth ulcers also can be a sign of other conditions such as lupus and syphilis.

### **Hepatobiliary**

IBD is strongly associated with primary sclerosing cholangitis (PSC), a disease causing chronic fibrosis and biliary duct strictures (Lazaridis and LaRusso, 2016). Damage to the ducts causes cholestasis that gradually progresses to cirrhosis. Ninety percent of patients with PSC have IBD, 80% of which will be UC. Colectomy does not stop disease progression. Unlike regular UC, many patients with PSC have inflammation localized mostly to the right side of the colon. Some have an open, atrophic ileocecal valve with a fish mouth appearance. These patients are at particularly high risk for developing colorectal cancer and require annual surveillance colonoscopy. They also are highly prone to cholangiocarcinoma and gallbladder cancer.

Bile salt malabsorption in CD predisposed to the formation of gallbladder stones, which can cause biliary cholangitis or cholecystitis. Bile salt malabsorption also can induce chronic diarrhea independent of IBD activity.

### Kidney Disease

Frequent dehydration and aberrant absorption of oxalate predispose to calcium oxalate and other types of kidney stones. Aminosalicylates (5-ASA) medications, commonly used in UC, can cause interstitial nephritis.

### Other Diseases With a Link to Inflammatory Bowel Disease

Other immune-mediated diseases have some association with IBD. Patients with IBD are more likely to have psoriasis, and patients with psoriasis are more apt to develop IBD (Takeshita et al., 2017). There also are links to multiple sclerosis and asthma. More frequent in IBD is alopecia areata, an autoimmune disease in which lymphocytes attack the hair follicles causing hair loss.

Nonimmunologic autoimmune disease associations include hidradenitis suppurativa and osteoporosis. The latter association is at least in part due to corticosteroid use.

### Cancer

Patients with IBD have higher cancer risks. Patients with UC and CD are at increased risk for colon cancer depending on the extent, severity, and duration of colitis (Velayos et al., 2017). Screening colonoscopy commences after about 8 years of disease and continues at frequent intervals (1–3 years) for patients with disease involving more than a third of the colon. Patients with just proctitis or CD with limited colon involvement are at low risk for the colon cancer compared to other IBD patients and require colonoscopy perhaps less frequently. CD also predisposes to small bowel cancer for which there currently is no screening test.

Patients with PSC are extremely prone to colon and biliary cancers. They receive screening colonoscopy annually commencing at the time of PSC diagnosis.

The aim of screening colonoscopy is to detect dysplastic lesions that predispose to colon cancer. Using high-definition colonoscopy, chromoendoscopy increases the dysplasia detection rate in some circumstances. Patients with dysplasia may require colectomy or local endoscopic resection (Velayos et al., 2017).

Medications used to treat IBD also can predispose to cancer. For instance, azathioprine increases the risk for lymphoma, some skin cancers, and a select group of other malignancies.

## PATHOLOGICAL FEATURES

Endoscopic biopsies are helpful in the diagnosis of IBD and the differentiation of UC from CD through the recognition of microscopic changes suggestive of UC, CD, or both (Magro et al., 2013). They help differentiate IBD from other conditions associated with intestinal inflammation such as lymphocytic colitis, collagenous colitis, ischemic colitis, radiation colitis, some forms of infectious enteritis (Nostrant et al., 1987), celiac disease, and graft-versus-host disease.

At times, the differentiation of CD from UC is problematic when CD only involves the colon (Feehans, 2014). In active colitis, both CD and UC display an inflammatory cell infiltration of the mucosa and submucosa with associated epithelial crypt abscesses and crypt distortion suggestive of chronic epithelial injury. Crypt abscesses are aggregates of neutrophils that invade degenerating crypt epithelium. There can be Paneth cell metaplasia distal to the ascending colon, the depletion of goblet cell mucin and ulceration. Chronic, focally severe mucosa injury due to inflammation and ulceration can regenerate producing “pseudopolyps,” which are finger-like outgrowths of the mucosal lining. These are benign lesions composed mostly of normal or regenerative epithelial lining.

The most histologically specific feature of CD is the presence of noncaseating granulomas anywhere in the gut (Mathew and Weinstock, 1994). However, these are identified in only about 30%–50% of patients with CD. The granulomas in CD can take on one of three distinct forms. The presence of granulomas is not pathognomonic for CD since some bacterial, chlamydial, fungal, and helminthic infections also induce intestinal granulomas, and they can be found in sarcoidosis, granulomatosis with polyangiitis (formerly called Wegener's granulomatosis), and idiopathic granulomatous gastritis. The distinct morphology of CD granulomas helps distinguish them from granulomas of other causes.

CD may have other distinguishing features. A primarily T-cell and macrophage infiltration is somewhat more supportive of CD. In addition, CD can display transmural inflammation, but this feature is more fully

appreciated in surgical resections than in superficial endoscopic biopsies. Also, supporting the diagnosis of CD is the microscopic evidence of interspersed areas of normal mucosa next to diseased tissue (skip lesions).

Typically, UC displays a neutrophilic infiltrate mostly near the epithelial crypts with a chronic inflammatory infiltrate in the lamina propria—containing T lymphocytes and plasma cells, and variable numbers of eosinophils and mast cells. The inflammatory infiltrate does not extend deeper into the intestinal wall unless UC is severe. Skip lesions are not the histologic features of UC. In UC, areas of normal mucosa often mark the proximal extent of the diseased mucosa. Granulomas are infrequent and small in UC, forming only at the boundary of a degenerating epithelial crypt.

The absence of granulomas, skip lesions, or transmural inflammation does not exclude CD, and clinicians must rely on the entire clinical scenario when diagnosing UC or CD ([Table 46.1](#)). It is not possible to distinguish UC from CD in about 10% of the patients with inflammation suggestive of IBD limited to the colon. This is called “indeterminate” colitis.

## ETIOLOGY INCLUDING AUTOIMMUNE FEATURES

The intestinal lumen contains a huge number of microorganisms, mostly concentrated in the colon and distant small bowel, food antigens, and various mitogenic and toxic substances. These factors constantly interact with the intestinal lining. The intestinal surface is covered with epithelial cells under which lay many inflammatory cells of various types. This normal inflammatory layer in the intestinal lining is evident on microscopic examination of histological sections of the gut wall and is called the “physiological inflammation.” These immunocytes function to corral our intestinal microbiota and gate our immune responses to luminal substances to prevent inappropriate immune reactions to food antigens and other molecules. Yet, the gut immune system is able to respond to maladjusted, invading intraluminal pathogenic organisms and clear them from the body. Studies using animals and some human investigation over the last few years provided remarkable insight into the complex processes of immune regulatory, epithelial biology, and mucosal barrier function that leads to mucosal homeostasis.

It seems increasing likely that IBD is a series of chronic inflammatory disorders with somewhat similar pathological expression. This makes identification of a precise etiology for these diseases most difficult. IBDs presently are not considered autoimmune disorders induced by an autoantibody or cellular immunological response directed to self-antigens. Instead, they are considered inappropriate immune reactions to intraluminal organisms and other substances. This hyperreactive immune response indirectly damages the intestinal lining. A predisposing factor is considered intestinal dysbiosis, which is an alteration in the composition and functional state of our “normal” intraluminal organisms resulting from “modern day” living. Two proposed factors that may contribute to dysbiosis are the use of antibiotics and changes in diet ([Chan et al., 2015](#)). Probably other not yet well defined environmental factors also promote these diseases. Also, some patients carry gene variants that affect susceptibility for IBD. The topics of environment and genetics are discussed elsewhere in this chapter. There are inconclusive and controversial data suggesting that some forms of IBD are caused by “infectious agents.”

The current hypotheses of disease pathogenesis do not adequately explain some of the clinical observations related to these diseases. For unexplained reasons, these diseases usually manifest themselves during the second and third decades of life. The triggers that induce disease are mostly not defined. IBD can damage some regions of the gut, while leaving others alone, often with a clean demarcation between healthy and diseased tissue. Also, biopsies taken throughout the intestines, which clearly disrupt barrier function, do not spread the disease to these physician-induced areas of mucosal injury. IBD does not spread to spouses or healthcare workers in close contact with patients, which suggests IBD is not caused by a classical pathogen–host interaction. Immune suppression does not cause the disease to spread within the body. Patients can spontaneously go into complete remission without apparent explanation.

### Microbiota

There is growing recognition of the importance of the gut microbiome in maintenance of health ([Bellaguarda and Chang, 2015](#)). The human microbiome is quite heterogeneous in composition comprising 500 to several thousand species of bacteria. There also are fungi ([Richard et al., 2015](#)), viruses, and worm-like parasites (helminths); the latter are present much more often in less-developed countries ([Weinstock, 1996](#)). The composition and density of the gut flora/fauna varies in different regions of the intestine as well as to its proximity to the intestinal lining.

The diversity and composition of the intestinal flora form during early childhood and becomes more stable later in life. About 90% of our intestinal bacteria fall into one of two bacterial phyla: Firmicutes and Bacteroidetes.

Witnessed in daily medical practice is evidence of the importance of flora in the disease process. For instance, fecal diversion via construction of an ileostomy can promote healing of CD in distal regions of the bowel, and disease usually relapses with take-down of the ileostomy and reestablishment of the fecal stream.

Loss of diversity has been thoroughly documented in patients with IBD (Putignani et al., 2016). Studies of luminal bacterial composition in patients with IBD revealed a decrease in “beneficial” bacteria such as the bifidobacteria *Lactobacilli* and *Firmicutes* and an increase in putative pathogenic bacteria such as *Bacteroides* and *Escherichia coli*. Yet, human investigation still has not definitively shown if dysbiosis is an important cause or the result of having IBD.

Animal models of colitis support the premise. There are species of bacteria (Lathrop et al., 2011) and helminths (Weinstock and Elliott, 2014) that inhibit murine colitis through suppression of the adaptive immune response that drives the disease. Some of these organisms induce within the gut regulatory T cells, macrophages, and/or dendritic cells, and they promote the production of regulatory cytokines such as IL10 and TGF $\beta$ . Regulatory immune cells and factors inhibit the pathogenic T-cell responses that drive the inflammation. There are other organisms shown to promote, rather than inhibit colitis.

## Intestinal Epithelium and Barrier Function

The intestinal epithelium is the interface between the contents of the intestines and the body. Under normal circumstances, the epithelial lining of the gut turns over every 4–5 days. Intestinal stem cells at the base of the crypts drive this regeneration. The epithelial lining is comprised of many different, highly specialized cells that vary in function. Some display specialized activities depending on the region of intestine in which they reside. There are cells that participate in digestion, absorption, secretion, and host defense. Some produce hormones and other regulatory molecules.

It is proposed that defects in epithelial cell barrier function are risk factors for the development of IBD (Okamoto and Watanabe, 2016). As demonstrated in animal models, the disruption of the tight junctions that hold these cells together can lead to chronic intestinal inflammation (Rudolph et al., 1995; Hornquist et al., 1997). The surface epithelium is covered with a layer of mucus. The disruption of the cells that make this mucus (goblet cells) can result in murine colitis (Van der Sluis et al., 2006). Paneth cells located in the base of the lining secrete defensins and other molecules that help keep bacterial away from the lining. Genetic variants that affect Paneth cell function are mild risk factors for the development of IBD in humans (Welkamp et al., 2005; Kernbauer and Cadwell, 2014). Mice with extensive disruption of Paneth cell function spontaneously develop colitis (Adolph et al., 2013).

## Innate and Adoptive Immunity

Under normal circumstances, it is likely that innate, non-T-cell immune responses are the major guardians of mucosal homeostasis. Mice lacking both functional T and B cells survive without difficulty harboring a normal intestinal flora. Excessive adoptive immunity drives pathology.

The conductor of the mucosal immune response is the dendritic cell. Intestinal dendritic cells sample luminal contents. They may do so via allowing luminal molecules to engage their receptors of innate immunity (e.g., tolls, C-type lectins (CLECs), nucleotide-binding oligomerization domain containing 2 (NOD2))located on the cell surface or present in intracellular locations. The dendritic cells present antigen to nearby T cells and instruct the T cells to activate or go into the inactive state of anergy (Kalekar and Mueller, 2017). It is of intense interest to determine the factors that instruct intestinal dendritic cells to favor an innate, rather than an adoptive immune response.

Dendritic cells produce, or direct other immune cells to produce, regulatory cytokines such as TGF $\beta$  and IL10. They also promote the generation of regulatory T cells that dampen T-cell responses. Particularly in the intestines, TGF $\beta$  is an exceptionally important cytokine for driving T cells to differentiate into their regulatory phenotypes (Sekiya et al., 2016). In transgenic mice, T cells bio-engineered to express TGF $\beta$  receptors that cannot signal upon TGF $\beta$  ligation develop colitis (Ince et al., 2009; Gorelik and Flavell, 2000). This shows the importance of the interaction of TGF $\beta$  with T cells in preventing disease. Regulatory T cells in the gut are an important source of IL10 (Hang et al., 2013; Uhlig et al., 2006; Singh et al., 2001; Rubtsov et al., 2008), which, among other functions, inhibits the production T helper 1 (Th1) cells, IFN $\gamma$ , and perhaps IL17, all of which drive inflammation.

Dendritic cells and other cell types also can be sources of IL12 and IL23 that promote development of proinflammatory Th1 and T helper 17 (Th17) cells, respectively. Also, some of the important intracellular signaling

pathways used to promote gut inflammation include spleen tyrosine kinase (SYK) (Hang et al., 2016), Janus kinase (JAK), and nuclear factor of kappa light polypeptide gene enhancer in B-cells (NF $\kappa$ B).

The inflammation of CD is notable for the infiltration of gut tissue with abundant numbers of inflammatory T lymphocytes. These cells are drawn into the gut through the local production of chemokines and the ability of some T cells, via expression of integrins, to recognize gut-specific adhesion molecules (addressin) present on the gut vascular endothelium. One such T-cell-specific integrin called  $\alpha$ 4/ $\beta$ 7 binds the gut-associated, vascular addressin called MadCAM1.

It is believed that some of the key cytokines driving the inflammatory response in CD are IL12, IL23, IL17, and IFN $\gamma$ . IL12 and IL23 induce the T cells that produce IFN $\gamma$  and IL17, respectively. These factors, in turn, drive cells to produce tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), IL6, IL1 and other cytokines that amplify the inflammatory response.

These observations have pharmaceutical relevance in IBD. Agents that block IL12/IL13, TNF $\alpha$ , the JAK1 signaling pathway, or that promote TGF $\beta$  production (Monteleone et al., 2015) display clinical utility in subsets of patients with CD. Also of clinical importance are molecules that block gut-specific, integrins-like  $\alpha$ 4/ $\beta$ 7 which impede entrance of T cells into the gut. Under development are additional therapies that target other presumed critical inflammatory pathways relevant to IBD.

The inflammatory response in UC appears more complex and variable than that of CD. In addition to lymphocytes, there can be large numbers of neutrophils and eosinophils. The cytokine pattern of UC may contain additional cytokines such as IL13, IL5, and perhaps IL4. These are cytokines associated with Th2 cells and allergic responses. Yet, subsets of patients with UC respond equally well to most of the same medications displaying efficacy in patients with CD.

## GENETICS

Environmental factors influence the risk for IBD (Loftus and Sandborn, 2002). Cigarette smoking increases the likelihood of developing CD (Calkins, 1989). Appendectomy for appendicitis decreases the incidence of UC (Andersson et al., 2001; Derby and Jick, 1998; Russel et al., 1997). Some enteric infections due to exposure to organisms such as the ameba *Entameba histolytica* or cytomegalovirus can induce IBD. Studies have observed geographic variations in IBD frequency. IBD was more common in the northern versus southern regions of the United States and Europe in the latter half of the 20th century (Sonnenberg et al., 1991; Shivananda et al., 1996; Kappelman et al., 2007) and is more frequent in Western versus Eastern Europe. Greater risk for disease is departed to children born to people who relocate from regions of low CD or UC frequency to areas of high IBD prevalence (Carr and Mayberry, 1999; Jayanthi et al., 1992; Probert et al., 1993). IBD prevalence has increased in North America and Western Europe and is approaching about 1 in 250 people in some prosperous countries (Bernstein et al., 1999; Loftus et al., 2002). IBD is a growing problem in many Asian nations. People with blue-collar jobs exposing them to dirt (Sonnenberg, 1990) and US military personnel who served in tropical regions (Delco and Sonnenberg, 1998) are less likely to acquire IBD. Thus, environmental factors may play an equal or greater role in the development of IBD than genetic variation.

While 5%–15% of people with IBD have a first-degree relative afflicted with the disease (Binder, 1998), such associations could still result from shared environmental risk factors. Ashkenazi Jews are at high risk for development of IBD compared to non-Jew European ancestry cohorts. Genetic studies in this population have yet to discover prevalent, distinct disease susceptibility genes (Vacic et al., 2014).

Monozygotic twin studies were the first to provide convincing evidence that IBD had a genetic component (Gordon et al., 2015). This led to genome-wide association studies that have discovered about 200 genetic loci/regions that affect the risk for development of IBD. It now is clear that no one gene is “the cause” of IBD. Some gene variations affect the risk for UC or CD or for both conditions (McGovern et al., 2015). Many of the gene variants fall into one of three categories: regulation of (1) inflammation, (2) autophagy, and (3) microbial sensing to activate autophagy (Uniken Venema et al., 2017). Knowledge of these variants also has provided some insight into processes that may drive IBD. While these genes do depart risk, the vast majority of people with one or more of these risk factors will never develop IBD, and most patients with the condition fail to display known susceptibility genes. IBD develops in all racial and ethnic groups. Many susceptibility genes uniformly depart risk among different populations, although they are expressed at variable frequencies within different groups. Some are unique for a particular population. This latter observation may reflect the complex multigenetic nature of IBD susceptibility or perhaps worldwide differences in disease pathogenesis.

The first identified genetic variants associated with IBD, present mostly in Western societies, were loss-of-function mutations in the NOD2 gene. It predisposes to the development of CD particularly of the terminal ileum. The prevalence of the NOD2 defect ranges from 0% to 28% in CD and 0% to 14% in healthy control populations depending on the population studied. While NOD2 is perhaps the most clinically significant disease susceptibility gene, much less than 5% of people who carry one of the NOD2 variants will ever develop IBD. Carriers of two NOD2 variants are at even greater risk.

NOD2 is an intracellular receptor for muramyl dipeptide derived from bacterial lipopolysaccharides and has a role in driving the innate immune response to such organisms. Cells expressing the NOD2 variant fail to respond to NOD2 ligation with NF $\kappa$ B activation (Li et al., 2004), an important intracellular signaling pathway that drives proinflammatory responses. Within the gut, it is speculated that NOD2 helps protect us through promoting the production of  $\alpha$ -defensins that help destroy some types of microorganisms if they approach the intestinal lining (Wehkamp et al., 2005; Simms et al., 2008). Ligation of NOD2 also downmodulates Toll-like receptors expression in dendritic cells (Watanabe et al., 2006), which remain responsive in the NOD2-deficient state. It is speculated that loss of both of these functions promotes development of CD.

Also, variants of the autophagy-related 16-like 1 (ATG16L1) gene are expressed somewhat more frequently in people of European ancestry with CD compared to the healthy general population (Hampe et al., 2007; Rioux et al., 2007). Autophagy is the natural, regulated cellular mechanism through which cells allow the orderly degradation and recycling of unnecessary or dysfunctional intracellular components including bacteria. ATG16L1 encodes a protein important for the process of autophagy. The T300A variant of ATG16L1 is highly susceptible to cleavage by caspase-3 and -7, which are activated during cellular stress (Murthy et al., 2014). Reduction in the amount of this protein can lead to defective microbial clearance and increased cytokine production (Lassen et al., 2014).

Other gene variants afford protection from IBD. There are gene variants in the locus-containing IL23R that are associated with increased CD and UC susceptibility. However, people with the loss-of-function Arg381Gln variant of the IL23R gene are much less likely to get IBD (Duerr et al., 2006; Zwiers et al., 2012; Pidasheva et al., 2011). The gene is present in about 14% of people of European ancestry and is more protective for CD than UC. Among its functions, IL23, via engagement of IL23R, drives the development of T cells that express IL17 (Gaffen et al., 2014). Interleukin 17 is a proinflammatory cytokine (Burkett et al., 2015). It recruits monocytes and neutrophils to sites of inflammation in response to invasion by pathogens and stimulates the production of many other cytokines. Already in use or under clinical investigation are the inhibitors of IL23 that appears efficacious for some patients with CD (Deepak and Loftus, 2016).

Gene testing presently is of limited value in patients with IBD. IBD is a complex disorder in which gene mutations contribute to various extents to the disease. For instance, having the NOD2 defect at least doubles the risk for developing CD. Other variant genes associated with IBD depart relatively little risk. Most healthy people carrying these same genes will never develop IBD. Thus, genetic testing will not be helpful in predicting disease expression or the diagnosis of disease because of the lack of sensitivity and specificity. It currently is unknown if detection of gene variants will help predict disease prognosis, risk for EIM of disease, or pharmaceutical responsiveness (Gabryel et al., 2016).

## ANIMAL MODELS

It is likely that IBD is a heterogeneous group of conditions caused by expression of various different host and environmental factors what cumulate in chronic intestinal inflammation often with similar phenotypic appearance. Thus, it presently is not possible to develop a single, precise animal model of the human disease when the actual pathophysiology of the human condition remains murky and multifactorial.

However, the animal models of gut inflammation have grown in sophistication revealing various important intestinal mechanisms governing injury and repair, mucosal immune regulation, gut flora/mucosal interactions, epithelial cell biology, and inflammatory-induced carcinogenesis (Westbrook et al., 2016; Valatas et al., 2015) all of which are processes highly relevant to the human disease. Also, some of the animal models have demonstrated utility in early pharmaceutical testing of promising new therapeutic agents. For instance, they predicted the therapeutic safety and efficacy of molecules that block IL12, IL23, homing of T cells to the gut, SMAD7, and the JAK signaling pathway, which are now in use to treat IBD or are in the advanced stages of testing.

There are more than 75 distinct mouse models of intestinal inflammation (Mizoguchi et al., 2016). Due to the inconsistency of disease expression, relevance of the model and/or cost of murine colony maintenance, only a

relatively few of these models are used repeatedly and in many laboratories to study the mechanisms of mucosal homeostasis. Even the best models have their weaknesses. Thus, some models may prove superior to others for addressing particular questions pertaining to enteric biology and IBD.

Some induce short-term inflammation via injury to the intestinal lining, such as 2,4,6-trinitrobenzenesulfonic acid, which is given rectally, or dextran sodium sulfate (DSS) administered orally. The models dependent on DSS-induced injury have proven particularly important for the identification of mechanisms of mucosal injury and repair.

The genetic manipulation of mice allowing over- or underexpression of various molecules has created a large number of inflammatory models. They have revealed an array of complex interactions needed to maintain immune homeostasis in the gut mucosa, which abuts against many potentially harmful food antigens and a multitude of diverse and potentially invasive microorganisms.

Various genetic alterations in humans can increase the risk for developing IBD. Genetic manipulations in mice have provided insight into the function and importance of some of these disease susceptibility genes (Mizoguchi et al., 2016). For instance, some loss of function polymorphisms in NOD2 increases susceptibility to CD (Strober et al., 2014). Mouse models displaying NOD2 defects showed its role in sensing molecular components of some bacterial species and triggering innate immune responses. Defects in a process called autophagy also predisposes to CD disease. Study of autophagy in animal models revealed how it works to degrade invading intracellular microorganisms (Kernbauer and Cadwell, 2014; Baxt and Xavier, 2015).

Several models of IBD depend on the transfer of T-cell subsets or genetically manipulated cells into immune-deficient murine hosts. Most notable among these models have been the reconstitution of T and B cell-deficient mice (e.g., Rag<sup>-/-</sup>) with CD45RBhi or CD25+ T cells or T cells that cannot make IL10 (Blum et al., 2004; Keubler et al., 2015; Powrie et al., 1994; Izcue et al., 2009). The colitis that develops in these mice led to the discovery of the importance of TGFβ, IL10, and regulatory T cells in the control of intestinal inflammation.

Various models of IBD proved useful for studying the role of the host gut microbiota (Khanna et al., 2014) in the disease process. The microbiota comprises the various organisms that live within our intestines, such as bacteria, viruses, and fungi, and also includes the helminthic parasites (Weinstock and Elliott, 2014). Many of the IBD models fail to develop colitis in the absence of the intestinal microbiota, revealing the importance of the gut microflora in the disease process. In several animal models, the presence of some microbial species, such as *Helicobacter* or *Citrobacter*, helps to trigger disease, whereas other microbial species afford protection. However, in mice and humans with the NOD2 defect, *Bacteroides* species promote intestinal inflammation, whereas *Clostridiales* are protective (Ramanan et al., 2016). These studies have provided insight into the importance of the composition and functional state of the various components of the gut microbiome in maintaining mucosal integrity.

## DIAGNOSTIC PROCEDURES

IBD is a syndrome, not a specific disease. The diagnosis involves recognition of symptoms and other clinical observations associated with supportive endoscopic, radiologic, and pathologic findings in the absence of enteric infection. No one clinical observation or test is pathognomonic for IBD. Patients may have an acute colitis from an undiagnosed enteric infection that spontaneously resolves over time. Thus, another important element in diagnosis is documenting disease chronicity or recurrence in the absence of potential inciting factors such as infection, IBD-inducing drugs, vasculitis, or ischemia. Gaining favor is the use of several stool and serologic biomarkers to help predict ongoing intestinal inflammation, which could help decrease the repeated use of invasion and expensive testing in patients with dubious symptoms. They also may prove useful for predicting relapse in patients with IBD. However, all the presently used biomarkers are imperfect tools and should be used with care. In the absence of biomarkers that are strongly predictive for disease activity, clinicians often rely on endoscopy to monitor these patients (Chang et al., 2015). There are no available biomarkers with adequate sensitivity or specificity to directly diagnose IBD, rule out disease expression or that can distinguish hard to differentiate CD from UC.

### Serologic Markers

C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are acute phase reactants that often, but not always, elevate in active IBD. Neither is specific for intestinal inflammation (Chang et al., 2015; Panes et al., 2017). Both CRP and ESR increase in response to many inflammatory and infectious conditions and have limited

clinical utility in most patients with IBD. CRP frequently increases in patients with CD having transmural inflammation. The CRP 717 gene variant carried in 25% of people renders CRP an unreliable marker in many patients (Chang et al., 2015; Jones et al., 2008). Furthermore, there is no demonstrated association between clinical disease activity and elevated CRP in CD (Crohn et al., 1932). In UC, CRP elevation is associated with increased symptomatology and extent of inflammation, but not with severity of inflammation (Solem et al., 2005).

There is great interest in developing a serologic test that can accurately diagnose and/or exclude IBD. In principle, such markers would help decrease reliance on invasive endoscopic procedures in patients with a low pre-test probability of IBD (Iliev et al., 2012). Several marker antibodies have been identified in patients with IBD: perinuclear antineutrophil cytoplasmic antibody, anti-*Saccharomyces cerevisiae* antibody, anti-*E. coli* outer membrane porin (OmpC), anti-*Pseudomonas fluorescens*-associated sequence (I2) and antiflagellin (CBir1). As a panel, these serologic markers are not highly specific for IBD and are not used as routine screening tests in health people or those with nonspecific symptoms (Benor et al., 2010; Zhou et al., 2016). They do tend to predict UC or CD in patients whom the diagnosis of UC and CD already is quite evident. Specific antibodies are associated with particular IBD phenotypes, but they are not particularly useful in guiding management decisions or in differentiating between CD and UC in cases of indeterminate IBD (Zhou et al., 2016). Thus, they have little use in clinical practice.

## Stool Markers

Fecal biomarkers, as opposed to serologic markers, are more specific for luminal inflammation (Wright, 2016). Many stool markers have been explored for use in the diagnosis and surveillance of disease activity in IBD, though none are clinically validated for replacement of endoscopy with biopsy. The best studied and most commercially available are fecal calprotectin and fecal lactoferrin (Wright, 2016; Sipponen and Kolho, 2015; Mendall et al., 2016). Fecal calprotectin and lactoferrin concentrations often increase in the stool of patients with active IBD. They have been used to distinguish IBD from irritable bowel syndrome, which can have similar presentations and symptom overlap. Fecal calprotectin has value as a surrogate for severity of endoscopic- and histologic-documented, disease activity in both UC and CD. There is insufficient data to support the use of either fecal lactoferrin or calprotectin as a surrogate test to document mucosal healing, and neither biomarker distinguishes CD from UC.

## Imaging

Several nonendoscopic imaging modalities help in the diagnosis IBD and can define disease extent, activity, and associated complications such as stricture, abscess, and fistula (Panes et al., 2017; Fletcher et al., 2011). Before the availability of cross-sectional imaging via computed tomography (CT) and magnetic resonance (MR) imaging, small-bowel follow-through (SBFT) X-ray series was used to evaluate the small intestine for the thickening of the bowel wall, strictures, and fistulas. Barium enema X-ray and colonoscopy were used for the colon. SBFT and barium enema are time-consuming studies that require patients to swallow contrast or receive it rectally. Then, the radiologist uses fluoroscopy to visualize the bowel and takes still X-rays to document the findings. CT (CTE) and MR enterography (MRE) have largely replaced SBFT for the luminal assessment of the small intestines since they take less physician time and provide information pertaining to peri-intestinal pathology.

Patients with IBD are prone to receiving many X-ray studies over their lifetime resulting in potentially dangerously high cumulative radiation exposure. Several epidemiological studies suggest that there is an increased risk of all types of cancer with repeated X-ray exposure. Compared to MRE, CTE is a relatively fast imaging modality, but it delivers between 1 and 14 mSv of radiation per study (Guimaraes et al., 2010). MRE does not expose the patient to radiation. Thus, in IBD, it often is the procedure of choice for small bowel examination and for the assessment of pelvic pathology (Sheedy et al., 2017).

Endoscopy (colonoscopy and esophagogastroduodenoscopy) is the best imaging modality to directly assess luminal-side inflammation in the colon, terminal ileum, and upper GI track, and is the only procedure that allows biopsy. It permits visualization of the mucosal surface with reliable characterization of disease activity and remission. It facilitates the diagnosis and treatment of strictures and detection of luminal infections (e.g., infection with mycobacteria or cytomegalovirus and cancer).

Sometimes, video capsule endoscopy (VCE) is used to visualize hard-to-reach regions of the small intestine. The camera, which is the size of a pill, is swallowed providing direct visualization of the entirety of the inner surface of the small bowel. It is necessary to use VCE with extreme caution in CD, since the rigid device can obstruct the intestines at areas of stricture requiring surgery for removal (Al-Bawardi et al., 2015).

## TREATMENT

At the end of the 1980s, there were few useful treatments for patients with IBD. These included glucocorticoids with systemic side effects, aminosalicylates requiring frequent dosing, thiopurines, some antibiotics (e.g., metronidazole), total parenteral, or enteral nutrition to provide bowel rest and surgery. New therapies have emerged due to revelations in disease immune pathogenesis, growing knowledge of the mechanisms driving and controlling mucosal inflammation and the eagerness of the pharmaceutical industry to explore new therapeutic options for these conditions. Most of these medications are useful for management of both UC and CD. These advances come with the sobering recognition that IBD is increasing in frequency in developed countries and is rapidly spreading to less-developed nations around the world. Also, IBD is more virulent than in previous years. Many of these new and expensive therapies can cause significant side effects and, thus, require careful patient monitoring. Also, these agents only work on a limited number of patients whose therapeutic response cannot be predicted in advance of therapy. Not infrequently, responding patients are subject to disease relapse even after many years of successful management. Patient age, disease presentation (including EIM of IBD), concomitant illnesses, family history of various diseases, pregnancy, and more influence drug selection as do the various limitations and peculiarities of each of the medications on hand.

### Medical (Table 46.2)

**TABLE 46.2** Treatments for Inflammatory Bowel Disease

Class	Modes of administration	Disease	Common uses
5-ASA	Oral, rectal	UC, ± CD	Induce remission and maintenance
<b>CORTICOSTEROID</b>			
Systemic	Oral, rectal, IV	UC, CD	Induce remission, bridging therapy
Minimal systemic absorption	Oral, rectal	UC, CD	Induce remission, bridging therapy
Thiopurines	Oral	UC, CD	Steroid sparing, maintenance, block antibody development
Methotrexate	IM	UC, CD	Steroid sparing, maintenance, block antibody development
Cyclosporine	Oral, IV	UC	Urgent rescue therapy, bridging therapy
Anti-TNF	IV or SQ	UC, CD	Induce remission and maintenance
Antiintegrin	IV (oral, SQ in development)	UC greater than CD	Induce remission and maintenance
Anti-IL12/23	SQ	CD	Induce remission and maintenance
Tofacitinib (JAK 1/3 inhibitor)	Oral	UC	Induce remission and maintenance
Other JAK inhibitors (under development)	Oral	Probably UC and CD	Expected use: Induce remission and maintenance
Nutritional support	Oral, IV	CD	Induce remission, bridging therapy
Nutritional support	Oral, IV	CD, UC	Short bowel syndrome (CD), malnutrition, bridge for surgery, serious intraabdominal complications

CD, Crohn's disease; JAK, Janus kinase; UC, ulcerative colitis; 5-ASA, aminosalicylates.

## Aminosalicylates

5-ASA (mesalamine) is the treatment most commonly used for first-line therapy of mild-to-moderate UC ([Hauso et al., 2015](#); [Harris and Lichtenstein, 2011](#)). It has proven efficacious for both induction and maintenance of remission. It is an antiinflammatory medication that works via direct contact with the colonic mucosa. 5-ASA is rapidly absorbed in the small bowel and must be protected to reach the colon. The first 5-ASA derivative was sulfasalazine. This medication was sulfapyridine, an antibiotic, connected to 5-ASA via an azo-bond. Bacteria in the colon enzymatically cleaved the azo-bond releasing the 5-ASA. The drug was not “bioengineered” for the treatment of IBD. Its efficacy was discovered by happenstance. The sulfa moiety tended to cause allergic reactions, nausea, headaches, and other symptoms. Although still available, this medication has fallen mostly out of use due to the development of safer 5-ASA formulations.

Since the benefit of the drug rested mostly with the 5-ASA moiety, developed were oral formulations just containing 5-ASA (or similar medication, e.g., balsalazide) that were targeted for release in various regions of the gut. In some, the agent was enclosed in capsules designed to open near pH 7, which is the typical pH in the distal bowel. Additional targeting strategies led to the development of extended release forms of 5-ASA and formulations that would adhere to the colonic lining promoting longer drug retention. Most of these formulations only require once daily administration to achieve maximal benefit. Although most of the modern-day preparations contain the same 5-ASA (mesalamine), the various forms do not necessarily optimally target the same regions of the bowel. Thus, factors such as disease location and intestinal transit time may influence drug selection.

Also developed were rectally delivered 5-ASA preparations that had the advantage of providing extraordinarily high concentrations of the medication in the distal colon of patients with mostly distal colitis. They also found use in combination with oral 5-ASA to more effectively treat the entire colon. Disadvantages include the difficulty retaining rectally administered 5-ASA for an adequate length of time in the face of active proctitis, and patient emotional resistance to the use of rectal medications.

The use of 5-ASA in CD is controversial. It appears that 5-ASA is minimally effective in CD. Their use in CD is limited mostly to small subsets of patients with minimal disease who may not require or desire medications more adverse side effects. They also may be employed in patient with Crohn's or indeterminate disease limited mostly to the colon.

The drug has many proposed mechanisms of action. For instance, they are stated to inhibit proinflammatory processes such as NF $\kappa$ B activation ([Bantel et al., 2000](#)) and IL1 production ([Mahida et al., 1991](#)). Still others propose that they impede TNF $\alpha$  binding ([Shanahan et al., 1990](#)) and scavenger injurious free radicals ([Ahnfelt-Ronne et al., 1990](#)).

5-ASA has a high safety profile. Toxicity can include interstitial nephritis that develops in perhaps one in 500 patients. This can lead to permanent renal dysfunction. Thus, the chronic use of these medications requires routine monitoring of blood creatinine levels. Other problems may include temporary nausea or hair loss. There are unusual reports of 5-ASA-inducing pulmonary fibrosis, allergic reactions, and paradoxical worsening of disease. They appear safe for use during pregnancy.

## Glucocorticoids

Corticosteroids are commonly employed for the acute management of IBD ([Katz, 2004](#)). However, their use has greatly diminished since the development of new alternative therapies. No other treatment provides such a rapid and major clinical benefit in both patients with UC and CD. They can be life-saving for patients with extreme flares of UC (e.g., toxic megacolon). However, there are many patients with IBD flare who do not respond to corticosteroids or only do so if the medication is given at high dosage. Progressive steroid resistance is common in patients who repeatedly cycle on and off of these medications. Some patients relapse as the dose is diminished and cannot wean off. This is a condition called “corticosteroid dependency.”

Corticosteroids given rectally or orally, depending on the extent and severity of disease, can induce remission in patients with UC. Rectal medications of all types administered in foam formulation are retained the longest. Some patients with relatively mild or moderate UC, often taking maintenance 5-ASA, occasionally flare. Some of these patients can be brought back into prolonged remission with a 1–2 month course of steroid therapy associated with a slow and prolonged steroid taper. Such patients may not need to progress to other medications.

Steroids are less effective at inducing clinical remission in CD, and relapse occurs more readily since this therapy does not usually induce complete healing of intestinal lesions. Because of their speed of action, corticosteroids frequently are used as bridging therapy to allow some other concomitantly administered slower acting

medication to take hold. Corticosteroids are not effective maintenance therapy in either UC or CD. Thus, it is preferable to avoid their long-term use.

A major problem with corticosteroids is that they enter the systemic circulation and cause short and long-term side effects. The chronic use of steroids can induce cataracts and osteoporosis. They can induce aseptic necrosis of bones often requiring joint replacement. Other side effects may include insulin resistance (diabetes), hypertension, muscle weakness (myopathy), increased risk of infection, insomnia, acne, undesirable weight gain, mood changes, increased intraocular pressure (glaucoma), "moon face" and adrenal insufficiency.

Budesonide is an oral glucocorticoid that undergoes extensive first-pass metabolism in the liver (Abdalla and Herfarth, 2016). Perhaps 10% or less of this medication enters the systemic circulation when taken orally. Budesonide has been formulated to reach the terminal ileum and/or colon after oral administration, and it is much less likely to cause systemic side effects than conventional steroids. Budesonide given rectally can induce short-term improvement or clinical remission in UC of the distal colon (Rubin et al., 2015; Sandborn et al., 2015). Also, administered orally, it can induce improvement or remission in UC that extends throughout the colon and in CD. As with other corticosteroids, they quickly lose efficacy with long-term use. Budesonide is less efficacious than other corticosteroids that reach the systemic circulation. It is most commonly used in patients who have a relative contraindication for the use of the more powerful systemic corticosteroids or who cannot tolerate their side effects.

Corticosteroids work via the engagement of a specific cytosolic steroid receptor. The engaged receptors translocate to the nucleus affecting transcription of various genes in a multitude of cell types (Carlstedt-Duke and Gustafsson, 1987). They affect the production of many cytokines, activation of lymphocytes, release of arachidonic acid metabolites, and function of macrophages.

### **Thiopurines**

The thiopurines include azathioprine and 6-mercaptopurine (6-MP). Azathioprine is metabolized in the body to 6-MP, which in turn is broken down to other metabolites.

There is dispute regarding the overall value of thiopurines in the management of UC and CD (Axelrad et al., 2016). Thiopurines are used in UC and CD for the induction and maintenance of clinical remission. Thiopurines are slow-acting agents that may require 2–4 months to take effect. In highly symptomatic patients, their use may require temporary concomitant bridging therapy with corticosteroids-like prednisone or budesonide to suppress symptoms sufficiently to allow time for the thiopurine to work. They also can help close perianal fissures and fistulae.

Also, anti-TNF therapy achieves a higher rate of short- and long-term remission when used in combination with thiopurines. This is due, at least in part, to the ability of thiopurines to inhibit neutralizing antibody responses to anti-TNFs, which are immunogenic molecules. It also slows metabolism of anti-TNFs allowing higher anti-TNF blood level.

Thiopurine therapy has other applications. It is employed to decrease postoperative CD recurrence after bowel resection. They also have "corticosteroid-sparing" properties, allowing reduction or discontinuation of steroids in patients requiring continuous or frequent steroid use. However, recent trials in CD found azathioprine ineffective at achieving sustained corticosteroid-free remission (Cosnes et al., 2013; Panes et al., 2013).

Thiopurines are most effective when used at dosages just below the toxic range. Thus, the use of thiopurines requires close monitoring. Perhaps 20% of patients starting on thiopurines develop, in the first month of use, serious side effects including pancreatitis, myelosuppression, fever, rash, malaise, muscle, and/or joint pain requiring drug discontinuation. Leukopenia, hepatitis, and pancreatitis also can develop latter in therapy. Dose reduction can manage mild hepatitis and leukopenia. Acceptable therapeutic side effects of these medications are moderate lymphopenia and mild anemia with red-cell macrocytosis. Thiopurines predispose patients to infections. This includes cutaneous warts. Thiopurines are carcinogenic agents predisposing patients most notably to basal and squamous cell carcinoma of the skin as well as lymphoma. Azathioprine and 6-MP are similar medications. An adverse drug reaction to one predicts a similar adverse reaction to the other. However, with all these toxicities, present studies have revealed no reason to discontinue thiopurines during pregnancy.

In the body, competing metabolic pathways degrade 6-MP. The enzyme thiopurines methyltransferase (TPMT) converts 6-MP to 6-methylmercaptopurine. Patients with loss- or reduction-of-function genetic variants of TPMT shunt 6-MP into other metabolic products that can induce profound leukopenia. Screening patients for TPMT deficiency can reduce but does not obviate the risk of leukopenia and other toxicities in thiopurine therapy.

The mechanism of action of thiopurines is mediated by its metabolites (Coskun et al., 2016). 6-Thioguanine nucleotides incorporate as false purine analogs into RNA or DNA inducing immunosuppressive and cytotoxic effects. It also is proposed that the metabolite 6-thioguanine triphosphate inhibits T-cell activation and proliferation.

### **Methotrexate**

Methotrexate (MTX) has a place in the management of IBD (Coskun et al., 2016; Herfarth et al., 2016). It is a folate analog that inhibits dihydrofolate reductase, which interferes with DNA synthesis. It has antiinflammatory and proapoptotic activity. MTX is efficacious for induction and maintenance of remission in CD. MTX possibly is beneficial in UC when dosed properly. Due to better drug availability, the benefit of the drug is seen with weekly intramuscular (15–25 mg) but not oral administration. When used in combination with anti-TNF therapy, it suppresses anti-TNF antibody formation. MTX is given with folate supplementation to minimize side effects induced by the effect of the drug on folate metabolism and folate-dependent pathways.

The most common side effect is nausea developing shortly after drug administration. This may disappear with dose reduction or may be manageable with antiemetics. Among others, additional side effects may include diarrhea, hepatitis, and myelotoxicity. MTX is teratogenic making it risky to use in woman in their reproductive years and is contraindicated in lactating women.

### **Cyclosporine**

Cyclosporine is useful as a rescue therapy in patients with life-threatening, corticosteroid-resistant UC. It has significant side effects including nephrotoxicity, hypertension, and seizures, which limits its utility. Anti-TNF medications have better long-term tolerability relegating cyclosporine to second-class status, although they induce clinical remission at comparable rates (Narula et al., 2016). A potential utility is in patients with life-threatening UC with previously proven anti-TNF resistance. In this situation, cyclosporine may prove useful as a therapeutic bridge to some other slower acting alternative therapy. Cyclosporine inhibits calcineurin, which is a cytoplasmic enzyme needed for T-cell activation.

### **Anti-TNF Therapies**

Anti-TNF therapies [e.g., infliximab, CT-P13 (infliximab biosimilar), adalimumab, golimumab, certolizumab] were major advances in the management of IBD. All but certolizumabs are derivatives of IgG1 monoclonal antibodies directed against TNF and are given intravenously (infliximab, CT-P13) or subcutaneously. These bind Fc receptors strongly. Certolizumab is a pegylated anti-TNF(ab)2 fragment lacking the Fc-binding site. Anti-TNFs appear to work through engaging TNF bound to the surface of activated lymphocytes causing them to undergo cell death (apoptosis) (Levin et al., 2016). There also may be some Fc-dependent mechanisms of action as well.

Anti-TNFs can induce and maintain remission in UC and CD. They can close fistulae and may have efficacy in maintaining remission in postoperative patients with CD (Regueiro et al., 2016; Carla-Moreau et al., 2015). Infliximab remains the anti-TNF of choice for patients with steroid-resistant, life-threatening UC because of its perceived speed of action. Anti-TNF therapy was the first treatment to frequently induce total mucosal healing in patients with IBD. Unfortunately, large numbers of patients do not respond to anti-TNFs, and some drug responders eventually develop drug resistance and relapse.

One frequent cause of resistance is the development of antibodies that block the action of anti-TNF and speed drug clearance. Concomitant administration of immunomodulators (e.g., thiopurines or MTX) reduces the incidence of antibody development. Switching to a molecularly dissimilar anti-TNF medication will overcome antibody-induced, anti-TNF resistance. However, it is necessary to switch to other classes of medications that function independent of TNF blockade if a patient is a primary anti-TNF nonresponder or subsequently develops resistance to the medication in the absence of blocking antibodies.

Optimal dosing of anti-TNFs affords the best results (Ding et al., 2016). This requires occasional drug monitoring to check drug levels and to detect the early development of anti-TNF antibodies. However, drug testing is not yet a completely reliable science. Patients with low levels of drug in their blood stream just before the next dose of the medication are more prone to relapse. Another sign of “underdosing” is the development of symptoms prior to the next dose of the medication.

Anti-TNF therapy is not without significant potential side effects. These drugs leave patients more prone to infections. Patients with latent tuberculosis, occult histoplasmosis, or carriers of the hepatitis B virus are at great risk of the activation of their latent infection. Significant abscesses should be drained and treated with antibiotics before initiating anti-TNF therapy. Anti-TNFs can worsen congestive heart failure, exacerbate multiple sclerosis,

and trigger psoriasis. They can induce hepatitis, cause serious allergic reactions, and perhaps predispose to lymphoma. They appear safe to use in pregnancy (Androulakis et al., 2015).

### **Anti-IL12/13 Therapies**

Ustekinumab (Stelara) is a fully human IgG1 monoclonal antibody that binds to the shared p40 subunit of the IL12 and IL23 receptor, blocking IL12/IL23 activity. IL12 and IL23 drive the production of the important proinflammatory cytokines IFN $\gamma$  and IL17, respectively (Catana et al., 2015). One or both of these cytokines likely drive the pathological inflammation in some patients with CD.

In 2016, it was approved for the treatment of moderate-to-severe CD in patients older than 17. For several years, ustekinumab has been used for the treatment of psoriasis at lower doses than that for CD. Eight weeks after initiation of the therapy, two randomized double-blind phase III trials in CD revealed that ustekinumab induced remission in about 15%–20% more patients than that of placebo and proved efficacy. A 44-week extension trial containing patients who responded or went into remission at week-8 showed that about 15% more test subjects were in remission than those receiving placebo. Response rates were somewhat higher, although still only about 15% better than placebo. Patients who failed anti-TNF therapy were less likely to respond. More extensive use of this medication in clinical practice will help determine the actual benefit of ustekinumab in CD (Deepak and Loftus, 2016; Feagan et al., 2016).

Ustekinumab is a reasonable choice for patients refractory or intolerant to TNF antagonists. Its overall efficacy seems similar to that of the antiintegrin vedolizumab. It has the advantage of subcutaneous versus intravenous administration, which is required for vedolizumab. It could be advantageous for some CD patients with concomitant psoriasis or PG, which are conditions unresponsive to vedolizumab. It is not yet established if ustekinumab readily closes fistulae or benefits patients with various extracolonic manifestations of CD.

Ustekinumab appears to have a good safety profile in CD. Serious adverse events using this drug are similar or close to that of placebo. There is extremely limited data regarding the use of this medication during pregnancy. Also, there is a low incidence of antibody development against this biologic.

Under investigation is a selective inhibitor of the p19 subunit of the IL13 receptor that only blocks IL23. Present data suggest that this will prove beneficial in CD.

### **Inhibitors of Leukocyte Infiltration**

Another approach for the treatment of IBD is blocking the infiltration of lymphocytes into the intestinal wall. The first drug in this class was natalizumab, which bound the  $\alpha 4$  component of the two integrins  $\alpha 4\beta 1$  and  $\alpha 4\beta 7$ . While proving efficacious for CD, it also promoted the development of John Cunningham (JC) virus-induced, progressive multifocal leukoencephalopathy. This is a dangerous and neurologically devastating disease. Thus, natalizumab is rarely, if ever, used in the clinical management of IBD.

Vedolizumab, a humanized monoclonal antibody, is a selective inhibitor of the  $\alpha 4\beta 7$  integrin expression on lymphocytes. The integrin  $\alpha 4\beta 7$  binds exclusively to the mostly gut-specific addressin MAdCAM1, an adhesion molecule located primarily on intestinal vascular endothelial cells. Blockade of  $\alpha 4\beta 7$  impedes lymphocyte adhesion to the endothelium. This, in turn, prevents the egress of memory CD4+ T cells into the gut and perhaps mesenteric lymph nodes.

Vedolizumab has proven effective in UC and, to a lesser degree, in CD (Feagan et al., 2013; Sandborn et al., 2013). It is not proven that this drug can close fistula in CD, and it is of questionable value managing extraintestinal problems associated with IBD such as joint pain, ankylosing spondylitis, EN, and uveitis. It could be a desirable therapy in patients with ongoing nonintestinal infections, multiple sclerosis, heart failure, TNF-induce psoriasis, and patients undergoing chemotherapy for cancer.

The incidence of major adverse events to vedolizumab is close to that of placebo (Novak et al., 2017). Unlike natalizumab, the selectivity of vedolizumab only for  $\alpha 4\beta 7$  allows the infiltration of lymphocytes into the CNS, and it does not increase the risk of developing progressive multifocal leukoencephalopathy. Patients can develop antibodies to vedolizumab that block drug action (perhaps 5%), and can have allergic reactions. Over time, patients can develop nonantibody-mediated drug resistance. It may predispose to sinus and upper respiratory infections. This medication requires intravenous administration, which is an additional expense and inconvenience. Other similar agents under development will allow subcutaneous and perhaps oral use. Among these may include medication that directly blocks MAdCAM1.

Ozanimod is an inhibitor of the sphingosine-1-phosphate receptor subtype 1 and 5 (S1P1). It shows promise in UC (Sandborn et al., 2016). S1P1 is located on lymphocytes. Blockade of this molecule prevents the vascular adhesion and egress of lymphocytes out of lymph nodes. The drug is orally administered.

### **Janus Kinase Inhibitors and Some Other Medications on the Horizon**

Tofacitinib, an inhibitor of JAK 1 and 3, and upadacitinib and filgotinib, which are selective blockers of JAK1, appear to have efficacy in IBD. Tofacitinib is used to manage rheumatoid arthritis and psoriasis, and showed benefit in UC (Sandborn et al., 2017). Upadacitinib may prove effective in both UC and CD with fewer side effects. JAKs are important intracellular signaling pathways that drive proinflammatory responses.

Smad7 blockade, using an orally active, gut-directed mRNA inhibitory oligonucleotide, showed promise in CD (Monteleone et al., 2015). Smad7 is a natural inhibitor of T-cell TGF $\beta$  signaling. Blockade of Smad7 allows TGF $\beta$  to more effectively stimulate the development of regulatory T cells and block inflammation. However, advanced phase 3 trials in CD and UC failed to show efficacy.

### **Nutritional Support**

It is appreciated that patients with CD, but not UC, often quickly go into remission and close fistulae if they are nutritionally restricted to enteral or intravenous feeding solutions (called bowel rest). Some data suggest that enteral and parenteral feeding is comparably effective. The disease rapidly returns with the resumption of a regular diet. There is prolonged benefit if the patient maintains the dietary restriction. This form of therapy can prove beneficial as a bridging therapy in patients with advanced CD who need time to respond to some other, slower acting medication and who do not respond to or tolerate rapid acting corticosteroids. Also, it provides life-saving support to CD patients with short bowel syndrome often resulting from repeated small bowel resections and to people suffering from severe nutritional depletion.

The mechanism of action is unknown. It is assumed that patients benefit from the reduction of the bacterial and antigenic load in the distal bowel.

### **Surgical**

The development of new medications to manage IBD has decreased the need for major bowel resections and fistula repairs.

The surgical indications for UC include toxic megacolon, severe disease unresponsive to appropriate therapy, development of colonic dysplasia or cancer, significant side effects to medication, steroid dependency, severe hemorrhage, unremitting disease that severely impairs quality of life, and intractable severe EIM of IBD (Bohl, 2015). Surgery usually involves total colectomy often using minimally invasive surgical approaches.

Most patients, particularly below the age of 60, receive a surgically constructed ileal J-pouch attached to the anal verge to retain fecal continence and to avoid an ileostomy (Bohl, 2015). People with a J-pouch have to defecate about 5.5 times daily and some have seepage. Removal of the colon should in theory cure UC, since the inflammation of UC is limited to the colon with the exception of the occasional patient with "back-wash ileitis." However, patients with J-pouches can get complications, and they not infrequently develop "pouchitis" requiring intermittent medical therapy (Bohl, 2015). In perhaps 10%–20% of such patients, pouchitis morphs into a condition that looks like CD requiring intensive medical therapy and sometimes removal of the pouch.

Ileostomies may be desirable for people having dysfunctional anal sphincters, do not want the two to three surgeries required to create a J-pouch, or who are older and perhaps physically unfit for multiple surgeries. It also is needed for patients with J-pouches that failed due to recurring disease. Ileostomies require the patient to wear a bag to collect daily stool output, which necessitates emptying the bag a few times daily. Ileostomies are subject to various medical problems (Bafford and Irani, 2013). Also, perhaps 5%–10% of patients having an ileostomy for treatment of classic UC eventually develop CD in their terminal ileum.

The surgical indications for CD are similar to UC (Harb, 2015; Toh et al., 2016). After resection of the diseased segment of bowel, unlike UC, CD almost inevitably returns to previously healthy regions of the gut. CD occurs most frequently in the ileocecal area. Thus, the most common surgery is ileocecal resection with subsequent attachment of the residual ileum to the colon. For CD limited to the ileal/cecal region, recurrence rates after resection are about 70%–90% in the subsequent 5–10 years after surgery.

In CD, complications resulting from strictures and fistula formation may require surgery. Patients with previous extensive small bowel resection or with multiple short segments of small bowel narrowing may receive a "stricturoplasty" to widen these areas of narrowing avoiding further bowel resection.

Fistulae develop in about 30% of the CD patients (Schwartz et al., 2002). There are various bowel-sparing medical and surgical approaches for management of perianal fistula in CD.

## FUTURE PROSPECTS

We live in an exciting time in which scientific research has identified many of the molecules and processes that drive and regulate inflammation. Advances in our appreciation of the workings of mucosal immunity and the intestinal microbiome are no less spectacular. Serendipity no longer dictates drug discovery in IBD. The new medications to treat IBD and those under development represent attempts to block or modulate the newly discovered inflammatory pathways that are assumed to drive IBD. This has resulted in a high rate of success leading to increasing availability of exciting new medications to treat these diseases. This process will continue. "Biologic" therapy based on monoclonal antibody technology has its limitations. Newer targeting strategies will allow the oral administration of medications that inhibit the same pathways, which in many cases could render "biologics" obsolete.

We used to consider IBD just two distinct entities, UC and CD. Investigation of the genomics of IBD failed to identify distinct gene variants that underlay the pathology. Rather, IBD probably is a larger collection of disorders with overlapping clinical phenotypes.

This makes therapy much more difficult. Many of the new medications provide major benefit to small subsets of the entire IBD patient population. Each of these new agents requires several months of administration before establishing efficacy. Thus, successful therapeutic intervention could follow many months of trial and failure, a significant clinical problem. Thus, happenstance, rather than logical therapeutic selection, will be the approach to treatment until we learn more about the underlying pathophysiology of each of these diseases.

The therapeutic road in IBD is littered with patients who experienced spectacular successful treatment followed by relapse for unknown reasons. This just illustrates how much more we need to learn about mucosal immune regulation and our immune interactions with the intestinal microbiome.

The present understanding of disease pathogenesis does not explain many clinical observations. For example, in both UC and CD, disease can be highly segmental with razor sharp cutoffs. Extensive mucosal biopsy, which disrupts the mucosal barrier, does not spread the disease. Nutritional support can place nearly all forms of CD into temporary clinical and endoscopic remission but fails to control the raging inflammation of UC. We have a lot to learn.

Not all patients have an aggressive clinical course. Not every patient requires early intervention with expensive and sometimes risky therapies. Presently, we have limited ability to stratify patients according to risk.

Colonoscopy remains the "gold standard" for assessing disease progression and other risks. Symptoms often are unreliable indicators of disease activity. Required are more inexpensive and less invasive tests to predict disease activity. This could permit earlier, appropriate therapeutic intervention to prevent disease progression, permanent intestinal damage, and cancer.

IBD is a growing menace around the world with increasing clinical and economic impact. It was a rare disease in the early 20th century, but now is quite common. It has a huge emotional, financial, and social impact on the patients and their families. The solution to IBD is not just the development of new medications, but the discovery of the environmental factors which allow emergence of these diseases. Poorly defined changes in daily living are the major cause of IBD. Modifications in life style, everyday exposure or avoidance of particular environmental factors, could be the ultimate solution to these diseases.

## HISTORICAL BACKGROUND

The earliest descriptions of autoimmune hemolytic anemia (AIHA) date from the 19th century, and the disease was one of the first shown to have an autoimmune pathology. Pioneering work by [Donath and Landsteiner \(1904\)](#) demonstrated that the destruction of red blood cells (RBC) was dependent on the absorption of hemolysins and complement from serum. Further studies were impeded by the difficulty in distinguishing acquired from congenital hemolytic anemias, but an important advance was made using the antiglobulin, or Coombs', test, which detected RBC coated with autoantibodies by agglutinating them with antiserum to human globulin ([Coombs et al., 1945; Boorman et al., 1946; Loutit and Mollison, 1946](#)). Methods for measuring survival of circulating cells in vivo further demonstrated that RBC from patients with acquired hemolytic anemias were destroyed by a "random hemolytic process," rather than being "intrinsically defective" ([Loutit and Mollison, 1946; Mollison, 1959](#)). Together, these developments identified AIHA as a disease in which autoantibodies bind

**TABLE 47.1** Classification of Autoimmune Hemolytic Anemia (AIHA)

	Cold reactive	Warm reactive
<b>CLASSIFICATION BY AUTOANTIBODY TYPE</b>		
Optimum temperature for binding RBC	4°C	37°C
Predominant autoantibody class	IgM (cold agglutinin syndrome) IgG (paroxysmal cold hematuria)	IgG
Predominant site of hemolysis	Intravascular	Extravascular (spleen, liver)
Predominant mechanism of hemolysis	Complement lysis (membrane attack complex)	Phagocytosis via macrophage IgG Fc and complement receptors
<b>CLASSIFICATION BY UNDERLYING DISEASE</b>		
Primary (idiopathic)		Secondary
No underlying disease		Underlying disease (causal or shared etiology)
		Infection
		Other immune disease neoplasia
		Drug induced

RBC and shorten their lifespan, affecting 1–3 per 100,000 of the population (Sokol et al., 1992; Petz and Garratty, 2004a).

## CLASSIFICATION OF AUTOIMMUNE HEMOLYTIC ANEMIA

AIHA can be classified both by the type of autoantibody and by the presence of underlying disease (Sokol et al., 1992; Petz and Garratty, 2004a) (Table 47.1). Pathogenic autoantibodies are divided into either cold (Petz, 2008) or warm (Packman, 2008) reactive, depending on the optimum temperature at which they bind RBC. Up to 7% of the patients have “mixed” pathogenic autoantibodies of both types (Sokol et al., 1981, 1983, 1992). AIHA can also be described as primary, or idiopathic, in the absence of any associated condition, or as secondary if there is a concurrent disease that may be considered causal or has shared etiology (Packman, 2008; Petz, 2008).

## ANIMAL MODELS OF AUTOIMMUNE HEMOLYTIC ANEMIA

Examples of AIHA in laboratory mice have proved valuable in understanding the pathogenesis of the disease. The New Zealand Black (NZB) mouse (Helyer and Howie, 1963; Barker et al., 1993b) develops AIHA spontaneously, and hemolysis can be recapitulated by transgenic expression of a monoclonal anti-RBC autoantibody derived from this strain (Murakami et al., 1992). AIHA is also one of the autoimmune pathologies arising in the nonobese diabetic mouse (Baxter and Mandel, 1991) and from genetic modification to prevent expression of interleukin-2 (IL-2) (Hoyer et al., 2009). In addition to these spontaneous examples, the disease can be induced in healthy murine strains by repeated immunization with rat RBC (Playfair and Marshall-Clarke, 1973; Naysmith et al., 1981) or by infection of C3HeB/FeJ mice with the docile strain of lymphocytic choriomeningitis virus (LCMV) (Coutelier et al., 1994).

AIHA has also been described as a cause of anemia in the domestic dog (Barker et al., 1991), cat (Switzer and Jain, 1981), rabbit (Fox et al., 1971), horse (Mair et al., 1990), and ox (Dixon et al., 1978).

## MECHANISMS OF RED BLOOD CELLS DESTRUCTION IN AUTOIMMUNE HEMOLYTIC ANEMIA

AIHA is a classic example of type II hypersensitivity, with autoantibody-coated RBC removed from the circulation by phagocytes of the reticuloendothelial system (RES), predominantly splenic macrophages, and/or lysis by complement fixation (Packman, 2008; Petz, 2008). Anemia results if the hemolysis is insufficiently compensated for by increased RBC production.

### Cold Reactive Antibodies

Cold reactive anti-RBC autoantibodies are responsible for 15%–20% of human AIHA cases (Petz, 2008). They bind more strongly at 4°C than at higher temperatures, and the pathogenic effects of these antibodies depend more on their thermal amplitude than their titer. Cold autoagglutinins that bind RBC below 10°C–15°C can be demonstrated in the sera of most healthy individuals (Landsteiner and Levine, 1926). In contrast, cold autoantibodies active up to 30°C are associated with cold agglutinin syndrome (CAS) (Petz, 2008), since temperatures in the peripheral circulation can fall below this level. The antibody, usually immunoglobulin (Ig) M, causes intravascular hemolysis if it activates complement to form membrane attack complexes (MAC) (Engelfriet et al., 1981; Petz and Garratty, 2004b), overcoming protective regulators on the RBC such as CD35 (complement receptor 1 CR1), CD55 (decay-accelerating factor), and CD59 (protectin) (Nicholson-Weller et al., 1982; Krych-Goldberg and Atkinson, 2001; Ruiz-Argüelles and Llorente, 2007). RBC coated with C3b may also be temporarily sequestered by macrophages (Engelfriet et al., 1981). In some patients, cold IgM autoantibodies agglutinate RBC in extremities that become chilled, blocking small blood vessels and causing ischemia (Petz, 2008). CAS can be either transient, most frequently as a complication of mycoplasma infection (Costea et al., 1972), or chronic, typically associated with clonal lymphoproliferative disease (Berentsen et al., 2006).

Pathogenic cold reactive autoantibodies also include the Donath–Landsteiner (DL) hemolysins, which cause paroxysmal cold hemoglobinuria (PCH), a dramatic form of AIHA precipitated by chilling of the patient (Petz, 2008). These antibodies, which are IgG, bind RBC if the temperature falls below 37°C, and then fix complement to trigger MAC formation and fulminant intravascular hemolysis when warmed again. PCH was commonly secondary to syphilis when it was first described in the late 19th century but is now rare and typically follows childhood viral infections (Sokol et al., 1982, 1984, 1999).

### Warm Reactive Antibodies

Warm autoantibodies are the most common cause of AIHA and react as well, or more strongly, with RBC at 37°C than at lower temperatures (Sokol et al., 1992; Packman, 2008). Most are of the IgG class and cause extravascular hemolysis, predominantly by Fc receptor (FcγR)-mediated phagocytosis (Engelfriet et al., 1981; Petz and Garratty, 2004b; Packman, 2008). The complement regulators on the RBC membrane (Ruiz-Argüelles and Llorente, 2007) typically prevent MAC formation, but deposition of C3b and C3d is common and can strongly enhance opsonization (Kurlander et al., 1978) by interacting with specific receptors including CR1 and CR3 (Ross and Medof, 1985). Although blood monocytes and hepatic Kupffer cells also express appropriate sets of receptors, splenic macrophages are the main effectors of RBC destruction (Engelfriet et al., 1981; Petz and Garratty, 2004b; Packman, 2008). Some sensitized RBC may be only partially phagocytosed and released back into the circulation as spherocytes, which have a short half-life (Garratty, 1983).

Between 22% (Dausset and Colombani, 1959) and 81% (Pirofsky, 1976) of warm AIHA cases have been reported to be secondary, varying with different interpretations of this classification. The most common associations are with other immune-based conditions, most notably ulcerative colitis, rheumatoid arthritis, and systemic lupus erythematosus (SLE), with neoplasia, particularly chronic lymphocytic leukemia (CLL), with a growing number of drug treatments (Garratty and Arndt, 2014), and with a variety of infectious diseases (Sokol et al., 1992; Petz and Garratty, 2004a).

### Pathogenicity of Warm Reactive IgG Antibodies

Warm reactive IgG anti-RBC autoantibodies vary in their pathogenicity, exemplified by the finding of a positive direct agglutination test (DAT) in a small proportion (1 in 7–15,000) of healthy blood donors (Hernandez-

Jodra et al., 1990; Win et al., 1997; Petz and Garratty, 2004b). The ability to cause hemolysis has been attributed to multiple factors, including titer, subclass, affinity for autoantigen, patterns of heavy chain glycosylation, and also the activity of phagocytes responsible for clearance (Garratty, 1990; Sokol et al., 1992; Petz and Garratty, 2004b).

The amount of IgG blood group alloantibody-coating RBC determines their rate of clearance in healthy subjects (Mollison and Hughes-Jones, 1967; Kelton et al., 1985), but it is less easy to demonstrate a similar relationship for autoantibodies in human AIHA (Rosse, 1971; Chaplin, 1990; Petz and Garratty, 2004b). Serial measurements from individual patients reveal some correlation of hemolysis with autoantibody titer, but many cross-sectional studies fail to do so, using either the DAT or more sensitive and quantitative flow cytometric or ELISA-based techniques to measure RBC-bound IgG (Van der Meulen et al., 1980; Garratty and Nance, 1990; Sokol et al., 1992; Petz and Garratty, 2004b). Autoantibody titer alone also appears to be an unreliable predictor of the severity of hemolysis in canine (Barker et al., 1992b) and murine AIHA (Naysmith et al., 1981; Shen et al., 2003).

The subclass of RBC autoantibody is a potentially important factor in its ability to cause hemolysis, by determining interactions with different types of Fc $\gamma$ R and fixation of complement (Sokol et al., 1992; Petz and Garratty, 2004b). Comprehensive analyses of IgG subclass switch variants of monoclonal anti-RBC antibodies originally derived from NZB mice have established how differences in these Fc-associated effector functions can critically influence pathogenicity (Baudino et al., 2006), with affinity for autoantigen playing a less important role (Fossati-Jimack et al., 1999). In mice there are three activating Fc $\gamma$ R types (Fc $\gamma$ RI, Fc $\gamma$ RIII, and Fc $\gamma$ RIV), all of which are expressed on macrophages and can bind complexed IgG, while only Fc $\gamma$ RI also has high affinity for monomeric IgG (Nimmerjahn and Ravetch, 2008). IgG2a and IgG2b autoantibody switch variants, each of which interacts efficiently with Fc $\gamma$ RIII and activate complement, and mediate the most severe hemolysis in vivo (Baudino et al., 2006). Fc $\gamma$ RIV makes an additional contribution to uptake by these isotypes, and IgG2a also promotes clearance via Fc $\gamma$ RI if it coats RBC at sufficient density to compete with the free monomer in serum (Baudino et al., 2008). The next most pathogenic subclass is IgG3, which activates complement but does not bind any Fc $\gamma$ R, followed by the IgG1 subclass that interacts only with Fc $\gamma$ RIII and fails to fix complement. Overall, IgG2a and IgG2b autoantibodies are 20-fold more potent in causing hemolysis than IgG1 (Baudino et al., 2006). Complement fixation by the murine autoantibodies does not lead to MAC formation, but CR-mediated erythrophagocytosis can be important if there is an extensive opsonization of RBC by C3 associated with binding of high-affinity IgG2b or IgG3 (da Silveira et al., 2002).

Compared with murine studies, the relationships between human RBC autoantibody subclass and hemolysis are less clear (Petz and Garratty, 2004b). Based on interactions with Fc $\gamma$ R and complement, IgG3 would be predicted to be the most pathogenic subclass, followed by IgG1, with IgG2 and IgG4 relatively benign (Engelfriet et al., 1981; Petz and Garratty, 2004b; Sokol et al., 1992). However, in both patients with AIHA and healthy DAT-positive donors with no evidence of hemolysis, IgG1 autoantibody predominates and is the only isotype detected on RBC using agglutination-based techniques in up to 80% of each group (Garratty, 1989). Furthermore, IgG3 can be detected by DAT not only in patients but also in normal blood donors, although RBC sensitization with IgG4 alone may be restricted to healthy individuals (Garratty, 1989). Sensitive flow cytometric and ELISA methods (Sokol et al., 1990a; Garratty and Nance, 1990) have confirmed that increased levels of RBC-bound IgG3 are not necessarily associated with disease and suggest instead that autoantibodies of multiple IgG subclasses are common in AIHA and that this diversity is important in promoting hemolysis via synergistic effects (Sokol et al., 1990a). The three families of human activating Fc $\gamma$ R (Fc $\gamma$ RI, Fc $\gamma$ RIIa/Fc $\gamma$ RIIc, and Fc $\gamma$ RIIIa/Fc $\gamma$ RIIIb) (Nimmerjahn and Ravetch, 2008) may each play a role in RBC uptake. As in mice, only Fc $\gamma$ RI has a high affinity for monomeric IgG but may mediate erythrophagocytosis under conditions that allow RBC-bound IgG to compete with a monomer in serum, particularly in the hemoconcentrated environment of the spleen (Kelton et al., 1985; Barker et al., 1992b). Although MAC formation rarely contributes to hemolysis in the patients with warm antibodies, complement fixation appears to be an important determinant of disease (Petz and Garratty, 2004b). C3 can be detected by DAT in up to 50% of AIHA patients (Garratty, 1989) and is quantitatively associated with hemolysis (Freedman et al., 1982), reflecting synergy between Fc $\gamma$ R and CR in RBC uptake (Sokol et al., 1992).

Changes in glycosylation of the CH2 domain of the IgG heavy chain may also influence interactions with Fc $\gamma$ R and complement, with loss of either terminal sialic acid or galactose residues suggested to alter the pathogenicity of murine RBC autoantibody (Baudino et al., 2006). There is evidence in rheumatoid arthritis that IgG lacking galactose (G0) can interact with mannose-binding protein, thereby fixing complement and triggering inflammation (Malhotra et al., 1995). However, in AIHA it seems likely that RBC autoantibody may be less hemolytic than G0, since the loss of galactose reduces the affinity of IgG for Fc $\gamma$ RIII (Hadley et al., 1995). Although G0 RBC

autoantibodies have been identified in some AIHA patients and in NZB mice, the levels can vary widely over time in individuals and show no correlation with the severity of the disease (Barker et al., 1999a,b).

The final, important, factor determining the hemolytic potential of warm autoantibodies is the effectiveness of the RES in clearing sensitized RBC (Sokol et al., 1992; Petz and Garratty, 2004b). The ability of macrophages to phagocytose RBC can be enhanced by infections that upregulate Fc $\gamma$ R expression (Atkinson and Frank, 1974; Coutelier et al., 2007) or compromised by saturation with immune complexes in AIHA secondary to SLE (Frank et al., 1979). Drugs such as corticosteroids can also inhibit phagocytosis by downregulating Fc $\gamma$ R expression (Fries et al., 1983; Kelton, 1985). The cytokine milieu is a major influence on macrophage activation state, and the severity of NZB AIHA can be ameliorated by gene therapy to increase levels of circulating IL-4 (Youssef et al., 2005).

## Additional Mechanisms of Hemolysis by Warm Antibodies

Although Fc $\gamma$ R- and CR-mediated erythrophagocytosis of IgG-coated RBC is the major cause of hemolysis in warm AIHA, there is evidence for other pathogenic mechanisms (Sokol et al., 1992; Petz and Garratty, 2004b).

In rare patients with warm AIHA, the main autoantibody class may be IgM or IgA, and not IgG. If warm IgM autoantibodies predominate, they can trigger MAC formation and fulminant intravascular hemolysis (Freedman et al., 1987). IgA autoantibodies may cause hemolysis by Fc-mediated uptake and cytotoxicity (Clark et al., 1984), or hemagglutination in the spleen (Baudino et al., 2007). More sensitive techniques than the DAT detect a higher prevalence of cosensitization of IgG with low levels of IgM and/or IgA, and such coating of RBC with multiple antibody classes is associated with severe hemolysis, suggesting the importance of synergistic effects (Sokol et al., 1990b).

**TABLE 47.2** Red Blood Cells Autoantigens in Human Autoimmune Hemolytic Anemia (AIHA) Caused by Cold Autoantibodies

Form of AIHA	Common autoantibody Specificity	Rare autoantibody Specificity
CAS	I (~90% patients)	i, Pr, A, B
PCH	P (~90% patients)	i, p, HI, I

CAS, Cold agglutinin syndrome; PCH, paroxysmal cold hematuria.

**TABLE 47.3** Red Blood Cells (RBC) Autoantigens in Human and Animal Autoimmune Hemolytic Anemia (AIHA) Caused by Warm Autoantibodies

Species	B-cell autoantigen (dominant antigen in bold)	Th-cell autoantigen identified	Unprimed autoreactive Th cells in health	Regulatory T-cell response
Human AIHA	Rh proteins (~70% patients) Glycophorin A Band 3	Rh proteins	Yes	IL-10 response to Rh protein Epitopes
Canine AIHA	Glycophorins (~50% patients) Band 3	Glycophorins	Yes	Not examined
Murine AIHA				
NZB mouse	<b>Band 3</b> Band 4.1 (pr) Phosphatidylcholine (pr)	Band 3	Not applicable	Weak IL-10 response to Band 3
Induced by rat RBC	<b>Band 3</b> (cr) Glycophorins (cr)	Band 3	Yes	Recovery due to suppression by CD25 <sup>+</sup> cells
Induced by LCMV	<b>Band 3</b>	Not examined	Yes	Not examined

Pr, Polyreactive antibody also binds nuclear antigens, for example, histones; cr, cross reacts with rat RBC antigen.

Modified from Barker, R.N., Vickers, M.A., Ward, F.J., 2007. Controlling autoimmunity—lessons from the study of red blood cells as model antigens. *Immunol. Lett.* 108, 20–26 (Barker et al., 2007).

Another mechanism, which may be of particular relevance in patients with very low levels of RBC-bound IgG, is that splenic macrophages are instead “armed” with the autoantibody bound to Fc $\gamma$ RI, allowing them to capture circulating RBC (Griffiths et al., 1994). Antibody-dependent cell-mediated cytotoxicity may also play a role in hemolysis (Garratty, 1983; Griffiths et al., 1994), mediated not only by macrophages but also potentially by K cells (Urbaniak and Griess, 1980) or activated neutrophils (Engelfriet et al., 1981). In some patients, there is evidence that autoantibodies can interfere with erythropoiesis (Crosby and Rappaport, 1956) or RBC egress from the bone marrow (Conley et al., 1982), as well as causing hemolysis.

## Red Blood Cell Autoantigens

Many of the major RBC autoantigens in AIHA have been identified (Tables 47.2 and 47.3).

Serological studies have established that cold reactive RBC autoantibodies in healthy individuals, and pathogenic species with high thermal amplitude in CAS, are most commonly directed to the Ii blood group system of carbohydrate differentiation antigens (Berentsen and Tjønnfjord, 2012). On adult RBC, the I antigen predominates, while i is expressed at low levels. Antibodies from approximately 90% of CAS patients recognize the I antigen (Jenkins et al., 1960), with anti-i (Marsh and Jenkins, 1960) accounting for most of the remainder. Other, very rare specificities for autoantibodies in CAS include Pr (Dellagi et al., 1981). In PCH, anti-P autoantibodies are detected in at least 90% of the patients (Sokol et al., 1999).

The most common targets in human warm AIHA, recognized in over 70% of cases, are the Rh proteins (Weiner and Voss, 1963; Barker et al., 1992a; Leddy et al., 1993), which also express important blood groups (Avent and Reid, 2000). Autoantibodies reactive against the glycophorins, or against the RBC anion channel protein, Band 3, are produced in some patients (Victoria et al., 1990; Barker et al., 1992a; Leddy et al., 1993). The major canine RBC autoantigens are the glycophorins, with autoantibodies from some cases specific for Band 3 (Barker et al., 1991). In mice, Band 3 is the dominant autoantigen in NZB disease (Barker et al., 1993b; de Sá Oliveira et al., 1996) and in AIHA following LCMV infection (Mazza et al., 1997) and, together with glycophorins, is also a target for autoantibodies induced by rat RBC (Barker et al., 1993a).

In addition to the autoantigens relevant to AIHA pathogenesis, RBC can also express cryptic determinants recognized by naturally occurring IgG autoantibodies. These include spectrin, the major component of the internal RBC cytoskeleton (Lutz and Wipf, 1982; Ballas, 1989; Barker et al., 1991, 1993a) and senescent red cell antigen (Alderman et al., 1981), which is exposed on Band 3 by aged RBC (Kay et al., 1990). The autoantibodies are thought to provide physiological mechanisms for disposing of damaged and effete RBC (Wiener et al., 1986; Pantaleo et al., 2008).

## CLINICAL SIGNS OF AUTOIMMUNE HEMOLYTIC ANEMIA

In both CAS (Petz, 2008) and warm AIHA (Packman, 2008), the predominant clinical features reflect the anemia, which most commonly causes lethargy and dyspnea. Signs include pallor and icterus, and massive hemolysis may precipitate hemoglobinuria. In CAS there may also be cyanosis or even necrosis of the bodily extremities (Petz, 2008). AIHA due to DL antibodies is typified by recurrent bouts of anemia and hemoglobinuria precipitated by exposure to cold (Petz, 2008). In warm AIHA, splenomegaly or hepatomegaly can be associated with extravascular hemolysis (Packman, 2008). Where AIHA is secondary, the signs of the underlying disease may predominate.

## LABORATORY DIAGNOSIS OF AUTOIMMUNE HEMOLYTIC ANEMIA

In addition to anemia, most cases show evidence of erythroid regeneration, with reticulocytosis (Packman, 2008; Petz, 2008). However, there can be a poor erythroid response (Liesveld et al., 1987), due to the physiological lag in increasing RBC production following acute hemolysis, or to autoimmune reactions inhibiting RBC regeneration (Conley et al., 1982), or to an underlying bone marrow disorder (Lefrere et al., 1986). Evidence of hemolysis can also be provided by increased bilirubin, aspartate transaminase, and lactate dehydrogenase levels. RBC autoagglutination or spherocytes may be seen in cold and warm AIHA, respectively.

Detection of RBC autoantibodies confirms the diagnosis of AIHA. The DAT has been the classic tool for measuring RBC-bound autoantibodies and complement (Petz and Garratty, 2004a). However, benign immunoproteins on the RBC surface can cause a positive DAT (Heddle et al., 1988; Huh et al., 1988), and the test also gives false-negative results in 3%–11% of AIHA cases (Sokol et al., 1985, 1988; Petz and Garratty, 2004a). These limitations have led to more sensitive methods to detect RBC-bound immunoglobulins, including radioimmunoassay (Kaplan and Quimby, 1983), flow cytometry (Van der Meulen et al., 1980; Garratty and Nance, 1990), or ELISA (Sokol et al., 1985, 1988).

## TREATMENT OF AUTOIMMUNE HEMOLYTIC ANEMIA

Anemia in both cold and warm AIHA requires supportive care and, if life-threatening, transfusion (Packman, 2008; Petz, 2008).

Patients with pathogenic cold reactive autoantibodies should be protected from unnecessary exposure to low temperatures (Petz, 2008). Cases of secondary disease, for example, CAS or PCH associated with infection, may be transient or resolve with treatment of the underlying condition. Corticosteroids or cytotoxic drugs have been used to treat CAS, but the response is frequently poor (Petz, 2008), and better results have been obtained by targeting B cells with the anti-CD20 monoclonal antibody rituximab (Berentsen et al., 2004), which is now considered the first line of therapy (Zanella and Barcellini, 2014).

Corticosteroids, such as prednisolone, are the most common first-line therapy for warm AIHA and can be highly effective, although many patients relapse after withdrawal of these drugs (Packman, 2008). Corticosteroids can both downregulate macrophage Fc $\gamma$ R to improve the survival of IgG-sensitized RBC (Fries et al., 1983) and reduce autoantibody production (Rosse, 1971; Sokol and Hewitt, 1985), but the rapid response they typically elicit suggests the importance of the former effect (Packman, 2008). Cytotoxic drugs such as cyclophosphamide or azathioprine may be used as second-line therapies to suppress immune responsiveness, or splenectomy can also be considered to remove a major site of extravascular hemolysis (Packman, 2008; Crowther et al., 2011). Ablation of B cells with rituximab has emerged as an effective treatment for AIHA that is refractory to conventional treatments (Zecca et al., 2003; Peñalver et al., 2010; Crowther et al., 2011), is now the preferred second-line therapy after corticosteroids in some centers, and also shows promise as a first-line treatment when combined with steroids (Dierickx et al., 2015).

## ETOLOGY OF AUTOIMMUNE HEMOLYTIC ANEMIA AND PREDISPOSING FACTORS

It is clear that autoimmune diseases result from the interaction of multiple factors (Shoenfeld and Isenberg, 1989; Cho and Gregersen, 2011). Genetic background, gender, age, environmental factors such as infections, drugs, and neoplasia have all been implicated in the etiology of AIHA.

### Genetic Predisposition

The possibility of a genetic predisposition to human AIHA was raised by rare reports of familial disease (Cordova et al., 1966; Pirofsky, 1968; Pollock et al., 1970; Lippman et al., 1982; Olanoff and Fudenberg, 1983). Particular human leucocyte antigen (HLA) haplotypes are the strongest genetic determinants of many autoimmune diseases (Shoenfeld and Schwartz, 1984; Caillat-Zucman, 2009; Cho and Gregersen, 2011; Lessard et al., 2012), and warm AIHA is positively associated with HLA-DR15, with approximately 60% of the patients expressing this allele (Stott et al., 2002). Genome-wide association studies of other human autoimmune diseases reveal that large numbers of non-HLA genes further contribute to susceptibility (Cho and Gregersen, 2011; Lessard et al., 2012), and predisposition of the NZB mouse to AIHA has also been attributed to multiple loci (Chused et al., 1987; Lee et al., 2004; Scatizzi et al., 2012). The molecular bases of most such associations remain unknown. However, in common with other autoimmune-prone strains, the NZB mouse shares a promoter haplotype that is associated with reduced expression and function of the inhibitory Fc $\gamma$ R Fc $\gamma$ RIIb (Pritchard et al., 2000). The effects of the polymorphism on Fc $\gamma$ RIIb expressed by macrophages and B cells are enhanced phagocytosis of IgG-opsonized RBC and increased antibody responsiveness (Pritchard et al., 2000; Kikuchi et al., 2006).

## Gender and Age

Unlike most other human autoimmune diseases (Talal and Ahmed, 1987), the incidence of AIHA is no higher in women than in men (Pirofsky, 1976; Sokol et al., 1981, 1992). AIHA becomes progressively more common with age (Sokol et al., 1981, 1992), perhaps reflecting defects in immune regulation (Tomer and Shoenfeld, 1988; Talor and Rose, 1991; Akbar and Fletcher, 2005).

## Infectious Agents

Infectious agents are commonly implicated in provoking autoimmune disease in susceptible individuals (Shoenfeld and Isenberg, 1989), with almost 10% of human AIHA patients reported to have concurrent bacterial or viral conditions (Sokol et al., 1981, 1992), and RBC autoantibodies induced in mice by LCMV (Coutelier et al., 1994). Cross-reactivity between bacterial lipopolysaccharide and the blood group antigen I has been proposed to explain the high incidence of transient CAS which follows human *Mycoplasma pneumoniae* infection (Costea et al., 1972). The potential for mimicry to induce warm AIHA is exemplified by the disease that develops in mice following repeated injections of RBC expressing cross-reactive antigens from a closely related species, the rat (Playfair and Marshall-Clarke, 1973; Barker et al., 1993a). Studies of NZB mice also suggest that cross-reactivity between a microbe and a self-epitope can focus a predisposition to autoimmunity onto a particular target, even when not a primary or sufficient cause of disease (Hall et al., 2007). A second mechanism linking infection and AIHA is the ability of innate microbial stimuli and the cytokines they induce to activate antigen-presenting cells (APC) and therefore to enhance the immunogenicity of RBC autoantigens (Elson et al., 1995; Coutelier et al., 2007). Changes to the cytokine milieu resulting from infection, particularly IFN- $\gamma$  production, can also enhance RBC phagocytosis by modulating both the subclass of autoantibody and the activation of macrophages (Atkinson and Frank, 1974; Coutelier et al., 2007). Finally, particular infectious agents associated with AIHA, such as Epstein–Barr virus, may directly infect and dysregulate immune cells (Bowman et al., 1974).

## Drugs

Immune-mediated hemolytic anemias are a rare side effect of many drugs, including the penicillins, but in most cases, the antibodies are not strictly autoreactive and only bind RBC in the presence of the drug (Garratty, 2010; Garratty and Arndt, 2014). However, other examples such as  $\alpha$ -methyldopa can induce true RBC autoantibodies that may cause AIHA (Sokol et al., 1981), by perturbing immune regulation (Kirtland et al., 1980) or altering the antigenic structure of RBC (Owens et al., 1982).

## Neoplasia

Up to 22% of the human AIHA cases suffer from some form of concurrent neoplastic disease (Sokol et al., 1981, 1992). Many patients with CAS have a monoclonal RBC autoantibody associated with a clonal lymphoproliferative disorder (Silberstein et al., 1986), most frequently classified as lymphoplasmacytic lymphoma (Berentsen and Tjønnfjord, 2012). Warm AIHA and autoimmune thrombocytopenia are both closely associated with CLL. Over 10% of AIHA cases are also diagnosed with the condition (Sokol et al., 1992), and circulating leukocytes with an abnormal CLL-like phenotype can be detected in further 19% of the patients classified with apparent primary AIHA (Mittal et al., 2008). Conversely, up to 14% of CLL patients have AIHA or elevated levels of RBC-bound autoantibody (Dearden et al., 2008). One model to explain this association is that the large numbers of the malignant CLL cells present in the spleen drive an autoimmune response to circulating cells by acting as aberrant APC (Hall et al., 2005).

## IMMUNE MECHANISMS UNDERLYING LOSS OF SELF TOLERANCE IN WARM AUTOIMMUNE HEMOLYTIC ANEMIA

The study of specific pathogenic responses to RBC autoantigens has enabled mechanisms underlying the loss of self-tolerance in warm AIHA to be characterized.

## B Cells and Tolerance

Although RBC destruction is autoantibody mediated, it is not necessary to invoke a defect in B-cell repertoire selection to explain the loss of tolerance in AIHA. Central tolerance of self-reactive B cells is incomplete in healthy individuals, since anti-RBC autoantibodies with a wide range of specificities can be induced to cause AIHA in murine strains that have no predisposition to spontaneous disease (Day et al., 1989; Barker et al., 1993a). Nevertheless, one model of AIHA, created by transgenic expression of an anti-RBC monoclonal autoantibody from NZB mice, does illustrate the potential for pathology to result from failure to censor autoreactive B cells (Murakami et al., 1992). The B cells producing monoclonal antibody are sequestered in the peritoneal cavity and survive to cause disease in only a proportion of mice, depending on whether they are deleted by contact with RBC (Murakami et al., 1992).

## T-Help Cells and Tolerance

There is a long-standing belief that self-tolerance in the T-cell compartment is less secure than for B cells, and that, in health, antibody-mediated diseases such as AIHA are prevented due to lack of effective help (Naysmith et al., 1981; Elson and Barker, 2000). The vast majority of IgG responses are T dependent (Kelsoe, 1995), and the production of warm autoantibodies in AIHA appears to be no exception (Elson and Barker, 2000). NZB IgG autoantibody production in vivo is retarded by treatment with anti-CD4 monoclonal antibody (Oliveira et al., 1994), or by CD4 gene deletion (Chen et al., 1996), and splenic T-helper (Th) cells from NZB mice but not MHC-matched healthy strains, proliferate in vitro in response to the major murine RBC autoantigen, Band 3 (Perry et al., 1996; Shen et al., 1996). Furthermore, NZB disease is accelerated by immunization with an insoluble peptide bearing the dominant Th-cell epitope from Band 3 and ameliorated by mucosal administration of a soluble analog of this sequence (Shen et al., 2003). Other murine models are also Th dependent, since anti-CD4 mAb-treated mice do not develop AIHA induced by LCMV (Coutelier et al., 1994), and T-cell depletion prevents RBC autoantibody production in response to immunization with cross-reactive rat antigens (Naysmith et al., 1981). Findings in human AIHA are also consistent with the need for help. Rh autoantigen-specific effector Th cells that have been activated in vivo can be demonstrated in the peripheral blood and/or spleen from all patients with anti-Rh autoantibodies (Barker et al., 1997), but from very few healthy donors (Barker and Elson, 1994; Barker et al., 1997).

Warm AIHA in patients and NZB mice is associated with specific helper responses that are dominated by the Th1 subset, and inducing a corresponding Th2 bias can prevent or ameliorate NZB disease (Shen et al., 1996, 2003; Hall et al., 2002). Such a shift may be therapeutically beneficial partly because of the associated switch of the autoantibody to a less pathogenic isotype. Recent studies of human AIHA reveal that disease is also strongly associated with IL-17 responses to RBC, raising the possibility that Th17 cells may also provide help for autoreactive B cells to produce pathogenic IgG subclasses (Hall et al., 2012).

In common with B cells, it appears that potentially autoaggressive T cells can escape central tolerance as part of normal immune development and that failure of peripheral mechanisms to control their activation results in AIHA. Healthy mice (Naysmith et al., 1981; Barker et al., 1993a, 2002), dogs (Corato et al., 1997), and humans (Barker and Elson, 1994) all harbor naïve Th cells that can be stimulated to proliferate in vitro by RBC autoantigens. Comparison with AIHA patients demonstrates that they differ, not in the presence or fine specificity of circulating RBC-specific autoreactive Th cells but in the finding that these lymphocytes are activated in vivo (Barker and Elson, 1994; Barker et al., 1997). One possibility is that the surviving autoreactive Th cells are specific for RBC self-epitopes that are normally inefficiently processed and presented by APC from the intact antigen (Elson et al., 1995) and therefore unavailable to induce tolerance in the thymus. This model is supported by studies of human AIHA, where activated Th cells are specific for epitopes on the Rh protein autoantigens that are “cryptic” or subdominant (Hall et al., 1999). Such epitopes may be more efficiently presented and drive an autoaggressive Th response if APC are activated, for example, by infection (Elson et al., 1995) or by the accumulation of aberrant APC types such as CLL cells (Hall et al., 2005). The importance of antigen presentation is also illustrated by observations that the immunogenicity of RBC can be increased by changes in their innate receptor recognition by dendritic cells (Yi et al., 2015).

It is now recognized that CD4<sup>+</sup> regulatory T (Treg) cells are important mediators of peripheral self-tolerance (Roncarolo et al., 2006; Sakaguchi et al., 2010; Shevach, 2011). AIHA induced by rat RBC immunization of mice provided an early example of such “infectious tolerance,” since the autoimmune response is transient and the mice become refractory to further induction of disease, with splenocytes transferred from recovered animals

providing protection to naïve recipients (Playfair and Marshall-Clarke, 1973; Naysmith et al., 1981). Both the “adaptive” IL-10<sup>+</sup> (Roncarolo et al., 2006) and “natural” CD25<sup>+</sup>FoxP3<sup>+</sup> (Sakaguchi et al., 2010; Shevach, 2011) forms of Treg cell have been implicated in maintaining or restoring tolerance to RBC autoantigens. In murine AIHA induced by rat RBC, recovery is associated with protective CD251 T cells (Mqadmi et al., 2005) and the development of AIHA in gene-deleted mice that lack IL-2 has been attributed to a deficiency of the “natural” Treg population (Hoyer et al., 2009). Treg cells specific for the target Rh autoantigens can be found in the peripheral blood or spleen of patients with AIHA and are capable of inhibiting the Th1 effector responses in vitro by secretion of IL-10 (Hall et al., 2002). The Rh-specific Treg cells have been cloned and shown to mediate inhibitory activity only after stimulation by cognate antigen, and not in response to polyclonal activators, illustrating the importance of specificity in their function (Ward et al., 2008). Although able to secrete the “adaptive” inhibitory cytokine IL-10, these Treg cells also express the “natural” marker FoxP3, and the Th1 transcription factor T-bet, revealing plasticity between the different regulatory forms and effector subsets (Ward et al., 2008).

## CONCLUDING REMARKS

In AIHA, many of the pathogenetic mechanisms by which autoantibodies can cause disease have been defined. The identification of major human and murine RBC autoantigens has also provided unique insights into the control of specific, pathogenic immune responses in both human and experimental animal disease. This work to understand how immunological tolerance is lost and can be restored holds out the prospect of more effective, specific therapies.

## INTRODUCTION

ITP is an acquired autoimmune disorder characterized by a platelet count  $<100 \times 10^9 \text{ L}^{-1}$  due to accelerated platelet destruction and impaired platelet production (McMillan, 1981; Heyns Adu et al., 1986). It is generally believed that the autoimmune response is mediated by both antiplatelet antibodies and T cell-mediated cytotoxicity. Platelets are derived from megakaryocytes (MKs), whose production and maturation in the bone marrow are regulated by thrombopoietin (TPO) (Kaushansky, 1995). Normal platelet values range from 150 to  $450 \times 10^9 \text{ L}^{-1}$ . Bleeding due to impaired primary hemostasis and platelet plug formation is a major clinical consequence of thrombocytopenia.

ITP occurs in both children and adults. The incidence of ITP is estimated at 3.3/100,000 adults per year and between 1.9 and 6.4/100,000 children per year (Terrell et al., 2010). Adults and children have similar platelet counts at diagnosis and bleeding symptoms with severe thrombocytopenia. However, the underlying disease processes are likely distinct as the majority of children with ITP achieve spontaneous remission while most adults face a chronic disorder (Terrell et al., 2010; Lambert and Gernsheimer, 2017; Stasi et al., 1995).

**TABLE 48.1** Causes of Secondary Immune Thrombocytopenia

Infection	HIV, HCV, <i>H. pylori</i> , CMV, Varicella zoster
Autoimmune disorders	SLE, APS, Evans syndrome
Immunodeficiency	CVID, ALPS, mild SCID
Lymphoproliferative disorders	CLL, HD, LGL, NHL
Postvaccination	Especially MMR
Drug-induced	Depakote, quinine, quinidine
Bone marrow transplantation side effect	

*HIV*, Human immunodeficiency virus; *HCV*, hepatitis C virus; *H. pylori*, *Helicobacter pylori*; *CMV*, cytomegalovirus; *SLE*, systemic lupus erythematosus; *APS*, antiphospholipid syndrome; *CVID*, common variable immune deficiency; *ALPS*, autoimmune lymphoproliferative syndrome; *SCID*, severe combined immunodeficiency; *CLL*, chronic lymphocytic leukemia; *HD*, Hodgkin disease; *LGL*, large granular T-lymphocyte leukemia; *NHL*, non-Hodgkin lymphoma; *MMR*, measles-mumps-rubella.

Adapted from Neunert, C., Lim, W., Crowther, M., et al., 2011. The American Society of Hematology 2011 evidence-based practice guideline for immune thrombocytopenia. *Blood* 117 (16), 4190–4207; Cines, D.B., Bussel, J.B., Liebman, H.A., et al., 2009. The ITP syndrome: pathogenic and clinical diversity. *Blood* 113 (26), 6511–6521.

According to the 2010 International Working Group (IWG) consensus of ITP experts, the acronym ITP represents immune thrombocytopenia, avoiding the terms “idiopathic” and “purpura” that had been included in the past. This reflects the enhanced understanding of the pathophysiology of ITP and lack of purpura in many cases. The IWG defines primary ITP as an isolated thrombocytopenia in the absence of other identified conditions and secondary if occurring in the context of drug exposures or other disorders associated with immune dysregulation (Table 48.1) (Rodeghiero et al., 2009).

This chapter reviews the epidemiology, diagnosis, pathogenesis, and treatment of ITP with specific emphasis on the autoimmune aspects of the disease.

## EPIDEMIOLOGY

Studies indicate a slightly higher prevalence of ITP in males in childhood and in older adulthood with increased incidence in women in the middle (child-bearing) adult years (30–60 years age group) (Segal and Powe, 2006; Moulis et al., 2014). Peak incidence occurs during childhood and in adults greater than 60 years of age (Moulis et al., 2014). Though limited, there are some data suggesting decreased incidence among black populations and seasonal variation with a peak in the winter and spring months (Moulis et al., 2014, 2017).

Severe spontaneous or posttraumatic bleeding, such as gastrointestinal, genitourinary, and gynecologic hemorrhage, skin and mucosal hemorrhage, or intracranial hemorrhage (ICH), may occur with platelet values  $<10 \times 10^9 \text{ L}^{-1}$  and can occur but is less frequent in patients with platelets between  $10 \times 10^9$  and  $20 \times 10^9 \text{ L}^{-1}$  (Cortelazzo et al., 1991; Cines and Bussel, 2005). Factors associated with increased risk of bleeding include lower platelet counts, male gender, older age, and prior hemorrhage (Lambert and Gernsheimer, 2017; Cortelazzo et al., 1991; Neunert et al., 2011, 2015). Adults have a higher overall rate of intracranial bleeding than children, 1.4% versus 0.4% (Neunert et al., 2015) potentially reflecting the presence of medical comorbidities. ICH is especially prevalent in patients over the age of 60 (Cortelazzo et al., 1991).

Although bleeding is a significant concern with thrombocytopenia, recent reports indicate an increased risk of thromboembolism in ITP patients with a relative risk of 1.6 compared to the general population (Doobaree et al., 2016). The reasons behind this remain unclear but could be related to increased platelet activation and to cell-derived microparticles (Bidot et al., 2008; Sewify et al., 2013; Psaila et al., 2011) with possibly some contribution of treatment effect. For example, patients who have undergone splenectomy have a higher rate of thromboembolism than nonsplenectomized ITP patients (Doobaree et al., 2016; Boyle et al., 2013). Patients receiving TPO receptor agonists (TPO-RAs) also have a higher risk of thromboembolic events (6% over several years of treatment) (Wong et al., 2017).

In the US population, there was greater in-hospital mortality for ITP patients compared to non-ITP hospitalizations (Danese et al., 2009). This increased mortality also exists in ITP patients compared with the general population along with higher rates of cardiovascular disease, thromboembolic events, bleeding, and infection (Norgaard et al., 2011; Frederiksen et al., 2014).

## DIAGNOSIS

An isolated platelet count  $<100 \times 10^9 \text{ L}^{-1}$  in the absence of other underlying disorders characterizes ITP. Current guidelines recommend a thorough evaluation of a patient's history, physical examination, complete blood count (CBC), and peripheral blood smear (Neunert et al., 2011; Provan et al., 2010). In taking the history, particular attention should be given to the presence of systemic diseases, infections, chronicity, and severity of bleeding/bruising events, medications, vaccinations, and personal or family history of thrombocytopenia or easy bleeding/bruising. The physical exam should be unremarkable save for manifestations of bleeding or bruising. Careful examination of the liver, the spleen, the lymph nodes, and the radial ray is particularly warranted. Detection of a significantly enlarged spleen should prompt evaluation for disorders other than ITP. The CBC should show intact hemoglobin and white blood cell count. Abundant platelet clumping and signs of hemolysis (schistocytes) should be absent on the peripheral blood smear.

The IWG consensus report from 2010 recommends checking for human immunodeficiency virus (HIV), hepatitis C virus, *Helicobacter pylori*, quantitative immunoglobulin levels, and a direct antiglobulin test (DAT) (Provan et al., 2010). The evaluation of antiphospholipid antibodies, antinuclear antibodies, antiplatelet antibodies, thyroid function testing, and cytomegalovirus could be helpful but are not routinely recommended, unless guided by symptoms or history (Neunert et al., 2011; Provan et al., 2010). Both the IWG consensus report (2010) and the American Society of Hematology (ASH) 2011 practice guidelines advise against routine bone marrow biopsy in the evaluation of children and younger adults (Neunert et al., 2011; Provan et al., 2010; Jubelirer and Harpold, 2002; Mak et al., 2000). The IWG suggests consideration of bone marrow biopsy in certain situations such as patients older than 60 years of age, presence of systemic symptoms, or prior to splenectomy (Provan et al., 2010). Bone marrow aspirate and biopsy are important tools in patients with refractory disease to rule out other causes of thrombocytopenia. Note that both documents may be revised in the near future with the next rendition of the ASH guidelines expected by early 2018.

ITP remains a diagnosis of exclusion. The majority of ITP cases are primary and around 20% are secondary (Table 48.1), the most common causes varying by location. In the United States, the most common causes of secondary ITP are common variable immune deficiency (CVID), systemic lupus erythematosus, hepatitis C infection, and chronic lymphocytic leukemia (Moulis et al., 2014; Cines et al., 2009). Whether ITP is primary or secondary, transient substantial response to intravenous immunoglobulin (IVIG) is supportive of the diagnosis.

The phases of ITP are defined as acute, persistent, and chronic (Table 48.2). Once diagnosed, most adults will go on to have chronic ITP (Cuker et al., 2015). Those with clinically significant bleeding and very low platelet counts requiring initiation of treatment, additional therapies, or increased doses of medications are described as having "severe" ITP (Rodeghiero et al., 2009). Severe ITP can occur during any phase of ITP. "Refractory" ITP describes disease not responsive to splenectomy with severe ITP or significant risk of bleeding to warrant treatment (Rodeghiero et al., 2009).

**TABLE 48.2** Phases of Immune Thrombocytopenia

Acute	Diagnosis to 3 months
Persistent	3–12 months from diagnosis
Chronic	More than 12 months from diagnosis

*Adapted from Rodeghiero, F., Stasi, R., Gernsheimer, T., et al., 2009. Standardization of terminology, definitions and outcome criteria in immune thrombocytopenic purpura of adults and children: report from an international working group. Blood 113 (11), 2386–2393.*

## PATHOGENESIS

Primary ITP is a complicated acquired autoimmune condition with thrombocytopenia broadly resulting from pathologic antiplatelet autoantibodies (Shulman et al., 1965), T cell–mediated platelet destruction (Olsson et al., 2003), and impaired MK production (Khodadi et al., 2016). It is a very heterogeneous disease whereby immune dysregulation of many causes results in the antiplatelet response described above. It is worth noting that initially in the first stage of B-cell development, 50% or so are autoantibodies which, given the marrow milieu, are directed against blood cells especially platelets. Therefore with preformed antibodies that can be stimulated, ITP can develop as a loss of control (Nemazee et al., 1991).

## PLATELET AUTOANTIBODIES

Autoantibodies, typically IgG, are produced against single or multiple platelet surface antigens particularly components of the glycoprotein (GP) IIb/IIIa and GPIb/IX complexes but also others that may have been underestimated in the past such as anti-GPVI (He et al., 1995; Woods et al., 1984; Audia et al., 2017). IgA and IgM anti-platelet antibodies are seen less often and typically in conjunction with IgG autoantibodies (He et al., 1994); their role is largely unclear.

B lymphocytes may secrete autoreactive antibodies and are present in increased frequency in patients with ITP (Kuwana et al., 2014; Chen et al., 2012). The spleen is the main site of antiplatelet antibody production with the peripheral blood, bone marrow, and probably lymph nodes serving as secondary sources of antibody-producing B and plasma cells (McMillan et al., 1974). Phagocytes with Fc $\gamma$ -receptors recognize antiplatelet antibody bound to platelets, facilitating their phagocytosis and destruction. Given the local production of antibodies and the constant presence of about one-third of the intravascular platelet mass, the spleen is the primary site of platelet destruction with usually a smaller contribution via the reticuloendothelial system of the liver (Ballem et al., 1987; Zufferey et al., 2017; McMillan, 2007). In addition to antibody-mediated destruction via phagocytosis, antibody binding can activate complement-mediated platelet lysis (Tsubakio et al., 1986), though this has been poorly studied and the significance of complement components is not completely clear.

Currently, neither the IWG nor the ASH practice guidelines recommend routine testing for platelet autoantibodies (Neunert et al., 2011; Provan et al., 2010). No detectable antibodies are found in up to 30%–40% of the patients (Zufferey et al., 2017), and this is reflected in the low sensitivity (i.e., percent of patients with ITP with positive antibodies) of 49%–66% of platelet antibody testing in ITP. In addition, a specificity of only 78%–93% leads to a significant number of false-positive tests (Warner et al., 1999; Brighton et al., 1996; McMillan et al., 2003). Possible reasons behind the absence of detectable antibodies in a substantial percent of ITP patients include suppression of antibody levels due to preceding treatment, the presence of antibodies to other platelet antigens that are not being assayed, and a significant contribution of antibody-independent mechanisms of disease such as T cell–mediated platelet destruction and/or suppression of platelet production (Zufferey et al., 2017; McMillan, 2007).

In addition to the production of autoreactive antibodies, other mechanisms of immune dysregulation involving B cells may also participate in the pathogenesis ITP. B cell–activating factor (BAFF or B lymphocyte stimulator) is a cytokine that plays a critical role in regulating B-cell survival, maturation, and stimulation (Schneider et al., 1999). Elevated levels of BAFF in ITP may contribute to disease activity by rescuing autoreactive B and T cells from apoptosis and by promoting survival of long-lived splenic plasma cells (Audia et al., 2017; Zhu et al., 2009; Mahevas et al., 2013). A subset of IL-10 producing B-regulatory cells (Bregs) helps to maintain intact immune tolerance by promoting the differentiation of T-regulatory cells (Tregs), regulating T helper 1 (Th1)/T helper 2 (Th2) balance, and suppressing activation of monocytes, thus playing a vital role in immune suppression (Li et al., 2012; Semple, 2012; Lemoine et al., 2011). Not only are Bregs decreased in patients with ITP but they are also functionally impaired (Li et al., 2012).

## T-CELL INVOLVEMENT

T cells and dysregulation of T-cell populations are involved in the pathogenesis of ITP through a variety of mechanisms. A change in T-helper cell balance occurs with decreased Th2 polarization resulting in an increased Th1/Th2 ratio (Ogawara et al., 2003; Wang et al., 2005) and with an inverse correlation of the Th1/Th2 ratio with

platelet count in ITP (Takahashi et al., 2017; Panitsas et al., 2004). The significance of this altered T-cell balance is not yet known but as Th1 polarization is required for macrophage stimulation, this may result in increased platelet phagocytosis (Audia et al., 2017).

The most discussed mechanism, possibly due to the current lack of clarity, involves the role of cytotoxic T cells. CD8+ cytotoxic T cells can directly lyse platelets (Zhao et al., 2008) and accumulate in the bone marrow inhibiting platelet production (Olsson et al., 2008). T cells can also enhance antibody formation as demonstrated by a population of autoreactive GPIIb/IIIa CD4+ T cells that promote the production of antiplatelet antibodies (Kuwana et al., 1998). The latter may involve the CD40–CD40 ligand (CD154) interaction (Audia et al., 2014).

Tregs suppress self-reactive lymphocytes and preserve immunological self-tolerance (Hori et al., 2003; Sakaguchi et al., 2009). The spontaneous development of severe autoimmune disease in animal models with depleted Treg populations, and in humans with specific deficiency of Tregs, highlights the importance of Tregs in maintaining immune homeostasis (Kim et al., 2007; Yu et al., 2017). As shown in multiple studies, both decreased number and impaired function of Tregs characterize the abnormal immune environment of ITP (Sakakura et al., 2007; Liu et al., 2007).

Why all of these mechanisms result in ITP, rather than perhaps other autoimmune diseases, remains to be clarified. Possibilities include the preexistence of autoantiplatelet antibodies or the resemblance of platelets to lymphocytes with multiple immunologically active molecules. The latter may lead to platelet participation in the immune response resulting in the presentation of platelet GPs to antigen-presenting cells.

Another largely unresolved issue is why ITP resolves in certain cases and not in others. Several approaches have been explored. In children, if the initial inciting infection results in oxidative damage to the platelet membrane, then this increases the chance of developing chronic ITP (Zhang and Zehnder, 2013). In support of this hypothesis is an Egyptian study randomizing addition of antioxidative therapy showing a benefit to this form of treatment (Elalfy et al., 2015). Another study of children with chronic ITP suggested a number of polymorphisms in T-cell pathways contributed to chronic ITP (Zhang et al., 2014). One appeal of these findings is that they strongly support a polygenic instead of monogenic etiology of chronic disease. A corroborative set of findings comes from the study of a B cell–directed treatment (rituximab plus dexamethasone). Nonresponders had a significantly increased frequency of monoclonal and oligoclonal T-cell repertoires compared to responders (Chapin et al., 2016). This suggests that the persistence of abnormal T cells relates to the persistence of ITP. The majority of patients with ITP gradually improve but certain patients worsen over time. One of the reasons behind this appears to include processes such as epitope spreading whereby epitopes distinct from the initial inciting epitope become major targets of the ongoing immune response (Cornaby et al., 2015). But, as with many of the discussed immunologic phenomena, this has been shown to occur but to be of unclear clinical significance.

## MEGAKARYOPOIESIS

Despite the normal or increased number of MKs seen in bone marrow biopsies of ITP patients, the platelet production is actually impaired (Louwes et al., 1999; Dameshek and Miller, 1946). Abnormalities in MK development contribute to insufficient platelet production. Early microscopy studies demonstrated extensive damage to 50%–75% of MKs (Stahl et al., 1986). More recent studies confirm these findings showing features of apoptosis and para-apoptosis in the majority of mature MKs with surrounding neutrophils and macrophages (Houwerzijl et al., 2004). Since MKs express platelet surface antigens (i.e., GPIIb/IIIa, GPIb/IX), these antiplatelet antibodies, and potentially autoreactive T cells, can affect MK maturation/platelet production in the bone marrow (Houwerzijl et al., 2004; McMillan et al., 2004; Chang et al., 2003).

Another reason for the suboptimal platelet production involves TPO, produced by the liver and the main growth factor for MKs (de Sauvage et al., 1996). After TPO binds to its receptor, c-Mpl, on platelets and MKs, it is internalized and eventually destroyed along with the platelet (Kuter and Rosenberg, 1995; Debili et al., 1995). Thus the total cell mass of c-Mpl expressing cells regulates circulating TPO levels; the same is true of granulocyte colony-stimulating factor although not erythropoietin (Corbacioglu et al., 2000). While patients with ITP have low absolute platelet number, TPO levels remain low due to uptake by the increased population of MKs and platelets with a short lifespan (Chang et al., 1999).

An additional pathway leading to TPO production has recently been discovered. Desialylation of membrane proteins occurs as platelets age, leading to their binding by the hepatic Ashwell–Morell receptor which induces platelet phagocytosis and TPO production (Audia et al., 2017; Grozovsky et al., 2015). However, in ITP, the majority of antibody-coated platelets are believed to be destroyed via FcR-mediated phagocytosis and not in this

fashion. These findings of low circulating TPO levels in ITP may partly explain why TPO-RA is an often effective treatment.

Reduced proplatelet formation in patients with undetectable antiplatelet antibodies suggests a nonimmune, inherent defect in late megakaryopoiesis (Riviere et al., 2015). As mentioned briefly above, CD8+ cytotoxic T cells accumulate in the bone marrow (Olsson et al., 2008) where they suppress proper MK apoptosis, a step required for platelet production (Li et al., 2007). In one study, nonresponders to TPO-RAs had increased MKs in the marrow but reduced platelet reticulocytes suggesting that their lack of response was due to impaired ability of proplatelets to release platelets (Barsam et al., 2011). Responders to TPO-RAs had clearly increased platelet reticulocytes compared to those patients who responded to treatments such as IVIG, IV anti-D, and even an anti-FcR III antibody, demonstrating their unique mechanism of effect, that is, stimulation of platelet production (Barsam et al., 2011).

## TREATMENT

Generally, patients with platelets above  $30 \times 10^9 \text{ L}^{-1}$  are not at risk for serious bleeding and may be followed by observation alone. Patients with platelets  $<10 \times 10^9 \text{ L}^{-1}$  are treated, and the decision to treat those with platelets between  $10 \times 10^9$  and  $30 \times 10^9 \text{ L}^{-1}$  depends on factors such as bleeding/bruising symptoms, medical comorbidities, and fatigue (Cooper, 2017); most adults with platelet counts in this range are likely to be treated. The goal of treatment is to achieve a durably improved platelet count without the need for ongoing therapy.

## FIRST-LINE THERAPIES

Historically, first-line treatments include steroids, IVIG, and IV anti-D. The overall aim of these therapies is to decrease autoantibody-mediated platelet destruction, although which of their multiple potential mechanisms of action are most significant is not completely understood (Zufferey et al., 2017). IVIG slows platelet destruction and increases platelet half-life but exactly how this occurs remains controversial. There are various types and doses of steroids used in ITP but no consensus regarding the optimal regimen. Some studies suggest improved response rates using one or multiple rounds of high-dose dexamethasone ( $40 \text{ mg/day} \times 4 \text{ days}$ ) compared to a prolonged prednisone taper (Wei et al., 2016; Mazzucconi et al., 2007). In patients with contraindications to high doses of steroids, IVIG  $1 \text{ g/kg}$  may be used for 1 or 2 days depending on platelet response (Cooper, 2017). The primary common toxicity is headache, which can be severe.

Patients who are RhD antigen positive, are DAT negative, and have intact spleens are candidates for treatment with IV anti-D (Scaradavou et al., 1997; Cooper et al., 2002). IV anti-D has been shown to be particularly efficacious in children and in HIV-related ITP (Scaradavou et al., 1997), though all treated patients must be monitored for intravascular hemolysis. Intravascular hemolysis and fever–chill–nausea–vomiting cytokine-driven reactions to IV anti-D can both be ameliorated substantially by premedication with high dose IV steroids, for example, methylprednisolone  $30 \text{ mg/kg}$  up to  $1 \text{ g}$ .

## SECOND-LINE THERAPIES

If the initial attempt at therapy does not result in lasting improvement and/or clinical remission, multiple agents are available as second-line treatments. The selection among these agents is very difficult and the only clear, unequivocal tenet is *not* to continue steroids.

## SPLENECTOMY

Splenectomy remains a reasonable option with around 60% of the patients achieving a normal platelet count postsurgery and maintaining a sustained response at 5 years (Kojouri et al., 2004; Kumar et al., 2002; Ahmed et al., 2016). However, this potential benefit should be balanced with the surgical risk and long-term increased risk of infection/sepsis and thrombosis especially stroke (Ahmed et al., 2016). The decreased usage of splenectomy (Boyle et al., 2013) reflects the possibility of other treatment options, the long-term response in only 60%,

the inability to predict the response except in very few centers, and the hope that the ITP will improve over 1–3 years such that no ongoing treatment will be necessary. If very good prediction of response were widely available, it would probably be selected more frequently.

## RITUXIMAB

Rituximab is an anti-CD-20 monoclonal antibody that depletes circulating CD-20-positive antibody-producing B cells. The overall response rate is around 50%–60% and about 20%–30% of the patients have a long-term (>5 years) response (Patel et al., 2012; Arnold et al., 2007). Apparently, the population with the best response to the combination of rituximab and three cycles of dexamethasone is women with ITP of <1 year's duration (Chapin et al., 2016). Caution should be taken as B-cell depletion can lead to decreased vaccine response for up to 6 months (Nazi et al., 2013) and repeated courses of rituximab, especially in combination with dexamethasone, can lead to severe hypogammaglobulinemia (Cooper et al., 2009). Those with existing CVID, and patients who are on immunosuppressive medications, may be at greater risk for hypogammaglobulinemia and infection but those with CVID should already be on IVIG and they respond to rituximab particularly well (Gobert et al., 2011). Obtaining baseline immunoglobulin levels is recommended prior to treatment with rituximab (Cooper, 2017; Kado et al., 2016). In addition, patients should be tested for hepatitis B due to the risk of viral reactivation with rituximab. Overall, rituximab is generally well tolerated with toxicities including very occasional severe infusion reaction, serum sickness, prolonged immunosuppression, and rare reports of progressive multifocal leukoencephalopathy, only one or two of which occurred in patients with ITP (Carson et al., 2009; Cuker and Neunert, 2016).

## THROMBOPOIETIN RECEPTOR AGONISTS

TPO-RAs bind to the TPO receptor stimulating megakaryopoiesis and hence platelet production. Currently, there are two TPO-RAs, eltrombopag and romiplostim, approved by the US Food and Drug Administration (FDA) and European Medicines Agency. Both agents lack sequence or structural homology with endogenous TPO avoiding the risk of developing cross-reactive antibodies (Kuter, 2007). Eltrombopag is an orally available, small molecule, nonpeptide TPO-RA that binds the transmembrane domain of the TPO receptor (Kuter, 2007; Rodeghiero and Carli, 2017). It is FDA approved for the treatment of ITP in adults and children  $\geq 1$  year-old refractory to corticosteroids, IVIg, or splenectomy; adults with severe aplastic anemia; and thrombocytopenia due to chronic hepatitis C infection. Romiplostim is a recombinant fusion protein, a so-called peptibody, given weekly via subcutaneous injection that shares the same TPO receptor binding site as endogenous TPO (Rodeghiero and Carli, 2017). Romiplostim is FDA approved for the treatment of chronic ITP in adults refractory corticosteroids, IVIg, or splenectomy.

In a double-blind randomized controlled trial of 63 splenectomized and 62 nonsplenectomized patients with ITP, Romiplostim had an overall response rate (4 of 24 weeks) of 80%–90% with durable platelet response rates (platelet count  $\geq 50 \times 10^9/L$  for at least 6 of the final 8 weeks of the study) of 38% in splenectomized and 61% in nonsplenectomized patients. The majority of patients who had been on concomitant treatment were able to reduce the dosage of or discontinue other ITP medications, and rescue treatments for low counts were reduced as was bleeding (Kuter et al., 2008). Longer term studies of up to 5 years demonstrated ongoing efficacy and safety of Romiplostim (Bussel et al., 2009a; Kuter et al., 2013). Randomized controlled trials of eltrombopag in adults and children show initial platelet response rates of 59%–79%, with a significant proportion of patients able to decrease or discontinue concomitant ITP therapies (Bussel et al., 2009b; Grainger et al., 2015; Cheng et al., 2011).

Potential risks of both TPO-RAs include thrombosis, headaches, and myalgia and bone marrow fibrosis. Eltrombopag may result in cataracts and transaminitis or hyperbilirubinemia (Bussel et al., 2009a; Kuter et al., 2013). Romiplostim has a higher rate of cycling counts in some responders, and there appears to be a 1% incidence of neutralizing antibodies (which do not cross-react with native TPO) (Carpenedo et al., 2016). Should a patient not respond to or not tolerate one of the TPO-RAs switching to the other is a reasonable option (Khellaf et al., 2013). Although not meant as curative therapy, there are reports of patients sustaining adequate platelet counts after TPO-RA discontinuation (Cuker et al., 2015) but how to decide when to taper or stop a TPO-RA remains uncertain. The Sunshine Pharmaceutical Co., Ltd. has a TPO-RA that resembles native TPO which is licensed in China and several Asian countries (Zhao et al., 2004). Two additional TPO-RAs are in clinical trial at present.

Multiple other agents are used as second-line treatments in ITP including mycophenolate mofetil, danazol, azathioprine, dapsone, vincristine, and cyclophosphamide. There are a number of single arm studies with each of these agents albeit with response rates mostly <50% in difficult patients (Taylor et al., 2015; Hou et al., 2003; Maloisel et al., 2004; Provan et al., 2006; Quiquandon et al., 1990; Stirnemann et al., 2016). The latter two agents (vincristine and cyclophosphamide) have been used much less frequently in recent years because of their toxicities.

## CONCLUSION

ITP is a prototypic organ-specific autoimmune disease. Its relative frequency is attributed to the development of immature pre-B and B cells in the marrow where they are exposed to platelets. Studies of tolerance have shown that the most immature B cells have an autoselectivity in approximately 50% of cells that steadily falls to <1%. Rupture of tolerance in one of many areas can thus readily result in ITP.

ITP is a final common pathway disease that can result from many different etiologies. The current inability to dissect out which one is occurring in a given patient has been one of the primary limitations in improving the management of ITP. With the increasing number of acceptable treatment options, it can be very difficult to decide which one to select in a given patient. Studies not only of various polymorphisms or mutations in patients linked to their outcomes of their ITP, for example, not only bleeding and fatigue but also response to different therapies and whether spontaneous improvement will occur are badly needed. If and when this happens, the information should allow a more rational approach to the management of ITP in the future. There is general agreement that curative therapies are more effective in patients very close to diagnosis so that prediction of outcome, for example, chronicity, would be very useful in the decision of minimal treatment, just enough to avoid bleeding, as compared to a rituximab and dexamethasone-based regimen intended to be curative.

Animal Models	926	Concluding Remarks—Future Prospects	931
Therapy for Aplastic Anemia	926	References	932
Bone Marrow Transplantation	926		
Bone Marrow Transplantation From Unrelated Donors	927		

Aplastic anemia manifests with pancytopenia and a hypocellular bone marrow (Brodsky and Jones, 2005). The disease may be acquired or inherited. Most cases of acquired aplastic anemia result from autoimmune destruction of hematopoietic stem/progenitors and respond to immunosuppressive therapies. The inherited forms of aplastic anemia are less common and usually present within the first decade of life (Tsangaris et al., 2011). The inherited bone marrow failure may be due to a variety of genetic mutations such as DNA repair defects (Fanconi anemia), telomerase defects [dyskeratosis congenita (DKC)], ribosomopathies (Shwachman–Diamond syndrome), or cMPL mutations (amegakaryocytic thrombocytopenia). Immunosuppressive therapy is not helpful for the most inherited forms of bone marrow failure. This chapter will predominantly focus on acquired aplastic anemia; however, it is important to be aware of these less common inherited forms of aplastic anemia since they can sometimes be hard to distinguish from the acquired form of the disease.

## HISTORIC BACKGROUND

The earliest case description of aplastic anemia in 1888 was by Dr. Paul Ehrlich (Ehrlich, 1888). He described a young woman who died following an abrupt illness characterized by severe anemia, bleeding, high fever, and a markedly hypocellular bone marrow. Until the early 1970s, most patients with severe aplastic anemia (SAA) died within a year of diagnosis. The advent of allogeneic (allo) bone marrow transplantation (BMT) and

immunosuppressive therapy markedly improved the outcome for these patients and prompted vigorous clinical and laboratory investigation. These studies have generated an important insight into hematopoietic stem cell biology, immunology, and autoimmunity. Today the majority of patients will survive this potentially fatal autoimmune disorder.

## GENETIC FEATURES

Distinctive genetic abnormalities are more common with congenital bone marrow failure syndromes since most acquired aplastic anemia is autoimmune. Congenital aplastic anemia tends to present in the first decade of life and is often, but not always, associated with other physical anomalies. Fanconi anemia, the most common form of congenital bone marrow failure, predisposes to cancer and is frequently associated with other congenital abnormalities (e.g., short stature, upper limb anomalies, hypogonadism, café-au-lait spots, etc.) (Bagby, 2003). DKA is another congenital bone marrow failure disorder that can be either X-linked recessive, autosomal dominant, or autosomal recessive (Dokal and Vulliamy, 2003). The X-linked recessive form results from mutations in a gene known as *DKC1* whose gene product, dyskerin is important for stabilizing telomerase. The resulting telomerase deficiency leads to short telomeres, bone marrow failure, and premature aging. The autosomal dominant form of DKA results from human telomerase RNA component (*hTERC*) gene mutations, the RNA component of telomerase. This chapter will focus on the acquired form of aplastic anemia. Genetic abnormalities are less well characterized in acquired aplastic anemia; however, there appears to be an underlying genetic predisposition to acquired aplastic anemia, as evidenced by the overrepresentation of human leukocyte antigen (HLA) DR2 subtypes (Nimer et al., 1994).

## CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Aplastic anemia manifests as pancytopenia in conjunction with a hypocellular bone marrow. The disease may present abruptly (over days) or insidiously, over weeks to months. The most common clinical manifestations reflect the low blood counts and include dyspnea on exertion, fatigue, easy bruising, petechia, epistaxis, gingival bleeding, heavy menses, headaches, and fever. A complete blood count, leukocyte differential, reticulocyte count, and a bone marrow aspirate and biopsy are essential for diagnosis. Peripheral blood flow cytometry to detect glycosylphosphatidylinositol (GPI) anchor deficient blood cells (Brodsky et al., 2000; Borowitz et al., 2010) as well as cytogenetics and fluorescent in situ hybridization (FISH) analysis should be performed on the bone marrow aspirate. Up to 70% of patients with acquire aplastic anemia have a detectable paroxysmal nocturnal hemoglobinuria (PNH) clone which essentially rules out inherited forms of aplastic anemia (Dezern et al., 2014). Cytogenetic or FISH abnormalities are suggestive of a hypoplastic form of myelodysplasia. Patients under the age of 40 years old should be screened for Fanconi anemia using the clastogenic agents diepoxybutane or mitomycin C, and telomere lengths should be obtained on patients with a family history of bone marrow failure, premature graying, pulmonary fibrosis, or other stigmata of DKA.

A hypocellular bone marrow is required for the diagnosis of aplastic anemia. However, some patients will have residual pockets of ongoing hematopoiesis; thus an adequate biopsy (1–2 cm in length) is essential for establishing the diagnosis. Dyserythropoiesis is not uncommon in aplastic anemia, especially in cases with coincidental small-to-moderate PNH populations; however, a small percentage of myeloid blasts, or dysplastic features in the myeloid or megakaryocyte lineages, is more typical of hypoplastic myelodysplastic syndromes (MDS). CD34 is expressed on early hematopoietic progenitors and the number of CD34<sup>+</sup> cells has also been used to help discriminate between aplastic anemia and hypoplastic myelodysplastic syndrome (hMDS). In aplastic anemia the percentage of cells expressing CD34 is usually less than 0.1%; in hMDS the CD34 count is either normal (0.5%–1.0%) or elevated (Matsui et al., 2006).

As with other autoimmune diseases, there is a wide spectrum of disease severity in aplastic anemia. The prognosis in aplastic anemia is proportional to degree of peripheral blood cytopenias. Accordingly, aplastic anemia is classified as nonsevere, severe, and very severe based largely upon the degree of neutropenia (Table 49.1). SAA is defined as bone marrow cellularity of less than 25% and markedly decreased values of at least two of three hematopoietic lineages (neutrophil count <500/ $\mu$ L, platelet count <20,000/ $\mu$ L, and absolute reticulocyte count of <60,000/ $\mu$ L). Very SAA satisfies the above criteria except the neutrophil count is <200/ $\mu$ L, while non-SAA is characterized by a hypocellular bone marrow but with cytopenias that do not meet the criteria for severe disease.

**TABLE 49.1** Aplastic Anemia: Diagnosis and Definitions

Peripheral blood counts	Nonsevere aplastic anemia (not meeting criteria for severe disease)	Severe aplastic anemia (any 2 of 3)	Very-severe aplastic anemia (meets criteria for severe disease and absolute neutrophils <200)
absolute neutrophils		<500/ $\mu$ L	<200/ $\mu$ L
platelets		<20,000/ $\mu$ L	
reticulocyte count		<1.0% corrected or <60,000/ $\mu$ L	

Bone marrow cellularity <25%.

The 2-year mortality rate with supportive care alone for patients with SAA exceeds 50% (Camitta et al., 1979), with invasive fungal infections and overwhelming bacterial sepsis being the most frequent causes of death. Non-SAA is seldom life-threatening and in many instances requires no therapy. Although some cases of non-SAA will progress, many will remain stable for years, and some may spontaneously improve.

Aplastic anemia has been associated with drugs, benzene exposure, insecticides, viruses, and other agents. However, over 80% of cases are classified as idiopathic. The disease most commonly affects children and young adults but may occur at any age. Precise estimates of the incidence of aplastic anemia are difficult due to the rarity of the disease and imprecision in establishing the diagnosis. The best estimates of incidence are case-control studies that report an incidence of two cases/million inhabitants in Europe (Kaufman et al., 1991) and Israel (Modan et al., 1975), but the incidence may be two to threefold higher in Southeast Asia (Issaragrisil et al., 1997; Szklo et al., 1985). A population-based case-control study of aplastic anemia in Thailand found that drugs, the most commonly implicated etiology, explain only 5% of newly diagnosed cases (Issaragrisil et al., 1997).

An intriguing association exists between seronegative hepatitis and aplastic anemia. The hepatitis-aplastic anemia syndrome accounts for 3%–5% of newly diagnosed cases of aplastic anemia. The disease predominantly affects young males, with a precipitous onset of severe pancytopenia occurring within 2–3 months after the onset of hepatitis (Brown et al., 1997). Moreover, aplastic anemia has been reported to occur in up to 30% of patients following orthotopic liver transplantation for seronegative hepatitis (Tzakis et al., 1988; Cattral et al., 1994). The aplastic anemia in the hepatitis/aplastic anemia syndrome is also thought to be autoimmune since most cases respond to immunosuppressive therapy (Savage et al., 2007; Locasciulli et al., 2010).

## AUTOIMMUNE FEATURES AND PATHOGENIC MECHANISMS

Aplastic anemia was originally thought to result from a quantitative deficiency of hematopoietic stem cells precipitated by a direct toxic effect on stem cells. However, the attempts to treat aplastic anemia by simple transfusion of bone marrow from an identical twin failed to reconstitute hematopoiesis in most patients. Retransplant of many of these patients following a high-dose cyclophosphamide preparative regimen was successful, suggesting that the pathophysiology of aplastic anemia was more complicated (Champlin et al., 1984; Hinterberger et al., 1997). In the late 1960s Mathe et al. (1970) were among the first to postulate an immune basis for aplastic anemia. They performed BMT in patients with aplastic anemia using partially mismatched donors after administering antilymphocyte globulin as an immunosuppressive conditioning regimen. Although the patients failed to engraft, the investigators witnessed autologous recovery of hematopoiesis in some patients. This suggested that functional hematopoietic stem cells exist in aplastic anemia patients and that the immune system was somehow suppressing the growth and differentiation of hematopoietic stem cells. The response to immunosuppressive therapy was the first clear evidence that aplastic anemia was truly an autoimmune disease.

The first laboratory experiments implicating an autoimmune pathophysiology were coculture experiments showing that T lymphocytes from aplastic anemia patients inhibited hematopoietic colony formation in vitro (Hoffman et al., 1977; Nissen et al., 1980). Since then, it has been shown that the immune destruction of hematopoietic stem cells in aplastic anemia is mediated by cytotoxic T cells and involves inhibitory Th1 cytokines and the Fas-dependent cell death pathway. The cytotoxic T cells are usually more conspicuous in the bone marrow than in the peripheral blood (Zoumbos et al., 1985; Selleri et al., 1994; Melenhorst et al., 1997) and overproduce interferon- $\gamma$  and tumor necrosis factor (TNF) (Nakao, 1997; Nistico and Young, 1994). TNF and interferon- $\gamma$  are

direct inhibitors of hematopoiesis and appear to upregulate Fas expression on CD34<sup>+</sup> cells (Maciejewski et al., 1995). Immortalized CD4<sup>+</sup> and CD8<sup>+</sup> T-cell clones from some aplastic anemia patients have been shown to secrete Th1 cytokines and are capable of lysing autologous CD34 cells (Nakao et al., 1997; Zeng et al., 2001). Evidence for a humoral autoimmune response in aplastic anemia has also been reported (Hirano et al., 2000; Feng et al., 2004). Studies examining T-cell diversity using complementarity-determining region (CDR3) spectratyping have further implicated the role of the immune system in aplastic anemia. Several groups have now found limited heterogeneity of the T-cell receptor β-chain (BV) in aplastic anemia, suggesting that there is oligoclonal or even clonal expansion of T cells in response to a specific antigen (Melenhorst et al., 1997; Zeng et al., 2001; Manz et al., 1997).

## ENVIRONMENTAL FEATURES

The medical literature is replete with reports of environmental exposures, most notably benzene and radiation, causing aplastic anemia. However, rigorous epidemiologic studies supporting an association between environmental toxins and aplastic anemia are lacking. A major confounder is that benzene, radiation, and other toxins also predispose to MDS and leukemia. Older literature was unlikely to have been able to distinguish different types of marrow failure, such as aplastic anemia, MDS, and hypoplastic leukemia, leading to an overestimation of the association between benzene and aplastic anemia. While the magnitude of the risk remains uncertain, benzene is probably not a major risk factor for aplastic anemia in countries with modern standards of industrial hygiene. A large case-control study in Thailand employing modern diagnostic and epidemiologic methods found that individuals of lower economic status and younger age are at greater risk than their counterparts in other countries following exposure to solvents, glues, and hepatitis A (likely a surrogate marker). Grain farmers were also found to have a higher risk of developing aplastic anemia (relative risk = 2.7) regardless of whether they use insecticides (Issaragrisil et al., 1997). These same investigators noted marked differences in the incidence between northern and southern rural regions of Thailand and among Bangkok suburbs implicating potential environmental factors in causing the disease (Issaragrisil et al., 1999).

## ANIMAL MODELS

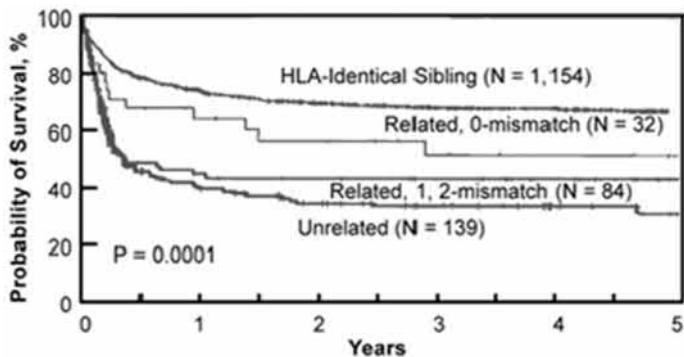

Animal models of bone marrow failure exist, but none of these models fully replicate the human disease acquired aplastic anemia (Chen, 2005). Busulfan, benzene, and irradiation have all been used to establish the models of marrow failure. All three of these agents lead to pancytopenia, and a hypocellular marrow but the marrow failure is due to stem cell injury and damage to the microenvironment rather than autoimmune-mediated suppression of hematopoiesis. More recently, infusion of lymphocytes from congenic mice was used to model immune-mediated marrow failure; this model induces a hypocellular bone marrow and severe pancytopenia but is not truly autoimmune (Chen et al., 2004).

## THERAPY FOR APLASTIC ANEMIA

Definitive therapy for aplastic anemia includes BMT or immunosuppressive therapy. A variety of immunosuppressive agents have been studied, but antithymocyte globulin (ATG) and cyclosporine A (CSA) are the most commonly employed (Bacigalupo, 2017). Supportive care with blood transfusions and antibiotics is commonly required. Administration of hematopoietic growth factors has not been shown to improve survival in aplastic anemia.

### Bone Marrow Transplantation

BMT is the treatment of choice for young patients who have an HLA-matched sibling donor. Cyclophosphamide (50 mg/kg/day × 4 days) with or without ATG is most commonly used for conditioning before BMT. This regimen is nonmyeloablative; however, the immunosuppression is sufficient to allow engraftment in most cases (Storb et al., 1997; Kahl et al., 2005). Alternative regimens using fludarabine,

**FIGURE 49.1** Survival after allogeneic bone marrow transplantation for severe aplastic anemia. Data for HLA-identical siblings and related matched/mismatched transplants is from the IBMTR. Data for unrelated donor transplants is from the EBMT registry, Fred Hutchinson Cancer Research Center, IBMTR, and the IMUST study group. Survival curves are not adjusted for varying patient, disease, and transplant regimen characteristics. Source: Reproduced with permission from the National Bone Marrow Donor Program.

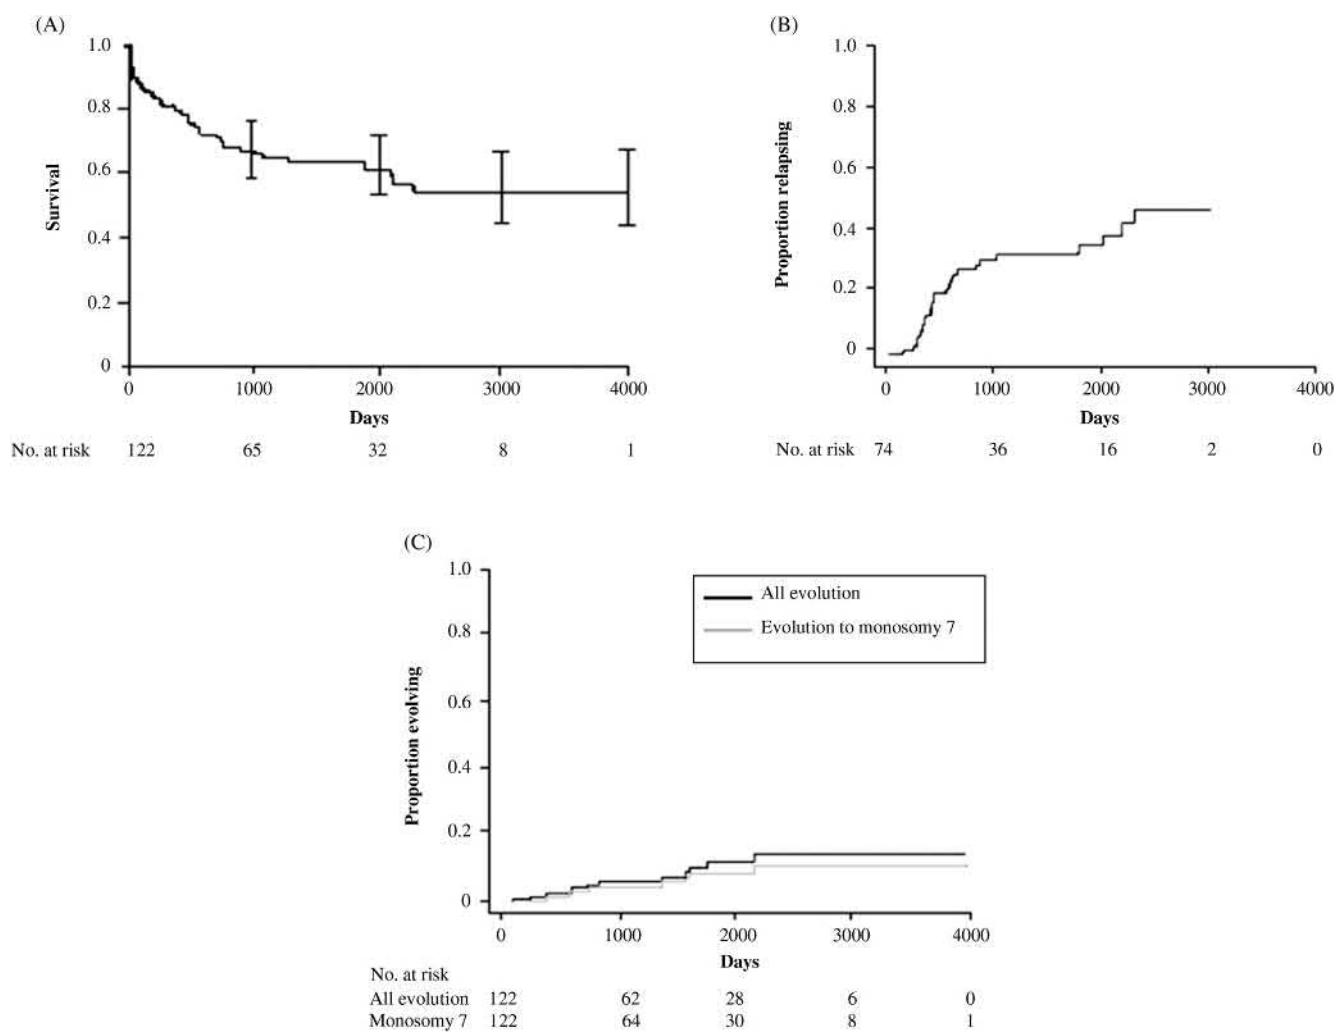

cyclophosphamide, and ATG are increasingly being used (Bacigalupo et al., 2010). Survival rates following matched sibling allo BMT have steadily improved since the 1970s largely because of improved supportive care, improved HLA typing, and better graft-versus-host disease (GVHD) prophylaxis (Bacigalupo, 1999). Late BMT-related complications such as chronic GVHD occur in up to one-third of patients, with many of these patients requiring long-term therapy for their GVHD (Storb et al., 2001). Patient age and the type of allograft (HLA-matched sibling, unrelated, or mismatched donors) are the most important factors influencing outcome. In patients under 30 years of age the cure rate after HLA-matched sibling BMT ranges from 70% to 90% (Ades et al., 2004; Horowitz, 2000). However, the risk of GVHD steadily increases with age, leading to reduced survival.

### Bone Marrow Transplantation From Unrelated Donors

BMT from HLA-matched unrelated donors is usually reserved for patients who fail to respond to one or more courses of immunosuppressive therapy. The risk for transplant-related mortality and GVHD is almost twice that of BMT from matched sibling donors (Bacigalupo, 2017). The European Group for Blood and Marrow Transplantation has been conditioning SAA patients for BMT with fludarabine, cyclophosphamide, and ATG  $\pm$  total body irradiation. The European Society for Blood and Marrow Transplantation (EBMT) has reported survival rates as high as 75% using this conditioning regimen (Bacigalupo et al., 2010). Survival was the best in children and in patients who undergo BMT within 2 years of diagnosis (Fig. 49.1).

## IMMUNOSUPPRESSIVE THERAPY

ATG is produced by immunizing animals (horse or rabbit) against human thymocytes and kills human T cells through its cytolytic activity. Both horse (hATG) and rabbit (rATG) are approved for the use in the United States; hATG appears to be superior as first-line treatment (Scheinberg et al., 2011). Cyclosporine A (CSA) suppresses T-cell function by inhibiting the expression of nuclear regulatory proteins. Both single-agent ATG and single-agent CSA can induce remissions in acquired aplastic anemia; however, the combination ATG/CSA leads to a higher response rate and a greater likelihood of achieving transfusion independence (Frickhofen et al., 1991; Marsh et al., 1999). A randomized controlled demonstrated that hATG/CSA is superior to rATG/CSA (Scheinberg et al., 2011). The combination of ATG/CSA leads to 5-year survival rates comparable to BMT, but most of these patients are not cured of their disease. Response rates to hATG/CSA range between 60% and 80%, but in contrast to BMT, most patients do not acquire normal blood counts (Frickhofen et al., 1991; Rosenfeld et al., 2003). Another limitation of this approach is that many patients relapse, become dependent on cyclosporine, or develop secondary clonal disease such as PNH or MDS (Rosenfeld et al., 2003; Bacigalupo et al., 2000; Scheinberg et al., 2006). These late events often lead to substantial morbidity and mortality. The National Institutes of Health treated 122 patients (median age, 35 years) with the combination of ATG/CSA and methylprednisolone over a period of 8 years (Rosenfeld et al., 2003). The response rate was 58% and actuarial survival at 7 years was 55%; 13% of patients died within 3 months of treatment, most from fungal infections (Fig. 49.2). The relapse rate for responders was 40% and 13 patients developed MDS. In an attempt to improve response rate and survival, and to decrease the relapse rate and secondary MDS that occurs after hATG/CSA, the NIH added mycophenolate (1 g twice daily for 18 months) to the standard hATG/CSA

**FIGURE 49.2** (A) Survival probability for 122 patients with severe aplastic anemia following treatment with antithymocyte globulin and cyclosporine. (B) Probability of relapse in 74 patients with aplastic anemia classified as responders at 3 months after treatment with antithymocyte globulin and cyclosporine. (C) Proportion of patients experiencing clonal evolution. Source: Reproduced from Rosenfeld, S., Follmann, D., Nunez, O., Young, N.S., 2003. Antithymocyte globulin and cyclosporine for severe aplastic anemia: association between hematologic response and long-term outcome. *JAMA* 289 (9), 1130–1135 with permission from JAMA.

regimen. This three drug regimen resulted in a 62% response rate, but 37% of the responders relapsed (most while taking mycophenolate) and 9% progressed to either MDS or leukemia; thus the addition of mycophenolate did not improve response or survival (Scheinberg et al., 2006). Alemtuzumab is a highly immunosuppressive monoclonal antibody that binds to cell surface CD52, which is expressed primarily on B and T cells and monocytes. Alemtuzumab has activity in treating SAA, but response rates in therapy naive patients are less than 30% (Scheinberg et al., 2012).

## ELTROMBOPAG

Eltrombopag is a small molecule agonist of the c-mpl (TpoR) receptor, which is the physiological target of the hormone thrombopoietin, and is the only new drug approved for the treatment of SAA in the past 30 years. Eltrombopag may be used in an attempt to improve the cytopenias in patients at the refractory state (Desmond et al., 2015). Up to 20% of patients with refractory SAA become transfusion-independent within 3 months; however, similar to immunosuppressive therapy, there is a relatively high likelihood of relapse and secondary clonal disease (Desmond et al., 2014; Marsh and Kulasekararaj, 2013; Olnes et al., 2012). Eltrombopag is now

being studied as an adjuvant to ATG/CSA in newly diagnosed patients in the hopes that it will improve response rates and prevent relapse.

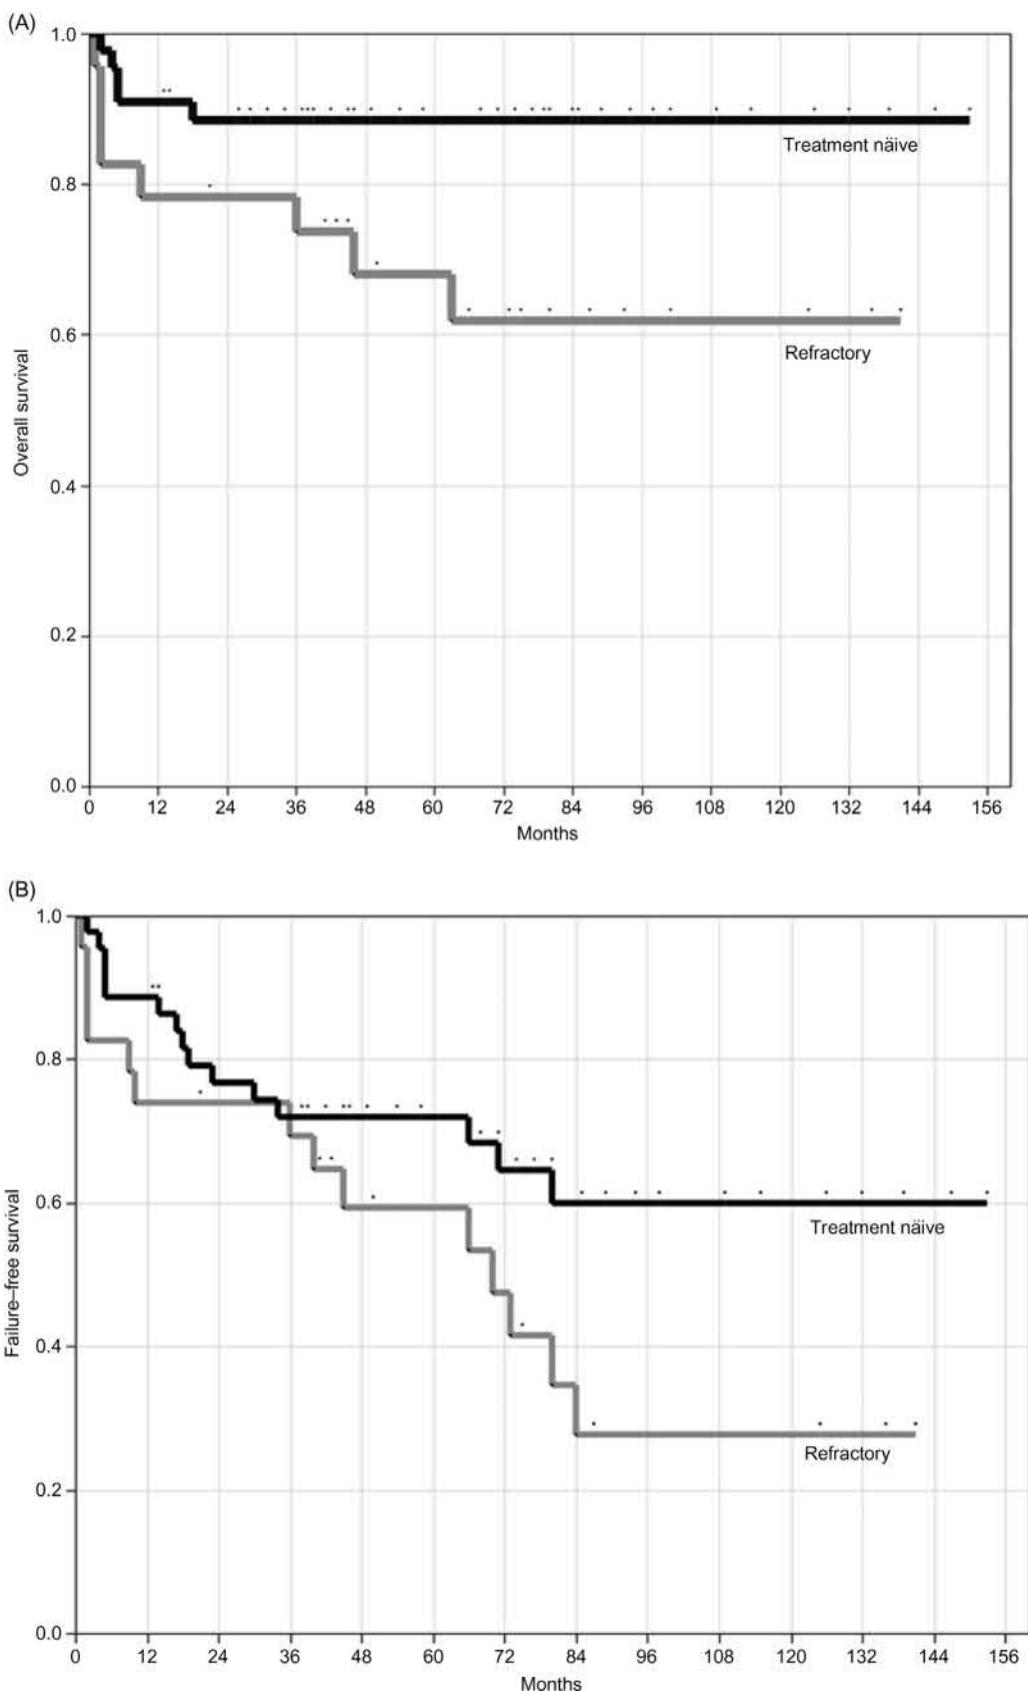

## HIGH-DOSE CYCLOPHOSPHAMIDE WITHOUT BONE MARROW TRANSPLANTATION

The first successful human allo BMT, reported in 1972 by Thomas et al. (1972) in a patient with aplastic anemia, employed high-dose cyclophosphamide, and this remains (often in conjunction with ATG) the most commonly employed conditioning regimen for aplastic anemia (Storb et al., 2001). Complete reconstitution of autologous hematopoiesis occurs in 10%–15% of patients undergoing allo BMT for aplastic anemia (Thomas et al., 1976; Sensenbrenner et al., 1977; Gmur et al., 1979). The EBMT reported that 10% of SAA patients experience autologous reconstitution following BMT using a cyclophosphamide + ATG conditioning regimen. Interestingly, 10-year survival (84%) in patients with autologous recovery was better than in patients who engrafted (74%) (Piccin et al., 2010).

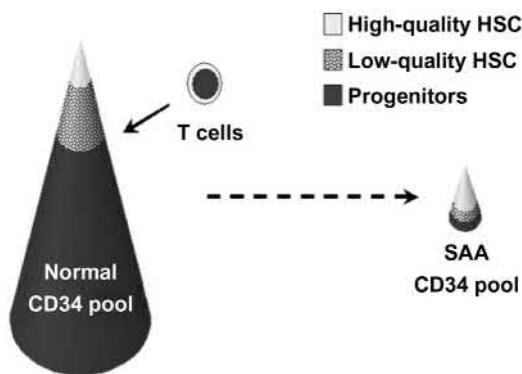

The unique pharmacology of cyclophosphamide explains the autologous hematopoietic recovery (Emadi et al., 2009). Cyclophosphamide is a prodrug that is converted to 4-hydroxycyclophosphamide and its tautomer aldophosphamide in the liver. These compounds diffuse into the cell and are converted to the active compound phosphoramide mustard, or they are inactivated by aldehyde dehydrogenase to form the inert carboxyphosphamide. Lymphocytes have low levels of aldehyde dehydrogenase and are rapidly killed by high doses of cyclophosphamide; hematopoietic stem cells possess high levels of aldehyde dehydrogenase and are resistant to cyclophosphamide (Hilton, 1984; Jones et al., 1995). Thus, high-dose cyclophosphamide is highly immunosuppressive, but not myeloablative, allowing endogenous hematopoietic stem cells to reconstitute hematopoiesis. With this background, high-dose cyclophosphamide without BMT was used successfully in aplastic anemia patients who lacked appropriate donor (Brodsy et al., 1996a; Tisdale et al., 2000; Jaime-Prez et al., 2001; Brodsky et al., 2010). The largest and most mature study with high-dose cyclophosphamide is from Johns Hopkins (Brodsky et al., 2010; Gamper et al., 2016). These investigators treated 67 SAA patients with high-dose cyclophosphamide; 44 patients were treatment-naïve and 23 were refractory to one or more previous immunosuppressive regimens. At 10 years, the overall actuarial survival, response rate, and event-free survival were 88%, 71%, and 58%, respectively, for the 44 treatment-naïve patients. Patients with refractory SAA fared less well; at 10 years, the overall actuarial survival, response, and event-free survival rates were 62%, 48%, and 27%, respectively. For the treatment-naïve patients, the median time to a neutrophil count of  $0.5 \times 10^9/L$  was 60 (range, 28–104) days, and the median time to last platelet and red cell transfusion was 117 and 186 days, respectively. Relapse occurred in just two of the treatment-naïve patients, one of whom was retreated with high-dose cyclophosphamide into a second complete remission. Despite the high response rate and low risk of relapse and secondary clonal disease, the duration of deep aplasia (median 60 days to neutrophil recovery) and risk for invasive fungal infections is a major drawback for this approach (Fig. 49.3).

## HUMAN LEUKOCYTE ANTIGEN HAPLOIDENTICAL BONE MARROW TRANSPLANT WITH POSTTRANSPLANT CYCLOPHOSPHAMIDE

Investigators at Johns Hopkins, in an effort to expand the donor pool for patients in need of a allo bone marrow transplant, have pioneered the use of high-dose cyclophosphamide 3 and 4 days after bone marrow transplant to improve engraftment and decrease the risk of GVHD after HLA-haploidential bone marrow grafts (Luznik et al., 2008). These authors recently reported on a prospective trial of this approach in 16 consecutive patients with refractory SAA (DeZern et al., 2017). Between July 2011 and August 2016, 16 patients underwent allo BMT for refractory SAA from 13 haploidential donors and 3 unrelated donors. All 16 patients engrafted and survived with a median follow-up of 21 (range, 3–64) months at the time of publication. Two patients had grade 1 or 2 skin-only acute GVHD. These same two also had mild chronic GVHD of the skin/mouth requiring systemic steroids. One of these GVHD patients was able to come off all immunosuppressive therapy (IST) by 15 months and the other by 17 months. All other patients stopped IST at 1 year (Fig. 49.4).

**FIGURE 49.3** Survival probability following high-dose cyclophosphamide without BMT in 67 patients with SAA. (A) Overall survival for 44 patients with treatment-naïve SAA (topline) and 23 patients with refractory SAA. (B) Failure-free survival after high-dose cyclophosphamide therapy for 44 patients with treatment-naïve SAA (topline) and 23 patients with refractory SAA. ## APLASTIC ANEMIA AND CLONALITY

The survivors of aplastic anemia are at high risk of clonal progression following immunosuppressive therapy (Socie et al., 1993). PNH and MDS are the most common clonal disorders to evolve from aplastic anemia (de Planque et al., 1989; Tichelli et al., 1988). Even before the widespread use of immunosuppressive therapy, 5% of the patients progressed to clonal hematopoiesis. This suggests that the increase in MDS and PNH following immunosuppressive therapy is not caused by the immunosuppression; rather, the increased survival following immunosuppressive therapy may allow time for these underlying clones to expand (Mukhina et al., 2001; Pu et al., 2011).

PNH results from the expansion of an abnormal hematopoietic stem cell that harbors a somatic mutation of the X-linked gene, termed phosphatidylinositol glycan class A (*PIG-A*) (Brodsy, 2014). The product of the *PIG-A* gene is required for GPI anchor biosynthesis; consequently, PNH cells are deficient in GPI-anchored proteins. Several GPI-anchored proteins (CD59 and CD55) protect cells from complement-mediated destruction, and their absence explains the hemolytic anemia associated with PNH. It is unclear how the PNH stem cell and its progeny achieve clonal dominance in the setting of aplastic anemia, despite the fact that PNH cells are more vulnerable to complement-mediated destruction; however, it may relate to relative resistance to the autoimmune attack due to intrinsic mutations (Brodsy et al., 1996b; Inoue et al., 2006). Specifically, it has been suggested that PNH cells may be relatively resistant to an autoimmune attack, because they are deficient in GPI-anchored ULBPs that serve as ligands for the NKG2D receptor found on natural killer cells and T cells (Hanaoka et al., 2006; Savage et al., 2009). Alternatively, it has been proposed that “second hit” mutations may also give the PNH clone a growth advantage (Inoue et al., 2006; Babushok et al., 2017).

MDS also commonly arises in aplastic anemia patients treated with immunosuppressive therapy. In a retrospective review of children with SAA, 11 of 86 patients who received immunosuppressive therapy developed MDS (Ohara et al., 1997). Up to 15% of adult patients with aplastic anemia will also develop MDS following immunosuppressive therapy with monosomy 7 being the most common chromosomal abnormality (Rosenfeld et al., 2003).

## CONCLUDING REMARKS—FUTURE PROSPECTS

Aplastic anemia was originally thought to be due to a defect in hematopoietic stem cells or their microenvironment. It is now clear that most cases of acquired aplastic anemia are caused by autoreactive lymphocytes that target bone marrow stem/progenitor cells. With modern therapies, the 5-year survival rate for SAA exceeds 85%. BMT offers the best chance for cure but is not available to all patients. Immunosuppressive therapy remains the standard of care for patients who are not suitable candidates for BMT. Remissions are achieved in up to 75% of patients, but the high rate of relapse and secondary clonal diseases limits the efficacy of immunosuppressive therapy. Even complete responders may relapse or develop MDS 5–10 years after immunosuppressive therapy.

Currently, the advances in mitigating graft failure and GVHD in the setting of alternative donor BMT appear to be outpacing the development of more effective IST therapies for SAA. In the coming years, there is likely to be great use of unrelated and HLA-mismatched BMT to treat SAA, especially in patients who don't respond or relapse after immunosuppressive therapy. The development of posttransplant cyclophosphamide (CY) to expand the donor pool and mitigate GVHD appears promising (DeZern et al., 2017).

Frankfurt am Main, Germany

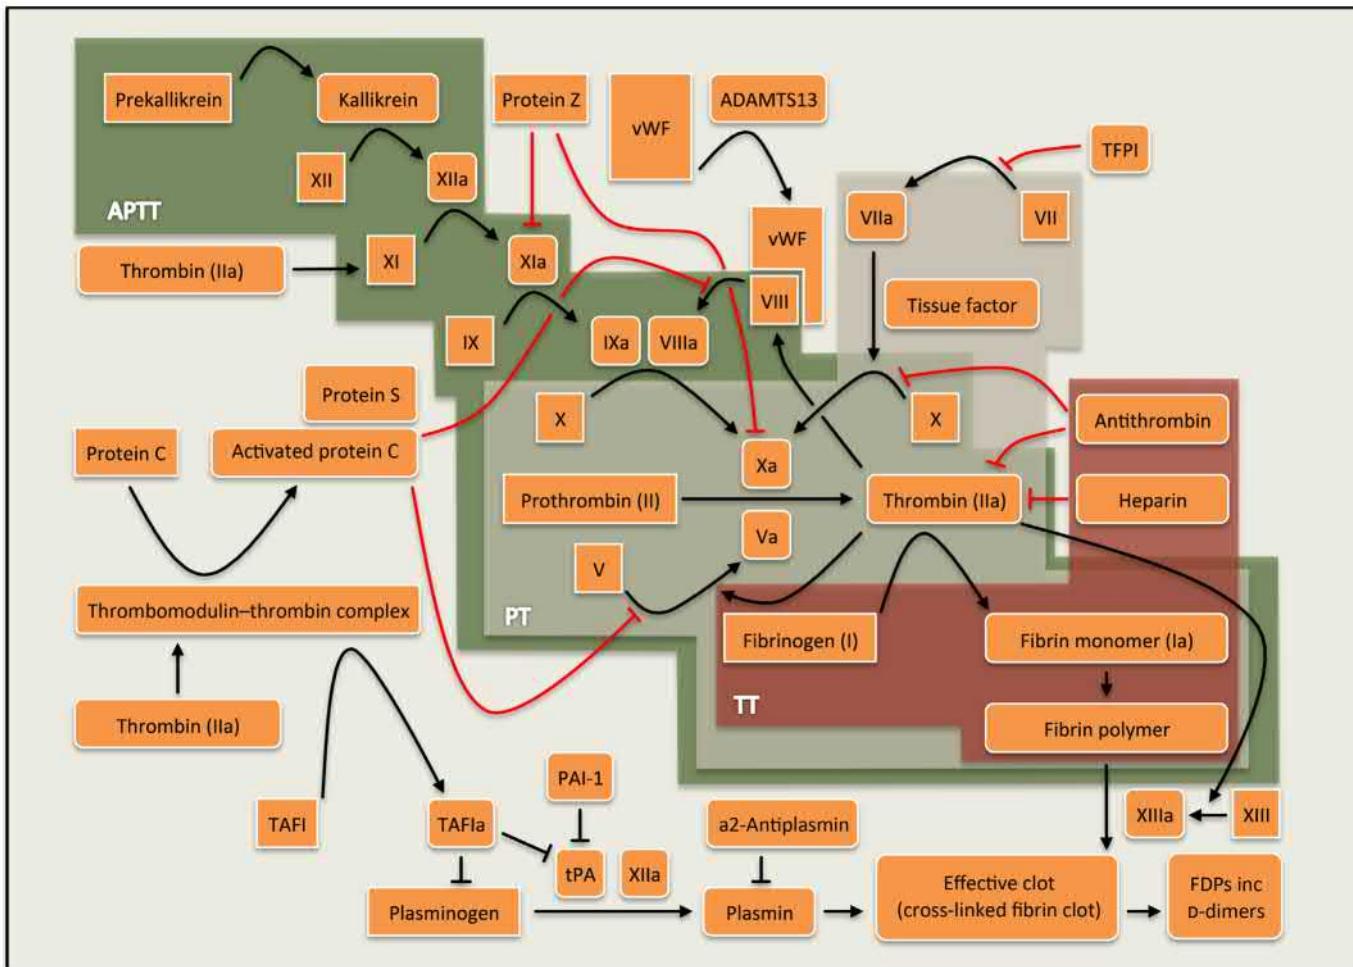

## OUTLINE

Prothrombotic Disorders	937	Autoimmune Inhibitors to Factor X	946
Autoimmune Inhibitors to a Disintegrin and Metalloproteinase With a Thrombospondin Type 1 Motif 13	937	Autoimmune Inhibitors to Factor XI	946
Anticoagulant Disorders	939	Autoimmune Inhibitors to Factor XII	947
Autoimmune Inhibitors to Fibrinogen (Factor I) and Fibrin	939	Autoimmune Inhibitors to Factor XIII	947
Autoimmune Inhibitors to Prothrombin (Factor II) and Thrombin	940	Autoimmune Inhibitors to Von Willebrand Factor	948
Autoimmune Inhibitors to Factor V	941	Autoimmune Inhibitors to Further Proteins	949
Autoimmune Inhibitors to Factor VII	942	Conclusion and Future Aspects	949
Autoimmune Inhibitors to Factor VIII	942	Acknowledgments	949
Autoimmune Inhibitors to Factor IX	945	References	949

Immunologically mediated dysfunction of coagulation is observed as a specific autoimmune response to the molecules of the coagulation system and occurs as specific disease entities or secondary to a number of different autoimmune conditions. The immune response directly or indirectly leads to an imbalance of hemostasis inducing hyper- or hypocoagulability.

Autoimmunity is found in primary and secondary—also called plasmatic—hemostasis. Primary hemostasis describes the initial reaction after injury, including the contraction of the blood vessel and the activation of platelets after exposure to subendothelial structures and tissue factor (TF). These steps lead to the initial closure of the injury. In parallel secondary hemostasis is initiated transforming the initial platelet clot into a stable fibrin clot, which is then cross-linked and further stabilized by FXIII and controlled by fibrinolysis. The classical schematic presentation of the plasmatic coagulation cascade and the interplay of activation and inactivation are shown in Fig. 50.1 to illustrate its complexity of regulation without showing the cellular aspects of coagulation.

This chapter aims to provide a short but comprehensive overview of autoimmunity to various proteins involved in secondary hemostasis, thus summarizing completely different and independent autoimmune entities (Chang and Chiang, 2014; Cugno et al., 2014). The autoimmune response to coagulation factors needs to be distinguished from alloantibodies in patients with congenital bleeding disorders after substitution of plasma or

**FIGURE 50.1** The coagulation cascade. The complexity of coagulation and the interplay of the different factors in regards of inhibition and activation are illustrated in the diagram. The classical scheme has been used to demonstrate the complexity of molecules and interaction. Although extremely rare, autoimmune inhibitors have been described against most coagulation factors. The factors influencing the different global tests aPTT, PT, and TT are shaded green, gray, and red, respectively. *aPTT*, Activated partial thromboplastin time; *PT*, prothrombin time; *TT*, thrombin time.

plasma proteins (antidrug antibodies), which are not covered in this chapter. Autoantibodies to platelets interfering with primary hemostasis are described in Chapter 47, Autoimmune Hemolytic Anemia.

In general, autoantibodies interfering with hemostasis are rare phenomena, for some proteins only individual cases have been described in literature. Nevertheless, the understanding of the autoimmune response and potential therapeutic options has increased in recent years for some autoimmune coagulation disorders. In general, such conditions remain extremely rare and most information on therapeutic interventions provided in this chapter reflects only data from individual reports or expert opinion based on cohort studies or case series.

## PROTHROMBOTIC DISORDERS

Several autoimmune entities are known to interfere with the homeostasis of the coagulation system leading to a procoagulant state. These include the antiphospholipid syndrome (APS), which interferes with several components of the coagulation cascade and is discussed in Chapter 34, Rheumatoid Arthritis. Except for APS and antibodies to a disintegrin and metalloproteinase with a thrombospondin type 1 motif 13 (ADAMTS13) (see next), only single reports on autoantibodies to other anticoagulant proteins of the coagulation system have been published.

Lupus anticoagulants are known to interfere with the protein C pathway and possibly block the inactivation of activated factor VIII (FVIII) (FVIIIa) ([Urbanus and de Laat, 2010; Saenz et al., 2011](#)). Antibodies to protein C and protein S itself have been described, whereas antibodies to protein S appear to be more clinically relevant. Both autoantibodies were found in higher frequencies in individuals with clinical relevant thrombosis compared to healthy controls. Antibodies to protein C have been suggested as a potential biomarker for the severity of thromboembolic events in patients with lupus anticoagulants ([Arachchillage et al., 2014](#)). The presence of specific IgM but not IgG as determined by enzyme linked immunosorbent assay (ELISA) correlated with the clinical phenotype ([Rossetto et al., 2009](#)). Also both isotypes have been associated with fetal growth restrictions and preeclampsia in pregnancy ([Torricelli et al., 2009](#)). Antibodies to protein S have been detected for example in Beçet disease associated with thrombosis in a few cases ([Guermazi et al., 1997; Lechner et al., 2011](#)). Further they were prevalent in a number of patients with acquired protein S deficiency and in patients with activated protein C resistance in the absence of the factor V (FV) Leiden mutation with or without underlying systemic lupus erythematosus (SLE) ([Sorice et al., 1996; Nojima et al., 2002a, 2009](#)). Antibodies to protein S and clinically relevant thrombosis have also been detected in children after infections including varicella or human herpes virus 6 ([Larakeb et al., 2009; Levin et al., 1995; Boccaro et al., 2009](#)).

IgG and IgM autoantibodies to protein Z, which inactivates FXa and FXIa, have been detected in women with recurrent spontaneous miscarriages but not in healthy controls and were also associated with pregnancy complications such as preeclampsia and fetal growth retardation in individual cases ([Sater et al., 2011; Erez et al., 2009; Gris et al., 2003](#)). In a case–control study, low protein Z levels and autoantibodies to protein Z were also found in patients with arterial or venous thrombosis ([Pardos-Gea et al., 2008](#)). The role of autoantibodies present in the APS on the protein Z–mediated inactivation of FXa and on the thrombosis is not clear ([Sailer et al., 2008; Forastiero et al., 2003](#)). Thrombotic complication also occurs due to inhibitors to prothrombin or ADAMTS13 (see next).

## AUTOIMMUNE INHIBITORS TO A DISINTEGRIN AND METALLOPROTEINASE WITH A THROMBOSPONDIN TYPE 1 MOTIF 13

Autoimmunity to ADAMTS13 causes the clinical picture of immune-mediated thrombotic–thrombocytopenic purpura (iTTP). Thrombotic events in terminal capillaries and arterioles are seen in iTTP. ADAMTS13 is a zinc protease mainly synthesized by hepatic stellate cells, which cleaves ultralarge von Willebrand multimers ([Tsai, 1996; Furlan et al., 1997; Zheng et al., 2001; Fujikawa et al., 2001; Dong et al., 2002; Zhou et al., 2005](#)). Prior to the discovery of the enzyme, the presence of ultralarge multimers has already been demonstrated in TTP patients ([Moake et al., 1982](#)). If not processed by ADAMTS13, the multimers rapidly form a hyaline thrombus together with thrombocytes mainly in brain, kidney, adrenal gland, heart, pancreas, and spleen.

The incidence of iTTP is estimated 2.17/million per year with women being affected 2.5–3.5 times as often as men. There is also a higher incidence and a more severe course seen in the individuals of African descent ([Torok et al., 1995; Miller et al., 2004; Terrell et al., 2005; Cataland et al., 2009](#)). iTTP is mostly seen in adults with a

median age of 42 years (range: 2–78), but also pediatric cases have been described (McDonald et al., 2010; Scully et al., 2008). In some patients iTPP is seen in combination with underlying conditions including malignancies, drugs, infections, autoimmune diseases, primary immunodeficiency, after bone marrow transplantation, and pregnancy (Murrin and Murray, 2006; Yamada et al., 2011; Scully et al., 2008; Kawasaki et al., 2013). A clinical pentad combining thrombocytopenia, hemolytic anemia, renal impairment, fever, and neurological symptoms was seen initially in almost 90% of the patients diagnosed with iTPP. Today the full classical pentad is present in less than 5% of the affected patients. Severe neurological symptoms are usually multifocal and often recurrent (Murrin and Murray, 2006). A characteristic presentation is the combination of thrombosis and thrombocytopenia accompanied by petechial bleedings. The full clinical picture depends on organs affected by microthromboses. This includes affection of the heart with pathological ECG and cardiac enzymes.

The differential diagnosis includes but is not limited to congenital TTP, hemolytic uremic syndrome, disseminated intravascular coagulation and other microangiopathies, or combinations of the above. The diagnosis may be difficult as ADAMTS13 is reduced in a number of conditions.

In suspected iTPP a blood cell count, von Willebrand factor (vWF) parameters including multimers, ADAMTS13 activity, antigen, and antibodies need to be determined. Different assays to determine ADAMTS13 antigen or activity are available. A residual activity of ADAMTS13 <10% appears to predict the clinical outcome of the first episode and potential relapses. Antibodies can be detected by ELISA using immobilized ADAMTS13. Inhibitory antibodies are detected by mixing studies. Von Willebrand antigen and activity appear higher in TTP. In the acute phase, the large vWF multimers are missing in the plasma of affected patients but reappear in remission. The extent of missing ultralarge multimers correlates with the severity of hemolysis and thrombocytopenia. Fragmented erythrocytes, an elevated lactate dehydrogenase and retention parameters depending on kidney affection, are observed (Lotta et al., 2011; Wu et al., 2006; Whitelock et al., 2004; Peyvandi et al., 2010; Kremer Hovinga et al., 2010, 2017, 2018). Mainly antibodies of the isotypes IgG, but also IgA and IgM are found in almost all patients with iTPP. Most antibodies are inhibitory, only in 10%–15% of the patients with ADAMTS13 deficiency noninhibitory antibodies are found, suggesting an increased clearance of the protease. Also antinuclear antibodies have been detected in most iTPP patients at first diagnosis (Tsai et al., 2006; Ferrari et al., 2007; Shelat et al., 2006; Scheiflinger et al., 2003; Pos et al., 2011; Kremer Hovinga et al., 2018). Antibodies isolated from peripheral B cells and switched memory B cells show somatic hypermutations suggestive for a role of T cells (Luken et al., 2005). IgG to ADAMTS13 is also seen in healthy controls but to a much lesser extent compared to iTPP patients (Tsai et al., 2006). Specific antibodies mainly belong to the IgG isotype, including the IgG4 subclass, but also IgG1, IgG2 and 3, IgA, and IgM have been identified (Ferrari et al., 2009). High levels of autoantibodies and in particular high levels of IgG4 and the combination of IgG1 and IgA have been associated with an unfavorable outcome. Antibody levels decrease during successful treatment (Coppo et al., 2006; Ferrari et al., 2007; Scully et al., 2007). In other study levels of IgA, IgG1 and IgG3 correlated with disease severity in the acute phase. In almost all patients antibodies against the cysteine-rich and the spacer region were identified, followed by antibodies against the metalloprotease. The cysteine-rich region is required for the cleavage of vWF. Antibodies against all other domains have been detected at lower frequencies. Longitudinal analyses including relapses showed antibody maturation and epitope spreading (Klaus et al., 2004; Luken et al., 2005; Zheng et al., 2010; Soejima et al., 2003; Yamaguchi et al., 2011; Thomas et al., 2015).

There are indications for a genetic predisposition for the development of anti-ADAMTS13 autoantibodies: in different cohorts the MHC class II alleles DRB1\*11, DQB1\*0301, DQB1\*02:02, and DRB3\* are found more frequently in patients with iTPP, while the DRB1\*04 and DRB4 alleles appear to be protective. Also heterozygous mutations in the ADAMTS13 gene have been associated with a potential higher risk of iTPP (Coppo et al., 2010; Scully et al., 2010; Pos et al., 2011; John et al., 2012; Kremer Hovinga et al., 2017).

Timely diagnosis and adequate treatment is crucial. In untreated iTPP, the mortality is around 90%. Thus treatment is often based on a presumptive diagnosis. Treatment is successful in most patients, but 30%–60% relapse over the following 10 years (Shumak et al., 1995; Tsai, 2006; Kremer Hovinga et al., 2010). The benefit of plasmapheresis and plasma transfusions compared to transfusions alone was shown in a randomized trial (Rock et al., 1991). With the combination of plasma exchange and steroids remission of 50% to >90% was achieved (Ferrari et al., 2007; Ferrari et al., 2014). Immunosuppression was mainly based on corticosteroids alone. Combinations with cyclosporine have also been successfully used (Cataland et al., 2007). Treatment with rituximab was successful and associated with a faster time to remission and a reduced number of relapses (Ojeda-Uribe et al., 2010; Scully, 2012; Ling et al., 2009; Foley et al., 2009; Tun and Villani, 2012; Westwood et al., 2017). A successful treatment with bortezomib has also been reported in a patient refractory to immunosuppression including rituximab (Shortt et al., 2013). The benefit of ivIg is doubtful. Single reports discuss the benefit of defibrotide

(Pogliani et al., 2000). In patients with refractory iTPP, splenectomy has been performed successfully (Kremer Hovinga et al., 2004). Thrombocyte transfusions are contraindicated and associated with a higher mortality. Many patients suffer from sequelae and a reduced life-expectancy even after successful treatment of the initial clinical presentation. A potential chronic affection even after the successful treatment of the acute episode is supported clinical presentations, the correlation of persistent antibodies with relapses and the detection of immunocomplexes (Ferrari et al., 2014; Bettoni et al., 2012).

Novel therapies are currently being evaluated including gain of function mutants resistant to autoantibodies and recombinant ADAMTS13, which restored the vWF-cleaving activity at higher doses in vitro despite the presence of autoantibodies to ADAMTS13. The clinical benefit remains to be determined. A novel antibody fragment (nanobody) targeting vWF is being evaluated. It reduces the clinical impact of the acute episode but does not promote immune tolerance induction (Jian et al., 2012; Plaimauer et al., 2011; Scully et al., 2017; Peyvandi et al., 2016).

## ANTICOAGULANT DISORDERS

Autoimmune inhibitors to proteins of the coagulation cascade potentially cause a severe bleeding phenotype. A rapid diagnosis of these rare conditions and appropriate treatment are often crucial for the prognosis of the patients. Inhibitors should be suspected in patients with hemorrhages without a personal or family history of bleeding, without trauma or anticoagulants. The provided algorithm describes a summary of a potential and rational approach to investigate patients with unexpected and unexplained bleeding events or abnormal coagulation tests and suspected inhibitors (Fig. 50.2).

As only limited data are available for each individual condition epidemiological, clinical, and immunological aspects of inhibitors are described next.

## AUTOIMMUNE INHIBITORS TO FIBRINOGEN (FACTOR I) AND FIBRIN

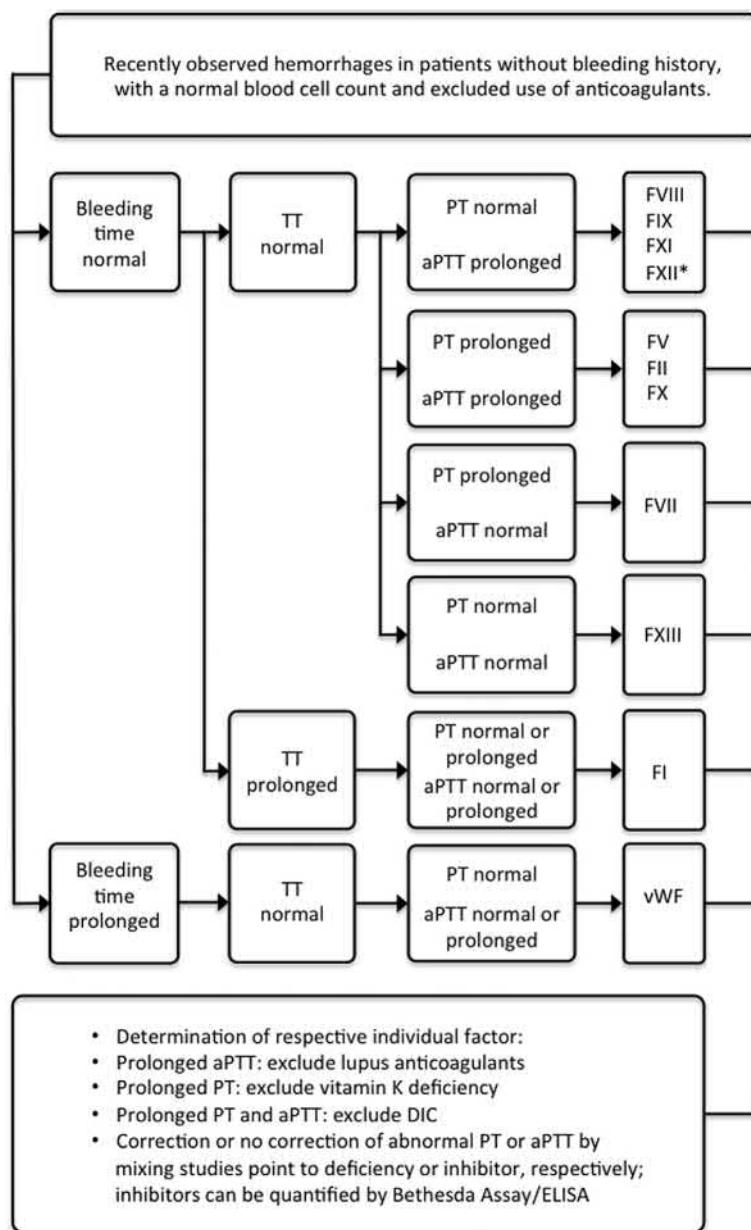

The fibrin clot is the final product of the coagulation cascade. Fibrin is generated from fibrinogen after thrombin cleavage. The glycoprotein fibrinogen is a heterohexamer composed of two  $\alpha$ -,  $\beta$ -, and  $\gamma$ -chains. Autoantibodies to fibrin or fibrinogen are rare. They have been described in combination with different underlying conditions, in pregnancy or as idiopathic. These conditions include other autoimmune disorders such as SLE or monoclonal gammopathies (Galanakis et al., 1978; Cohen et al., 1970; Coleman et al., 1972; Panzer and Thaler, 1993; Ruiz-Arguelles, 1988). The clinical phenotype ranges from mild-to-severe bleeding symptoms. Antibodies observed in pregnant women and newborns were not associated with a bleeding phenotype (Kondera-Anasz, 1998).

More frequently cross-reactive antibodies occurred after exposure to bovine thrombin glue [see next (Chouhan et al., 1997)].

Laboratory analysis reveals a prolonged thrombin time (TT) or reptiles time (RT), with both either normal or prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT). Fibrinogen levels may be normal or decreased. The TT is not corrected in mixing studies.

Antibodies against fibrinogen or fibrin usually belong to the IgG isotype. In a single report, the subclasses IgG1 and IgG3 were detected (Galanakis et al., 1978). Most antibodies described interfere with the monomer formation and the release of fibrinopeptide A (Marciniak and Greenwood, 1979; Gris et al., 1992) or with the monomer polymerization (Ghosh et al., 1983). Two further cases have been described with antibodies directed against the fibrinopeptide B also interfering with its release. These patients had no bleeding history, a prolonged TT normal RT (Llobet et al., 2007; Nawarawong et al., 1991). The correlation of the clinical phenotype and the epitope location might reflect the different kinetics of thrombin cleavage for the two different fibrinopeptides and their distinct role in the three-dimensional formation of the fibrin clot (Pechik et al., 2006).

The few published cases showed a spontaneous remission after the detection of an antiidiotypic antibody (Ruiz-Arguelles, 1988) or report a normalization of clotting assays after treatment of the underlying disease (Panzer and Thaler, 1993). There are no treatment algorithms; an immunosuppressive or modulative therapy with corticosteroids or ivIg may be necessary in case of severe symptoms.

**FIGURE 50.2** Possible guideline for the interpretation of coagulation tests for the diagnosis of factor inhibitors. \*, Factor XII deficiency/inhibitors are not associated with a bleeding phenotype; aPTT, Activated partial thromboplastin time; PT, prothrombin time; TT, thrombin time; vWF, von Willebrand factor. Source: Based on, extended, and modified from Kershaw, G., Favaloro, E.J., 2012. Laboratory identification of factor inhibitors: an update. *Pathology* 44, 293–302.

## AUTOIMMUNE INHIBITORS TO PROTHROMBIN (FACTOR II) AND THROMBIN

Thrombin plays a central role in the coagulation, activating fibrinogen and also to some extent other proteins of the coagulation cascade. This leads to a thrombin burst by a positive feedback amplification. Thrombin also binds to thrombomodulin, which then activates protein C to control coagulation in a negative feedback loop. Thrombin is generated from prothrombin by activated factor X (FX) and its cofactor activated FV. Prothrombin is a glycoprotein structurally including the gamma-carbylglytamic acid (Gla) domain, two kringle domains, and a C-terminal catalytic domain.

Antibodies to thrombin and prothrombin are rare and associated with a mild-to-severe bleeding phenotype. Such antibodies to prothrombin may also lead to a prothrombotic state (Bertolaccini et al., 1998). This is especially seen in patients with lupus anticoagulants (see Nojima et al., 2002b; Roubey, 1998; Knobe et al., 2012, also see Chapter 34, Rheumatoid Arthritis). The occurrence of such antibodies has been described as idiopathic (La Spada et al., 1995; Knobe et al., 2012) or in association with gammopathies, liver cirrhosis, SLE, or infections including epstein-barr-virus (Colwell et al., 1997; Barthels and Heimbürger, 1985; Atsumi et al., 2000; Bertolaccini et al., 1998).

More often antibodies to thrombin have been described after topical exposure to bovine thrombin during surgery with the use of fibrin glues (Chouhan et al., 1997; Berruyer et al., 1993; Fastenau and McIntyre, 2000). In some patients there is no bleeding tendency and the prolonged TT is an in vitro phenomenon and due to the use of bovine thrombin in the laboratory assay: when bovine thrombin is replaced by human thrombin, the TT is normalized due to lacking cross-reactivity of the antibodies with human thrombin (Stricker et al., 1988; Flaherty et al., 1989; Lawson et al., 1990; Berruyer et al., 1993). In contrast some patients develop antibodies with cross-reactivity to human thrombin: TT does not normalize if bovine thrombin is replaced by the human molecule in vitro (Lawson et al., 1990). In a prospective trial ( $n = 150$ ) the outcome for patients with exposure to bovine glue was less favorable (Ortel et al., 2001). The use of human recombinant thrombin has been shown to be less immunogenic in clinical trials. Antibodies developed in <1% of the patients without showing cross-reactivity with endogenous thrombin (Ballard et al., 2010; Singla et al., 2012).

Coagulation test show a markedly prolonged TT and a prolonged aPTT and PT without any correction in mixing studies. RT is normal. Thrombin levels and activity are reduced (Gabriel et al., 1987; Scully et al., 1982). Antibodies can also be detected by ELISA.

Antibodies to thrombin or prothrombin may be neutralizing or nonneutralizing increasing the clearance of prothrombin (Bajaj et al., 1985). Isotypes IgG or IgM have been identified (Bertolaccini et al., 1998). Antibodies directed to the catalytic center of thrombin (Sie et al., 1991) or the exosites of thrombin block the corresponding functions including the cleavage of fibrinogen (Mollica et al., 2006; Arnaud et al., 1994; La Spada et al., 1995). In an individual patient, antibodies have been described that form a complex with prothrombin leading to an interaction with antithrombin III and a direct inactivation without the conversion to thrombin (Madoiwa et al., 2001). The affinity of anticoagulant prothrombin antibodies appeared to be lower compared to the affinity of lupus anticoagulants (Bajaj et al., 1983; Field et al., 2001).

Establishment of a normal hemostasis in the presence of inhibitors to prothrombin or thrombin can be challenging. Fatal cases have been described (La Spada et al., 1995). The bypassing agents activated factor VII (FVII) (FVIIa) or activated prothrombin complex concentrate (aPCC) have been used (Giovannini et al., 2004). Also plasmapheresis, the use of fresh frozen plasma (FFP), immunosuppressive therapy including corticosteroids and ivIg has been applied (Scully et al., 1982). During therapy, a hypercoagulant situation may occur with the need for anticoagulation. A timely diagnosis and treatment reduces morbidity and mortality.

## AUTOIMMUNE INHIBITORS TO FACTOR V

Activated FV represents an essential cofactor of the complex converting prothrombin to thrombin. FV is structurally related to FVIII and composed of the A1, A2, A3, B, C1, and C2 domains. After activation by thrombin, the B domain is released and an A1-A2/A3-C1-C2 heterodimer is formed (Lollar, 2005).

Most FV antibodies have been described after surgical procedures especially after exposure to bovine thrombin glue, which contains traces of bovine FV (Chouhan et al., 1997; Berruyer et al., 1993; Spero, 1993; Zehnder and Leung, 1990; Muntean et al., 1994; Wang et al., 2017). These alloantibodies cross react with human FV. In addition autoantibodies to FV have been described as idiopathic (23%), related to the use of antibiotics (33%) (Knobl and Lechner, 1998), to surgery (even without the use of thrombin glue, 26%), malignancies (17%), infections (17%), or autoimmune diseases (11%), including SLE, hashimoto thyroiditis, primary biliary cirrhosis, or rheumatoid arthritis (Ang et al., 2009; Shastri et al., 1999; Takahashi et al., 2003; Franchini et al., 2012; Franchini and Lippi, 2011; Wang et al., 2017). In an analysis of FV inhibitors not associated with fibrin glue, 126 cases have been reported between 1955 and 2016. The estimated incidence was 0.09 (Singapore) to 0.23 (Australia) cases per million person years. About two-third of the patients with autoantibodies show a bleeding phenotype with hemorrhages mainly at mucosal membranes including hematuria, gastrointestinal, and gingival bleedings but also intracranial or retroperitoneal hemorrhages including fatal bleeds. Hemorrhages seem to correlate with the FV levels and with the aPTT (Ang et al., 2009; Favaloro et al., 2004; Olson et al., 2017).

Coagulation assays show a prolonged PT and aPTT, while the TT is normal. In contrast to FV deficiency or DIC mixing experiments fail to correct the test results. FV antigen and activity is reduced. FV inhibitors are also quantified by the Bethesda Assay.

Inhibitors belong to the isotypes IgG and IgA (Lane et al., 1978; Ortel et al., 1992; Takahashi et al., 2003). In a single publication an FV-specific IgG4 was described (Suehisa et al., 1995). The antibodies bind to the light chain of FV (A3-C1-C2) (Ortel et al., 1992). Interestingly, antibodies from patients showing a bleeding phenotype bind to the N-terminal part of C2 and inhibit the binding of FV to phospholipids and, therefore, interfering with the

formation of the prothrombinase complex (Ortel et al., 1998; Izumi et al., 2001). Platelet bound FV seems to be protected against most inhibitors, but severe bleedings have been described in a patient with inhibitors also against platelet associated FV (Ajzner et al., 2009; Nesheim et al., 1986). There are also noninhibitory antibodies that increase FV clearance. In addition to the anticoagulant nature of most FV inhibitors a single patient with an FV inhibitor was identified whose antibodies rendered FVa resistant to inactivation by activated protein C and therefore led to thrombophilic state (Kalafatis et al., 2002).

The initial therapy focuses on controlling the acute bleed. The use of platelets, FFP, PCC, aPCC, and FVIIa has been described. FFP was often given prior to diagnosis and needs critical assessment due to the low content of FV. The use of aPCC and FVIIa seems more effective (Ang et al., 2009; Franchini et al., 2012).

The need for eradication of FV inhibitors is discussed controversially. Inhibitors also disappear spontaneously within several weeks (Knobl and Lechner, 1998). There was no statistical difference in inhibitor elimination whether the patients were treated or not (Ang et al., 2009). Nevertheless patients with bleeding symptoms might benefit from inhibitor eradication. Several immunosuppressant approaches have been described including the use of corticosteroids, cyclophosphamide, or rituximab. ivlg, immunoabsorption, or plasmapheresis have also been used (de Raucourt et al., 2003; Jansen et al., 2001; Wang et al., 2017).

Prevention seems feasible as at least half of the published FV inhibitors occurred after the use of bovine thrombin or fibrin glue and therefore appear to be preventable with using alternative preparations (Streiff and Ness, 2002; Ballard et al., 2010).

## AUTOIMMUNE INHIBITORS TO FACTOR VII

Factor VII (FVII) is a serine protease composed of a Gla-domain, two epidermal growth factor (EGF) domains, and a protease domain. FVII binds to TF and is activated by thrombin, FXIa, factor XII (FXII), and FXa. FVIIa is a heterodimer of light chain (Gla and EGF domains) and the heavy chain (protease domain). The complex of TF and FVIIa activates FX and factor IX (FIX) (Vadivel and Bajaj, 2012).

Acquired FVII deficiency is mainly due to vitamin K deficiency and rarely an autoimmune pathology. Antibody mediated FVII deficiency has been described in less than ten reports so far, partly only with indirect evidence for autoantibodies. These inhibitors have been described as idiopathic, in combination with malignancies, autoimmune disorders, HIV-infection or after the administration of penicillin (Delmer et al., 1989; Aguilar et al., 2003; Campbell et al., 1980; de Raucourt et al., 1994; Ndimbie et al., 1989; Mehta et al., 1992; Weisdorf et al., 1989; Okajima and Ishii, 1999; Brunod et al., 1998). The intensity of hemorrhages varied from mild phenotypes to severe life-threatening bleedings and include hematomas, ecchymosis, gastrointestinal bleedings, hematuria, and intracranial hemorrhages (Delmer et al., 1989; Okajima and Ishii, 1999).

Coagulation assays show an isolated prolonged PT with normal aPTT, TT and bleeding time. FVII antigen and activity are decreased. Mixing studies do not correct the PT and inhibitors can be determined by the Bethesda Assay.

FVII inhibition is mediated by an IgG autoantibody belonging to the IgG1 subclass (Campbell et al., 1980; Weisdorf et al., 1989; Brunod et al., 1998). A direct inhibition of FVIIa interaction with TF or phospholipids has been proposed: the autoantibody bound to the light chain with an epitope on or near the Gla-domain in a Ca<sup>2+</sup>-dependent manner. In addition antibodies that increased the clearance of FVII without showing inhibition in vitro have been described (Weisdorf et al., 1989; Kamikubo et al., 2000).

The initial hemorrhage is controlled by administration of FFP, FVII, or FVIIa concentrates (Delmer et al., 1989; Mullighan et al., 2004). Tranexamic acid has also been used (Aguilar et al., 2003). The use of FVII concentrate has been associated with thrombotic events in patients with FVII inhibitors and underlying disease (Brunod et al., 1998). Inhibitor eradication has been achieved by immunosuppression and modulation with corticosteroids with or without azathioprine, ivlg or plasma exchange (Delmer et al., 1989).

## AUTOIMMUNE INHIBITORS TO FACTOR VIII

The FVIII protein includes the domains A1, A2, A3, B, C1, C2, and acidic spacers (Toole et al., 1984; Wood et al., 1984). The domain structure is shared between FV and FVIII. FVIII is mainly produced in endothelial cells; the main source of the protein is liver sinusoidal endothelial cells. During processing FVIII is cleaved into the heavy and the light chain, which include the domains A1-A2-B and A3-C1-C2, respectively. Heavy and

**FIGURE 50.3** Severe soft-tissue hemorrhage in a patient with acquired hemophilia A.

light chains form a noncovalent heterodimer, which is complexed to vWF. Upon activation by thrombin, the B domain and the acidic a3 region are cleaved off and vWF dissociates. FVIIIa interacts with the phospholipid membrane, FIXa and the substrate FX, which form the tenase complex and activate FX (Lenting et al., 1998; Saenko et al., 2002).

Despite rare, acquired hemophilia A (AHA) is by far the most frequent anticoagulant autoimmune condition (Fig. 50.3). In addition to numerous case reports, a small number of studies including one recent prospective trial and metaanalyses with 175–501 patients have been published (Green and Lechner, 1981; Collins et al., 2007; Delgado et al., 2003; Tiede et al., 2015). The reported incidence varies between 1.2 and 1.48/million/year (Collins et al., 2004; Tay et al., 2009). Patients presenting with AHA show a biphasic age peak with postpartum women dominating an early peak between 20 and 40 years (mean: 33.9 years) and men dominating the age peak above 60 years. Overall age groups men (58%) appear to be slightly more affected. The mean age at diagnosis is 73.9–78 years depending on the cohort (Collins et al., 2007; Green and Lechner, 1981; Knoebel et al., 2012; Tiede et al., 2015). A number of AHA cases in children have also been described (Moraca and Ragni, 2002; Brodeur et al., 1980).

AHA should be suspected patients presenting with spontaneously or traumatic bleeds without a prior bleeding history and a prolonged aPTT. The majority of patients show a severe bleeding phenotype. In contrast to congenital hemophilia A (CHA) most observed bleedings are large subcutaneous hematomas, ecchymosis and other soft-tissue bleeds. Many different clinical presentations have been reported including hematuria, gastrointestinal bleedings, intracranial hemorrhage and hemothoraces. Around 6% of the patients do not present with bleeding symptoms at time of diagnosis. Diagnosis is often prolonged, which is associated with increased bleeding but not with overall outcome (Knoebel et al., 2012; Fukushima et al., 2012; Micic et al., 2011; Rezaieyazdi et al., 2012; Webert, 2012). Similar to autoimmunity to other coagulation factors, AHA is associated with underlying conditions in about half of the cases. Malignancies (11.8%) including solid tumors, hematological neoplasias and autoimmune disorders (11.6%) including rheumatoid arthritis, SLE and others have been reported. Postpartum inhibitors comprised 7%–15% of the cohorts (Collins et al., 2007; Knoebel et al., 2012; Delgado et al., 2003; Green and Lechner, 1981). Others include exposure to certain drugs, surgery, infections, primary immunodeficiency and dermatological conditions. The remaining half with no concomitant condition identified is termed idiopathic AHA (Kim et al., 2008; Ozgur et al., 2007; Knoebel et al., 2012; Shetty et al., 2011; Reitter et al., 2011). A significant number of pregnancy associated FVIII autoantibodies are present antepartum. Hemorrhages during birth have been observed. The diagnostic evaluation of the newborn is crucial due to placental transfer of IgG (Tengborn et al., 2012).

Mortality is between 7.9% and 31%, whereas early mortality is related to bleeding and a much higher percentage of the patients experience later mortality due to complications of the immunosuppression or due to the underlying condition (Green and Lechner, 1981; Collins et al., 2007; Lottenberg et al., 1987; Morrison et al., 1993;

Hay et al., 1997; Bossi et al., 1998). In the largest cohort study at the end of follow-up survival of the patients with postpartum inhibitors was 100%, with concomitant autoimmune disease or malignancy 71% or 32%, respectively, and 58% for idiopathic AHA (Collins et al., 2012). In the recent prospective trial, 32% of the patients died during the first year after diagnosis (Tiede et al., 2015).

Laboratory results reveal a prolonged aPTT, low FVIII and normal PT or TT. Mixing studies do not correct the aPTT. Antibodies are measured by ELISA and by the Bethesda assay (Nijmegen modification). Bethesda units or residual FVIII activity do not correlate with the bleeding phenotype (Lindgren et al., 2002; Toschi and Baudo, 2010). Interestingly in a recent prospective trial FVIII activity <1 IU/dL and higher concentrations of FVIII specific IgG but not Bethesda units were associated with a lower rate of remission and a higher rate of death (Tiede et al., 2015; Werwitzke et al., 2016). Type I and type II kinetics of FVIII inactivation are observed with the latter being the dominant kinetic not inactivating FVIII completely. There are indications that type I inhibitors block the activation of FVIII by thrombin, whereas type II inhibitors block the binding to phospholipids resulting in different clinical phenotypes (Matsumoto et al., 2012; Nogami et al., 2001). Affinity for FVIII might also influence the type of kinetics observed. Isotypes IgG, mainly the subclasses IgG4 and IgG1, but also IgA and IgM have been detected at low titers (Whelan et al., 2013). The IgG population is polyclonal. In an analysis of 115 patients antibody epitopes were mainly found on the C1 (78%) and C2 (68%) domains followed by the A2 domain (23%) indicating a different epitope signature than found in the alloimmune response in patients with CHA and inhibitors (Kahle et al., 2017). The FVIII specific IgG subclasses and the recognized epitopes differ in different clinical conditions: while a general dominance of IgG4 is described, in postpartum AHA FVIII specific IgG2 and 3 were more frequent than in patients with other concomitant conditions. In addition, postpartum inhibitors recognized more often the heavy chain especially the A1a1 domain (Lapalud, 2012). The presence of FVIII specific IgA was associated with a higher risk of not achieving complete remission, relapse and death (Tiede et al., 2016). Antibodies block the interaction of FVIII with different molecules of the coagulation cascade including vWF, phospholipids, thrombin, FIX and FX by competition or steric hindrance. Proteolytic FVIII antibodies have also been described (Mahendra et al., 2012; Wootla et al., 2008). In addition, there are indications that inhibitors with type II kinetics also inhibit the proteolysis of FVIIa by activated protein C and establish circulating immune complexes (Nogami et al., 2001). Recently, the presence of hydrolyzing and activating FIX antibodies in AHA patients leading to thrombin generation in about a third of the patients was described (Wootla et al., 2011). The clinical relevance remains to be determined.

Some T-cell epitopes in the C2 domain (amino acids 2291–2330) are shared between AHA, patients with CHA with inhibitors and healthy individuals with additional disease group specific epitopes including the region 2241–2290 for AHA patients. In addition, distinct T-cell epitopes on the A3 domain have been identified for patients with AHA that are not shared by patients with CHA (Reding et al., 2003; Reding et al., 2004).

Polymorphisms in immune response genes as well as HLA genotypes have been described to be associated with AHA: a higher frequency of the CTLA4 49A/G polymorphism has been observed in patients with AHA compared to healthy controls. Interestingly the G allele was more frequent in patients with no idiopathic AHA or with an underlying autoimmune disease. HLA class I haplotypes were not associated with AHA, but for HLA class II haplotypes a higher frequency of DRB1\*16 and DQB1\*0502 and a lower frequency of DRB1\*15 and DQB1\*0602 were detected in affected patients. These results do not correspond to HLA haplotypes seen in CHA patients with inhibitors. The influence of polymorphisms in the FVIII gene remains to be investigated (Pavlova et al., 2008, 2010; Tiede et al., 2010).

The treatment of patients with AHA focuses initially on reestablishing hemostasis followed by the induction of tolerance and treatment of the underlying disease (if applicable). In a recent prospective trial, an immunosuppressive regime based on corticosteroids with the addition of cyclophosphamide and rituximab in a step-wise approach was evaluated in 102 patients. Hemostatic control without the necessity of further hemostatic treatment was achieved in 83% of the patients after a median of 31 days (range: 7–362 days) (Tiede et al., 2015). In current AHA treatment, in about 70% of the patients bypassing agents including FVIIa and aPCC are used to control acute bleeds. Around one-third of the patients did not require any hemostatic treatment. In the largest cohort FVIIa was used in more than half of bleeds and aPCC in 20%. Both agents were equally effective overall (91.8% and 93.3%) but treatment success for each agent differs in the individual patient. The remaining number of patients was treated with FVIII products, D-amino D-arginine vasopressin (DDAVP) and with porcine FVIII. Treatment with bypassing agents was more effective than treatment with human FVIII or DDAVP (69.9%) (Collins et al., 2007; Baudo et al., 2012; Morrison et al., 1993; Kessler and Ludlam, 1993). In about 4% of the patients thromboembolic events occurred during treatment with bypassing agents

(Knoebel et al., 2012; Sumner et al., 2007). Recently recombinant porcine (rp) FVIII was licensed for the treatment of AHA. In the initial treatment rpFVIII provides an alternative to classical bypassing agents with the opportunity to monitor the treatment (Kruse-Jarres et al., 2015). Current guidelines recommend the use of rpFVIII, rFVIIa and aPCC for the control of acute bleeds. The use of human FVIII might also be possible to control bleeds in patients with low titer inhibitors; further immune adsorption high-dose of FVIII treatment is successfully used in the European centers (Kruse-Jarres et al., 2017; Collins et al., 2013).

Immunosuppressive therapy is necessary to induce tolerance in most AHA patients. Various regimens based on corticosteroids, cytotoxic agents, rituximab, ivIg, plasmapheresis, immune adsorption, and protocols for the induction of immune tolerance from CHA with inhibitors using high-dose FVIII have been applied (Stasi et al., 2004; Nemes and Pitlik, 2000; Zanon et al., 2013; Barillari and Pasca, 2013; Tiede et al., 2009; Collins et al., 2007, 2012; Muzaffar et al., 2012; Wiestner et al., 2002; Freedman et al., 2003). Inhibitor eradication (complete remission) was achieved in about two-thirds of the patients. In the largest cohort to date (EACH2,  $n = 501$ ) most patients were treated with corticosteroids alone (43%), in combination with cyclophosphamide (25%) or with rituximab-based regimens (15%) achieving complete remission in 58%, 80%, or 61%, respectively. Successfully treated patients who received a combination of corticosteroids and cyclophosphamide experienced more adverse events (41%), mainly infections compared to the group treated with steroids alone (25%). The final outcome “alive and inhibitor free at last follow up” was 67% of the patients treated with steroids alone compared to 62% of the patients treated with corticosteroids and cyclophosphamide (Collins et al., 2012). In the prospective GTH trial complete remission was achieved in 61% of the patients after a median of 79 days (range: 26–856 days) (Tiede et al., 2015). The modified Bonn–Malmö protocol combining immune adsorption, immunosuppression, FVIII administration and FVIIa to control acute bleeds achieved remission rates of >90% for nonmalignancy associated AHA (Zeitler et al., 2012, 2013). Current guidelines recommend the use of corticosteroids alone, corticosteroids in combination with cyclophosphamide or—as second line—corticosteroids in combination with rituximab are recommended for different clinical situations (Kruse-Jarres et al., 2017; Collins et al., 2013). Treatment success appears to be associated with the underlying condition, younger age and the FVIII specific antibody signature (see above). Spontaneous remissions have also been described, especially in postpartum inhibitors. These groups also showed the highest rates of complete remission when treated with corticosteroids (Baudo and de Cataldo, 2003). When complete remission was achieved life-expectancy appears equal to nonaffected individuals of the same age (Collins et al., 2007).

## AUTOIMMUNE INHIBITORS TO FACTOR IX

FIX is a serine protease structurally related to FVII and FX including a Gla-domain, two EGF-like domains and a protease domain. FIX is activated by FXIa and FVIIa. FIXa forms with FVIIIa the tenase complex, which activates FX (see above).

Autoimmune inhibitors of FIX have been only described in single case reports (Largo et al., 1974; Roberts, 1970; Ozsoylu and Ozer, 1973; Reisner et al., 1977). The incidence is unknown. They mainly occurred in elderly people, but few cases in children have also been described (Jedidi et al., 2011; Mazzucconi et al., 1999; Miller et al., 1978). The condition occurred idiopathic or with underlying diseases including hepatitis C (under therapy), autoimmune liver disease, Sjögren syndrome, immune thrombocytopenia and arthritis, and SLE (Campos-de-Magalhaes et al., 2011; Jedidi et al., 2011; Krishnamurthy et al., 2011; Carmassi et al., 2007; Castro et al., 1972; Torres et al., 1980). Three cases have been reported with both, FVIII and FIX inhibitors (Carmassi et al., 2007) and one patient with an inhibitor to FIX, FX, and prothrombin (Rochanda et al., 2012).

Laboratory assessment reveals a prolonged aPTT while PT, TT and bleeding time are normal. In mixing studies the aPTT does not correct. FIX inhibitors are detected and quantified by the Bethesda Assay.

Due to the few cases, data are scarce on the nature of the autoantibodies to FIX. Alloantibodies described in hemophilia B patients are mainly IgG, belonging to the subclasses IgG1 and IgG4. The antibodies are mainly directed against the protease and the GLA-domain, but also the EGF-like domain (Torres et al., 1980). In one patient antibodies that bound to FIX, FX, and prothrombin belonged to the IgG4 subclass and bound to a common motif on the Gla-domain (Rochanda et al., 2012).

In the few cases described, the acute bleeding situation was treated with FVIIa (Abshire and Kenet, 2008) accompanied by immunosuppression with prednisolone alone (Krishnamurthy et al., 2011), in combination with ivIg (Mazzucconi et al., 1999) or with addition of azathioprine (Carmassi et al., 2007).

## AUTOIMMUNE INHIBITORS TO FACTOR X

FX also is a zymogen of a serine protease in its activated form and related to FVII and FIX with the identical domain structure including the Gla-, EGF-, and protease domains. Upon activation by FVIIa and TF or the tenase complex composed of FVIIIa and FIXa, FXa cleaves prothrombin in the presence of FVa (prothrombinase complex) and phospholipids which generates active thrombin.

Acquired FX deficiency has been described in the context of amyloidosis due to the adsorption of FX to fibrils (Mumford et al., 2000; Gollard et al., 2013; Chan and Ogunsile, 2017) and of malignancies including solid tumors and leukemias. Acquired FX deficiency unrelated to amyloidosis is extremely rare and has been reported in 36 patients with only 11 case reports with evidence for autoantibodies. Acquired inhibitors to FX have been associated with respiratory tract infections (Mulhare et al., 1991; Bayer et al., 1969; Hosker and Jewell, 1983; Currie et al., 1984; Broze, 2014; Chan and Ogunsile, 2017; Lee et al., 2012). One case has been described in a child after extensive burns (Matsunaga and Shafer, 1996). Antibodies as inhibitors were only identified in recent cases. The clinical picture includes hematoma, ecchymosis, mucosal bleeds, hematuria, and also intracranial hemorrhages (Lankiewicz and Bell, 1992; Rochanda et al., 2012; Smith et al., 1998; Edgin et al., 1980).

In laboratory findings PT and aPTT are prolonged while TT and bleeding time are normal. Inhibitors are quantified by the Bethesda assay.

Anti-FX inhibitors belong to the IgG isotype. Several antibodies that were analyzed bound to the light chain near or on the Gla-domain. The antibody inhibited the activation of FX by the TF–FVIIa complex and by the tenase complex (Rao et al., 1994; Lankiewicz and Bell, 1992; Smith et al., 1998; Matsunaga and Shafer, 1996). Another report described the recognition of a common epitope for FII, FIX, and FX also on the Gla-domain (Rochanda et al., 2012). This antibody population belonged to the IgG4 subclass.

Treatment of acute bleeds due to FX inhibitors is challenging due to the central role of FX in the coagulation cascade. The successful use of aPCC has been described but has also been complicated by thromboembolic complications and cerebral infarctions (Smith et al., 1998; Henson et al., 1989; Mulhare et al., 1991). Further PCC, vitamin K, and transfusions of FFP have been described with different success rates to control bleeds. Autoimmune inhibitors of FX are mainly transient, thus inhibitor eradication is not a focus of the primary treatment but corticosteroids or ivIg have been used in individual cases (Matsunaga and Shafer, 1996; Edgin et al., 1980).

## AUTOIMMUNE INHIBITORS TO FACTOR XI

Factor XI (FXI) is a zymogen and after activation by FXIIa, thrombin or autocatalytically it is a serine protease. It is composed of four so-called apple domains in the heavy chain and a protease domain and circulates as a homodimer. FXIa then activates FIX (Gailani and Smith, 2009).

Autoimmune inhibitors to FXI are also extremely rare. The incidence is unknown. Most reports are on elderly people, but also a few children have been described. FXI inhibitors have been found with underlying conditions such as SLE, leukemias, autoimmune gastrointestinal diseases, psoriasis, or membranoproliferative glomerulonephritis (Vercellotti and Mosher, 1982; Goodrick et al., 1992; Kyriakou et al., 2002; McManus et al., 2012; Bortoli et al., 2009; Rustgi et al., 1982; Vazzana et al., 2014). Different bleeding phenotypes due to FXI inhibitors occurred including mostly mild or no bleeding but also life threatening bleedings have been described (Bortoli et al., 2009; Reece et al., 1984).

In coagulation assays, FXI inhibitors present with a prolongation of aPTT with a normal PT, TT, and bleeding time. Inhibitors are quantified by the Bethesda assay.

The isotype of FXI inhibitors is IgG or IgM (Krieger et al., 1975). Antibodies in patients with congenital FXI deficiency are of the IgG1 or three subclasses and are directed against the heavy chain of the molecule (De La Cadena et al., 1988). The mode of FXI inhibition has been identified as increased clearance of FXI or blocking of the activation of FXI (McManus et al., 2012; Krieger et al., 1975; Poon et al., 1984). No such data are available on acquired inhibitors to FXI.

For the treatment of hemorrhages in the presence of FXI inhibitors, the use of FXI-concentrate, FFP, PCC, and rFVIIa have been described. Inhibitor eradication has been achieved by immunosuppression with corticosteroids or by immunosuppression as part of the therapy of the underlying condition (Vercellotti and Mosher, 1982; Billon et al., 2001; Bern et al., 2005; Goodrick et al., 1992).

## AUTOIMMUNE INHIBITORS TO FACTOR XII

FXII is a monomeric zymogen of the serine protease FXIIa. FXII consists of a heavy chain including two fibronectin-type domains, two EGF-like domains, a kringle domain, and a proline-rich domain plus a light chain including the catalytic center. Polyphosphates on the surface of procoagulant thrombocytes (contact phase) preactivate FXII, which is then activated by kallikrein. FXIIa then activates FXI and plasminogen. In addition to initiating the coagulation cascade, FXIIa starts the kallikrein–kinin system.

FXII inhibitors have been described in combination with autoimmune diseases such as SLE, APS, autoimmune hepatitis, malignancies including lymphoma and gastric carcinoma or infections such as hepatitis B (Bertolaccini et al., 2007; Jones et al., 2000; Davidson et al., 2005; Chalkiadakis et al., 1999). The pathology of FXII inhibitors is still being discussed; they are not associated with bleeding symptoms but possibly with a prothrombotic state (Aberg and Nilsson, 1972). In addition FXII inhibitors have been described in context with fetal loss (Jones et al., 2001; D'Uva et al., 2005).

Laboratory results show a very prolonged aPTT with a normal PT, TT, and bleeding time typically without any bleeding symptoms. Antibodies can be detected by ELISA.

For FXII inhibitors, isotype IgG or IgM has been identified (Jones et al., 2000; Davidson et al., 2005). In women with fetal loss most antibodies recognized the N-terminal portion of the heavy chain, which interacts with thrombocytes, whereas in patients with APS epitopes were identified in the catalytic domain and in the EGF-like domain (Inomo et al., 2008; Harris et al., 2005).

Treatment is not required, but anticoagulation may be considered particularly in context of pregnancy and miscarriages.

## AUTOIMMUNE INHIBITORS TO FACTOR XIII

FXIII is a tetrameric molecule composed of two A and two B domains, which is activated by thrombin and stabilizes the fibrin clot by cross-linking fibrin  $\gamma$ -chains (Ariens et al., 2002). Autoantibodies to FXIII occur very rarely but are likely to be under diagnosed. In recent years reported cases rose close to 100 due to a national registry (Ichinose and Japanese Collaborative Research Group on AH13, 2017). FXIII inhibitors are also associated with underlying conditions, including a monoclonal gammopathy (Luo et al., 2010) or other autoimmune diseases including SLE (Lorand et al., 2002; Ahmad et al., 1996; Ajzner et al., 2009; Luo and Zhang, 2011). Antibodies to FXIII have also been described after exposure to drugs such as isoniazid (Otis et al., 1974; Shires et al., 1979; Krumdieck et al., 1991). Almost half of cases have been termed idiopathic without any apparent underlying condition (Nijenhuis et al., 2004; Ichinose and Japanese Collaborative Research Group on AH13, 2017; Franchini et al., 2013).

Patients present clinically with recurrent hemorrhages of different intensity including mucosal, intramuscular, or large soft-tissue hematomas but also very severe to life-threatening events such as intracranial or retroperitoneal hemorrhages in 11% and 19% of the patients, respectively (Lorand et al., 2002; Daly et al., 1991; Ichinose and Japanese Collaborative Research Group on AH13, 2017). Mortality rate due to hemorrhages has been reported as high as 18%. An additional 18% of a subset of patients receiving immunosuppressive therapy died due to infections. The mean age at diagnosis was 65.8 years and ranged from 10 to 87 years with a median age between 60 and 70 years. Slightly more women than men were affected (Luo and Zhang, 2011; Ichinose and Japanese Collaborative Research Group on AH13, 2017). Diagnosis is based on a clinical score in combination with laboratory findings (Ichinose et al., 2016).

The laboratory findings typically reveal normal global coagulation tests including PTT, PT, bleeding time, and platelet counts. FXIII activity or levels are reduced and can be determined by chromogenic assays, ELISA for the FXIIIA or B subunits. The thromboelastogram reflects a reduced clot formation and increased fibrinolysis. Alternatively, a dissolved clot after treatment with 5 M urea indicates a FXIII deficiency. Inhibitors to FXIII can be measured by mixing studies and by ELISA to immobilized FXIII subunits. In addition immunocomplexes have been detected that may interfere with laboratory diagnosis. The residual FXIII activity correlates with the severity of bleeds (Ichinose and Japanese Collaborative Research Group on AH13, 2017).

Antibodies are mainly directed only against the enzymatically active A subunit of FXIII (80%) and rarely against the B subunit (7%) or against both (13%). Depending on the binding site, antibodies block the activation by thrombin, catalysis, and the binding to fibrin or other substrates of FXIII. Noninhibitory antibodies increase

the degradation of FXIII (Ahmad et al., 1996; Luo and Zhang, 2011; Ajzner et al., 2009; Lorand et al., 2002; Nakamura et al., 1988; Fukue et al., 1992).

The treatment of patients was based on replacement therapy and immunosuppression. Despite the presence of antibodies, treatment of acute bleeds with mainly FXIII concentrate or FFP (if concentrate was not available) has been successful. In addition antifibrinolytics, FVIIa and platelets have been used. Hemostatic therapy is mainly combined with immunosuppression, including corticosteroids and/or cyclophosphamide (Hayashi et al., 2012; Tosetto et al., 1995; Luo and Zhang, 2011; Ishida et al., 2010). The use of rituximab, ivIg, plasma exchange or immune adsorption, azathioprine, or cyclosporine has also been described. Despite initial successful treatment, recent data suggest an ongoing autoimmune response in around 10% of the patients (Ajzner et al., 2009; Gregory and Cooper, 2006; Ichinose and Japanese Collaborative Research Group on AH13, 2017).

## AUTOIMMUNE INHIBITORS TO VON WILLEBRAND FACTOR

Although vWF is not a classical coagulation factor, it plays a crucial role in primary as well as secondary hemostasis. The protein binds to FVIII prolonging its half-life prior to activation, interacts with subendothelial layers after vascular injury and promotes thrombocyte adhesion and aggregation. The glycoprotein includes the domains D', D1-4, A1-3, B, and C1-2. The vWF monomers assemble to multimers of different sizes up to 20,000 kDa. Ultralarge multimers are cleaved by ADAMTS 13 (see above, Section, Prothrombotic Disorders) (Schneppenheim and Budde, 2008).

Acquired von Willebrand disease (avWD) is also a rare condition. A few hundred patients have been described in literature, one report stated an incidence of 10% in a small, preselected cohort of patients with bleeding disorders (Mohri et al., 1998). Among patients with avWD, 10%–30% have a detectable autoantibody against vWF; their overall incidence has been estimated to be 0.04% (Kumar et al., 2003). The pathophysiology of avWD in most patients is not based on autoimmune phenomena but rather on a reduced production of vWF as seen in hypothyroidism, an increased clearance following attachment to tumor cells or paraneoplastic products, an increased mechanical clearance due to mechanical cardiac devices or due to certain drugs (Veyradier et al., 2000). Thus most cases of avWD are associated with underlying conditions such as hypothyroidism, lympho- or myeloproliferative disorders, solid tumors including Wilms tumor, infections, and acquired or congenital heart defects. Drugs that may cause avWD include certain antibiotics, hydroethyl starch, and valproic acid. Autoimmune avWD has been described as idiopathic or in combination with underlying autoimmune diseases, including SLE or monoclonal gammopathies (Will, 2006; Federici et al., 2000; Michiels et al., 2001). Patients present with a spectrum of no-to-severe bleeding symptoms including mainly ecchymoses but also epistaxis, gastrointestinal, and mucosal bleeds (Collins et al., 2008; Mohri et al., 1998). Patients with detectable inhibitors show a higher bleeding tendency than patients without inhibitors. Autoantibodies bind to the large or intermediate size multimers. They have been identified as mainly IgG isotypes, but also IgA and IgM have been described depending on the underlying condition. IgG antibodies belong to the subclasses IgG1 and IgG4. Epitopes have been mapped to the A1 and the A3 domain inhibiting collagen binding and binding to GP Ib and GP IIb/IIIa (Mohri et al., 1998; van Genderen et al., 1994).

Laboratory diagnosis of avWD and differentiation to congenital vWD is often difficult. The analysis reveals a prolonged bleeding time, with normal PT and normal or prolonged aPTT. The vWF antigen, ristocetin cofactor, or collagen-binding activity is reduced. The FVIII activity is often reduced as well. Large vWF multimers are often missing. Anti-vWF antibodies can be detected. In a Bethesda-like assay several approaches have to be considered due to the large size of vWF and different epitope-related effect of the antibodies. A pharmacokinetic analysis might be useful as noninhibitory antibodies that enhance clearance are not detected by the Bethesda assay (Siaka et al., 2003; Mohri et al., 1998; Tiede et al., 2008; Luboshitz et al., 2001; Federici et al., 2013).

The treatment of avWD is based on the underlying condition and pathomechanism. The use of desmopressin (DDAVP) to release vWF, the substitution of a vWF-containing FVIII concentrate or FFP, has been used successfully in nonautoimmune avWD and to control acute bleedings. The response to FVIII/vWF concentrates or DDAVP is usually very poor when an inhibitor is present. In severe uncontrollable bleedings FVIIa has also been used successfully. Autoimmune avWD has successfully been treated with immunomodulation, including the administration of immunoglobulins and immunosuppression with corticosteroids, rituximab, plasma exchange, or immune absorption (Collins et al., 2008; Sucker et al., 2009; Tiede et al., 2011; Gavva et al., 2017).

## AUTOIMMUNE INHIBITORS TO FURTHER PROTEINS

In addition to autoimmune responses to proteins described above, a case of an autoantibody to prekallikrein has been identified to date. An IgG1 and 4 polyclonal autoantibody population was detected in a patient who presented with a prolonged aPTT without any symptoms of bleeding or thrombosis (Page et al., 1994).

## CONCLUSION AND FUTURE ASPECTS

Autoimmune inhibitors to coagulation factors are rare phenomena and poorly understood entities of autoimmune diseases despite progress some entities. In case of bleeding in individuals without bleeding history, inhibitors to coagulation factors need to be assessed. The timely diagnosis and treatment of affected patients remains challenging. Further efforts are needed to understand the underlying pathology of autoimmunity leading to hemorrhages or thrombosis and to improve treatment outcome for affected individuals.

### Acknowledgments

The author would like to thank Stephan Schultze-Strasser, PhD, and Manuela Krause, MD, for assistance with or provision of figure, Christine Heller, MD, for critical comments on the manuscript and also his family, and the editors for support and patience.

## HISTORICAL BACKGROUND

It is widely held that the earliest known reference of multiple sclerosis (MS) can be attributed to Scottish pathologist Robert Carswell (reviewed by [Murray, 2009](#)). In his atlas, *Pathological Anatomy: Illustrations of the Elementary Forms of Disease* (1838), Carswell described two patients affected by paralysis, both with lesions along the spinal cord and lower brainstem accompanied by atrophy. Carswell believed that the extensive paralysis the patients suffered was directly related to the impressive pathology he encountered ([Behan, 1982](#)). However, compelling Carswell's account was that it was not until 30 years later that MS was named by a French neurologist, Jean Martin Charcot. Charcot first described a comprehensive account of the features of MS in 1868 by correlating the clinical and pathological features of the illness in patients he examined both while they were alive and at autopsy. While aspects of his findings would go on to be revised, he noted the accumulation of inflammatory cells in a perivascular distribution, demyelination, and axonal sparing within the lesions or "plaques" in the brain and spinal cord white matter of patients with intermittent episodes of neurologic dysfunction ([Charcot, 1868a,b, 1877](#)). This led to the term "sclérose en plaques disseminées," or MS.

Over the last 100 years, there have been many important historical milestones that have led to the fundamental understanding that MS is a multifocal inflammatory disease primarily affecting central nervous system (CNS) white matter resulting in progressive neurodegeneration in genetically susceptible hosts ([Nylander and Hafler, 2012](#)).

The hypothesis that MS is an autoimmune disease can be attributed to observations by Thomas Rivers at the then Rockefeller Institute. In 1933 Rivers demonstrated that injection of rabbit brain and spinal cord into primates resulted in a demyelinating disease in mammals (Rivers et al., 1933). This disease, known as experimental autoimmune encephalomyelitis (EAE), is the result of immunization of CNS myelin and has served as an important animal model for MS.

Schumacker et al. (1965) defined clinical diagnostic criteria based on the notion that MS is a disease disseminated in time and space throughout the CNS. Such criteria continue to be utilized and revised into the present day. Since then, the advent of magnetic resonance imaging (MRI) and the Food and Drug Administration (FDA) approval of disease-modifying immunotherapies, beginning with interferon (IFN)- $\beta$ 1b in 1993, have revolutionized how we examine and treat patients with MS (Young et al., 1981; Arnason, 1993). During the past 20 years, MS has evolved from a disease with no therapy to one with 15 approved therapies in the United States to date. These major advances have established MS as a treatable neurological illness. Nonetheless, the development of more effective and safer treatments that can be used at the time of diagnosis for this potentially disabling illness is paramount, and it is predicated on a more thorough understanding of the underlying immunopathology. Advances in immunology and neurology have provided clinicians with powerful tools to understand better the underlying causes of MS, leading to new therapeutic advances. The future calls for extending the original observations of Carswell and Charcot by continuing to define the molecular pathology of MS in relation to growing knowledge surrounding immune-related pathology and DNA haplotype structure, in addition to CNS and peripheral mRNA and protein expression, leading to the generation of a new series of disease-related hypotheses.

## CLINICAL FEATURES

The signs and symptoms of MS are variable as the disease can affect anywhere within the CNS. Demyelinating lesions may develop at any site along myelinated CNS white matter tracts, and symptoms of MS therefore depend on the functions subserved by the pathways involved. Although the primary insult involves demyelination, there is edema, inflammation, gliosis, and axonal loss which all contribute to the symptomatology of a lesion. The most common symptoms and signs involve alteration or loss of sensation due to involvement of spinothalamic or posterior column fibers, visual loss from optic neuritis, limb weakness and spasticity related to disruption of corticospinal tracts, tremors and incoordination of gait or limbs largely related to cerebellar or spinocerebellar fiber involvement, and abnormalities of cranial nerve function (such as double vision due to disturbance in conjugate eye movement) secondary to brainstem lesions (Noseworthy et al., 2000). Bowel, bladder, and sexual dysfunction occur in over two-thirds of the patients at some time during the course of their illness (Betts et al., 1993; Mattson et al., 1995), largely due to disruption in spinal cord pathways. Fatigue, depression, and cognitive changes are common symptoms of unclear etiology that can significantly interfere with daily functioning and are now being recognized as significant contributors to disability (Whitlock and Siskind, 1980; Freal et al., 1984; Sadovnick et al., 1996). A correlation with progressive brain atrophy, cognitive decline, and impairment on MRI has implicated axonal loss as the pathologic substrate of the cognitive deterioration in MS (Rao et al., 1989; Hohol et al., 1997; Amato et al., 2004).

While MS might have variability in clinical presentation and course of the illness, it can follow a number of rather predictable courses. MS can be divided into disease subtypes: radiologically isolated syndromes (RISs), clinically isolated syndromes (CISs), relapsing-remitting MS (RRMS), secondary progressive MS (SPMS), and primary progressive MS (PPMS).

### Radiologically Isolated Syndrome

RIS is often identified incidentally on MRI of the brain in the absence of signs or symptoms. However, in the presence of a high lesion burden and evidence of CNS inflammation with positive oligoclonal bands (OCBs) or increased IgG index in the cerebrospinal fluid (CSF), there is a significant risk of developing the clinical symptoms of MS. Patients with RIS are often followed with close serial examinations and MRIs over time. In some cases where new lesions occur in the absence of clinical symptomatology, immunotherapy should be considered.

## Clinically Isolated Syndrome

CIS generally occurs in young adults and is defined by the presentation of a first episode of demyelination, typically in the form of an optic neuritis, cerebellar, or brainstem syndrome. During an episode, neurological symptoms develop over hours to several days, persist for days to several weeks, and gradually dissipate (Miller et al., 2012). In order for such episodes of acute inflammatory CNS demyelinating events to be considered CIS, they must last for at least 24 hours with no more than 30 days between attacks (Polman et al., 2005). The resolution of symptoms appears to be due to the reduction of inflammation and edema at the site of the responsible lesion rather than to the reversal of demyelination, which may persist even in the absence of symptoms (McDonald et al., 2001).

A number of prospective studies have helped to risk-stratify patients with CIS. Those patients who have concurrent but clinically silent lesions on MRI are at a higher risk for developing MS, but those without MRI lesions in other parts of the CNS have a lower probability of developing MS (Achiron and Barak, 2000; Fisniku et al., 2008). It is prudent to consider that while the patient might not meet strict McDonalds Criteria, the presence of other inactive or clinically silent lesions on MRI likely indicates that the patient is hosting underlying pathology consistent with MS. We at times call CIS “singular sclerosis” thus explaining to the patients that we know what is going on and that there is a high likelihood of developing MS (Rovira et al., 2009). There should be a low threshold to treat such patients, particularly if the first clinical attack occurred in the presence of added risk factors for long-term physical disability, such as incomplete recovery from first attack and bladder or bowel symptoms at onset (Langer-Gould et al., 2006).

## Relapsing-Remitting Multiple Sclerosis

If a patient with a CIS develops further clinical episodes followed by relapses, then the patient meets criteria for a diagnosis of RRMS. Early in the course of RRMS, patients often make complete recovery from relapses. As the disease progresses, the recovery from a relapse diminishes, which causes a patient to accrue disability. A relapsing-remitting onset is observed in 85%–90% of the patients, with relapses often lasting an average of 4 weeks in duration. The outcome in patients with RRMS is variable; untreated, previous reports suggested that approximately 50% of all MS patients require the use of a walking aid by 10 years after clinical onset (Weinshenker, 1994). The consequences on prognosis of newer treatment regimens are not well delineated; however, many studies indicate improvement of disability status following continued treatment regimens (Bates, 2011). Increased attack frequency and poor recovery from attacks in the first years of clinical disease predict a more rapid deterioration (Confavreux and Vukusic, 2006). New treatment paradigms will be discussed later in this chapter.

## Progressive Multiple Sclerosis

Ultimately, approximately 40%–50% of the untreated RRMS patients stop having attacks and develop what may be a neurodegenerative progressive disease secondary to the chronic CNS inflammation, known as SPMS (Confavreux et al., 2000). The evolution to this secondary progressive form of the disease is associated with significantly fewer gadolinium-enhancing lesions and a decrease in brain parenchymal volume (Khoury et al., 1994; Filippi et al., 1995; Weiner et al., 2000). Similarly, while earlier RRMS is sensitive to immunotherapy (Hohol et al., 1999), as times goes on, responsiveness to treatment decreases and ultimately disappears in secondary progressive disease (Rieckmann et al., 2004).

Lastly, PPMS is a form of disease that occurs in close to 15% of the patients and unlike RRMS is more frequent in males. It is characterized from the onset by the absence of acute attacks and instead involves a gradual clinical decline traditionally in the form of a progressive myelopathy (Miller and Leary, 2007). Patients might also present with a progressive cerebellar syndrome in the form of ataxia. Clinically, this form of the disease is associated with a lack of significant response to immunotherapy, although anti-CD20 monoclonal antibody (ocrelizumab) has a modest effect on disease progression and has been FDA approved for patients with this form of disease. Given some challenges in making the diagnosis of PPMS, there are specific proposed diagnostic criteria that will be discussed later in the chapter.

## DIAGNOSTIC CRITERIA

In the absence of a specific immune-based assay, the diagnosis of RRMS continues to be predicated on the clinical history and neurological exam demonstrating multiple lesions disseminated in time and space within the CNS (McDonald et al., 2001). Using McDonald's criteria, the diagnosis of RRMS can be made solely on the basis of history of two relapses and objective findings on exam of two lesions disseminated in the CNS (periventricular, juxtacortical, infratentorial, or spinal cord). However, MRI of the neuroaxis is often sought to confirm the diagnosis or to rule out other mimics of the illness. The use of the MRI and other imaging modalities has had a major impact on early diagnosis. Moreover, in practice, MRI helps to monitor disease course and response to therapy. T1-weighted scans generally provide appreciable contrast between gray and white matter with water appearing darker and fat brighter. In T2-weighted scans, fat is also differentiated from water; however, fat appears darker and water lighter in the image, making T2-weighted scans well suited for imaging edema since CSF appears lighter (Filippi and Agosta, 2009). As part of revised 2010 McDonald's criteria for RRMS diagnosis, new T1-weighted lesions or T2-weighted gadolinium enhancing-lesions on follow-up MRI scans may serve as criteria for dissemination in space (DIS) or dissemination in time, thus allowing for a diagnosis fulfilling the criteria for MS. For diagnosis of PPMS under McDonald's Criteria, there must be 1 year of disease progression plus two of the following three elements: (1) evidence for DIS in the brain based on having  $\geq 1$  T2 lesions in MS characteristic regions; (2) evidence for DIS in the spinal cord based on  $\geq 2$  T2 lesions in the cord; and (3) CSF with presence of OCBs and/or elevated IgG index (Polman et al., 2011). In addition to meeting criteria for DIS and dissemination in time, a thorough evaluation should be done to rule out alternative diagnoses. The extent of the workup is often dependent on the appearance of the lesions, the patient's clinical course, and the patient's other medical risk factors. Differential diagnosis includes but is not limited to rheumatologic conditions, metabolic derangements, infections of the CNS, vitamin deficiencies, and malignancies of the CNS.

## IMAGING

MRI has gained a principal role in the assessment of MS because it allows clinicians to readily obtain an understanding of the pathophysiology of the lesions, CNS involvement, and ultimately the overall illness without invasive procedures. Currently, common MRI measures of disease burden include the quantification of brain lesions using T1- and T2-weighted images, gadolinium contrast, proton density, and fluid attenuated inversion recovery sequences. Each of these markers represents many possible histopathological correlates, including demyelination, edema, axonal loss, matrix destruction, and inflammation (Filippi and Rocca, 2011). The lesions on MRI are often ovoid in shape, ranging from a few mm to more than 1 cm in size. Their location is crucial, considering that MS lesions have a high propensity to locate in the periventricular white matter, brainstem, and cerebellum. In addition, MRI and pathological data suggest that the evolution of MS lesions depends on whether they occur during early versus chronic phases of the disease course (Filippi et al., 2012).

T2/FLAIR is the best sequence to date for visualizing the white matter lesions from MS, although it has some limitations in the posterior fossa, in which case a regular T2-weighted image might help to differentiate artifact from true hyperintensity. Typical MS protocol for MRI should include the following: precontrast axial, coronal, and sagittal T2/FLAIR sequences, axial T1- and T2-weighted images, and axial, coronal, and sagittal postcontrast T1-weighted images.

Lesions on T2-weighted images are often clinically silent and correlate weakly with a patient's disability despite correlating well with the location on plaques in the CNS of postmortem MS patients (Newcombe et al., 1991). Hypointense lesions on T1-weighted images may be persistent or nonpersistent (Rovaris et al., 1999). Persistent hypointense T1-weighted lesions represent areas indicative of axonal loss and severe tissue destruction and correlate better than T2 lesion load with clinical severity of the disease (Van Waesberghe et al., 1999). Multiple T2-weighted and/or gadolinium-enhancing lesions on initial MRI scans indicative of diffuse cortical lesions and atrophy also predict a more severe subsequent course related not only to physical disability but also to diminished cognitive outcome (Calabrese et al., 2009; Deloire et al., 2011). Nonpersistent hypointense lesions on T1-weighted images represent reversible edema due to abatement of inflammation. Postcontrast gadolinium enhancement of lesions on T1-weighted images represents acute disruption of the blood–brain barrier (BBB) from inflammation. On average, disruption can last 3 weeks but can range anywhere from 2 to 6 weeks and is

dependent on gadolinium dose, the characteristics and delay of image acquisition, and steroid treatment of acute attacks (Filippi, 2000).

Intermittent MRI imaging might underestimate severity of disease burden since weekly MRI scanning suggests that a significant proportion of MS lesions have very short-lived enhancement (Cotton et al., 2003). Brain and spinal cord atrophy may occur in MS and can represent loss of myelin, oligodendrocytes, and axons, in addition to contraction of astrocyte volume.

Quantitative susceptibility mapping (QSM) is a novel sequence derivative of susceptibility-weighted imaging that provides a direct measure of tissue susceptibility and can indicate the presence of iron deposition, a known component of activated microglia in chronically activated lesions. Therefore it is potentially a measure of chronically active lesions after gadolinium enhancement has subsided as well as a possible marker for lesions that will go on to cause atrophy and progressive features. Continued work in improving the use of various imaging modalities to more accurately characterize active disease is imperative in moving forward.

## IMMUNOLOGICAL MARKERS IN DIAGNOSIS

CSF immunologic markers can function as adjuncts to clinical findings when considering the diagnosis of MS. The CSF of patients with MS typically shows normal glucose, 0–5 lymphocytes (predominantly T cells), normal to mildly elevated total protein, increase in IgG CSF synthesis (IgG index), and OCBs. OCBs are uncovered when CSF from MS patients is electrophoresed. The cathode region reveals a number of discrete bands that represent excess antibody production by one or more clones of B cells. Such bands are not evident when CSF from healthy controls is electrophoresed. Often absent early in the disease, OCBs can eventually be detected in over 90% of the patients with MS (Cruz et al., 1987; Mclean et al., 1990).

CSF OCBs have also been described in conditions where there is CNS inflammation such as subacute sclerosing panencephalomyelitis (Mattson et al., 1980), neurosyphilis (Pedersen et al., 1982), Varicella zoster virus infection (Vartdal et al., 1982), HIV infection (Skotzek et al., 1988), and in multisystem autoimmune diseases. They are more rarely seen in cerebrovascular accidents, and up to 5% of the normal individuals. Of note, OCBs are continuously present in MS regardless of disease activity, whereas they are transient in other conditions due to infection clearance (Link and Huang, 2006). Furthermore, OCBs have been reported to correlate with disease course and disability progression (Link and Huang, 2006; Mandrioli et al., 2008) and with the conversion to MS in patients with CIS and a negative MRI or an MRI with few lesions (Tintore et al., 2008). In diseases such as the viral encephalitides, OCBs commonly bind virus determinants, in contrast to MS, where there is continued evidence to suggest that OCB antibodies are heterogeneous in their structures and roles without one particular antibody target identified to date (Olek, 2000; Brändle et al., 2016).

Due to intrathecal synthesis from plasma cells, CSF immunoglobulin levels are also elevated in patients with MS. The immunoglobulins are mainly composed of IgG, with lesser amounts being IgM and immunoglobulin A (IgA). Specifically, studies have delineated differences between IgG and IgM levels with the latter correlating more strongly with MS disease course and IgG reflecting local B-cell responses accompanying CNS inflammation. Nearly 90% of the patients demonstrate elevated levels of CSF IgG production when the IgG index formula (spinal fluid IgG/spinal fluid albumin)/(serum IgG/serum albumin) is calculated. A spinal fluid IgG index greater than 0.58 implies that IgG is being synthesized in the CNS.

Apart from OCBs, numerous CSF markers have demonstrated specificity for the MS disease process. Several nonspecific proteins may function as markers of disease process, including tau protein and myelin basic protein (MBP), in addition to light and heavy neurofilament chains appearing during relapse and correlating with long-term functional outcome and the likelihood of conversion from CIS to RRMS (Graber and Dhib-Jalbut, 2011). While measuring neurofilaments may have some future clinical utility, there is no usefulness in measuring MBP in the era of MRI imaging. This remains an example of a “legacy test” discovered over 35 years ago that is of no clear utility.

There are reports of serum and CSF anti-MBP, anti-myelin oligodendrocyte glycoprotein (MOG), and anti-proteolipid protein (PLP) autoantibodies (Warren and Catz, 1994; Warren et al., 1994; Berger et al., 2003) in patients with MS, and it has become clear that these findings represent nonspecific binding of low-affinity antibodies to denatured proteins on ELISA plates. There are observations that high-affinity antibodies against MOG epitopes are present in a small proportion of the patients (Menge et al., 2011). However, using sensitive solution phase assays, high-affinity autoantibodies to MOG can be detected in the serum and CSF of patients with acute disseminated encephalomyelitis and pediatric MS (O'Connor et al., 2003, 2005, 2007; Zhou et al., 2006). A recent

study aiming to characterize intrathecal MOG antibodies in MS indicated that the rMOG index, a marker of intrathecal MOG antibody production, may provide complementary information to routine CSF testing in the diagnosis of MS (Klawiter et al., 2010). Moreover, anti-MOG autoantibodies can be eluted from the brain tissue of a subset of patients with MS (O'Connor et al., 2005). Such markers support the ongoing hypothesis of MS as a disease linked to immune dysfunction, ongoing inflammation, and tissue damage and repair. A serum autoantibody, neuromyelitis optica immunoglobulin (NMO-IgG), was identified in patients with neuromyelitis optica, an inflammatory demyelinating disease similar to, and considered by some, to be a variant of MS affecting the optic nerves and spinal cord, thereby highlighting the importance of the differential diagnosis between MS, NMO, and NMO spectrum disorders. NMO and the associated autoantibody (NMO-IgG/anti-aquaporin 4) are discussed further in Chapter 57, Hepatitis.

## PATHOLOGY

Gross examination of MS brain tissue has largely been limited to autopsy specimens of individuals with long-standing disease. Such pathological examination reveals multiple sharply demarcated gray colored plaques in the CNS white matter with a predilection for the optic nerves and white matter tracts of the periventricular regions, brainstem, and spinal cord. The gray matter contains less myelin, and thus lesions in the gray matter are less conspicuous on gross examination (Geurts et al., 2005). When examining the histological features of an MS lesion, there exist three major components: inflammation, gliosis, and demyelination. The inflammation in lesions is composed of lymphocytes, monocytes, and macrophages whose proportions depend on the activity and age of the lesion (Frohman et al., 2006). The second component of a lesion occurs when reactive astrocytes and fibrillary gliosis are present in the lesion.

Demyelination is an important feature of the MS lesion. Although MS is described as a disease causing a loss of myelin, the notion of axonal loss has been suggested as the major cause of irreversible disability in patients with MS. Trapp et al. (1998) first reported that substantial axonal injuries with axonal transections are also abundant throughout active MS lesions, even in patients in the early stages of the disease process. Axonal reduction and acute damage have previously been correlated with demyelination and meningeal inflammation (Ferguson et al., 1997). Interestingly, one study suggested that differences in axonal loss exist among subsets of MS, with the least axonal loss being demonstrated in PPMS and the most pronounced in SPMS (Bitsch et al., 2000). Notably, there have been case reports of early RRMS presenting with inflammatory cortical demyelination prior to the appearance of white matter lesions, indicating possible inflammation being initiated at the subpial layer (Popescu et al., 2011). Recent work aimed at elucidating the pathogenesis of axonal damage and loss has implicated several mechanisms including inflammatory secretions, Wallerian degeneration, disruption of axonal ion concentrations, loss of myelin-derived support, damage from nitric oxide and reactive oxygen species, energy failure from mitochondrial dysfunction, and  $\text{Ca}^{2+}$  accumulation (Smith and Lassmann, 2002; Dutta and Trapp, 2007; Dziedzic et al., 2010).

MS lesions can also be classified from a pathogenesis point of view into three types based on the age of the lesion: active, chronic active, and chronic inactive (Lassmann, 1998). This classification system has recently been corroborated by interval MRIs of lesions in live individuals as well as MRIs of tissue specimens using QSM imaging modalities which show the evolution of acute lesions into either remyelinated areas, chronically active lesions, or chronically inactive lesions. Macrophages are most prominent in the center of the active plaques and are seen to contain myelin debris, while oligodendrocyte counts are reduced and generally present in lesions demonstrating signs of remyelination. Hypertrophic astrocytes and mild astroglial scarring are also characteristic of active lesions (Frohman et al., 2006). Lymphocytes may be found in normal appearing white matter beyond the margin of active demyelination (Prineas, 1975; Booss et al., 1983). The inflammatory cell profile of active lesions is characterized by perivascular infiltration of oligoclonal T cells (Wucherpfennig et al., 1992b) consisting predominantly of clonally expanded CD8<sup>+</sup> T cells in the plaque margins and perivascular cuffs, and to a lesser extent of CD4<sup>+</sup> cells invading the normal appearing white matter around the lesion (Traugott et al., 1983; Hauser et al., 1986; Babbe et al., 2000). The inflammatory infiltrate may also include monocytes, occasional B cells,  $\gamma\delta$  T cells, and rare plasma cells (Booss et al., 1983; Wucherpfennig et al., 1992a; Babbe et al., 2000). Remarkably, demyelination in acute lesions may be related to an antimyelin antibody-mediated mechanism in which normal myelin is coated with anti-MOG immunoglobulin and phagocytosed in the presence of complement by local macrophages (Genain et al., 1999). Chronic-active lesions are sharply demarcated with perivascular cuffs

of infiltrating cells, lipid- and myelin-laden macrophages, activated microglia, and hypertrophic astrocytes. These cells disappear from the center core suggesting the presence of ongoing inflammatory activity along the lesion edge. Within the hypocellular core, there are naked axons embedded within a matrix of fibrous astrocytes, lipid-laden macrophages, a few infiltrating leukocytes, and no oligodendrocytes. The chronic-inactive plaque does not have macrophages at the border or center of the plaque. There is vast hypocellularity and no ongoing demyelination with histology demonstrating demyelinated axons with fibrillary gliosis (Raine, 1991).

## EPIDEMIOLOGY OF MS

The prevalence rates of MS vary based on latitude and patient populations in North America. According to the Center for Disease Control (CDC), the prevalence in one part of Texas was 47.2 per 100,000 while it was 109.5 per 100,000 in Ohio, which is more than 1 in 1000 people (Noonan et al., 2010). It is possible that prevalence data do not reflect the true number of cases, with some populations being undiagnosed or not included in these statistics. The median age of onset of symptoms is 23–24 years, with a peak age of onset for women in the early twenties, and for men in the late twenties (Schumacker et al., 1965; Paty et al., 1994). As in most diseases classified as autoimmune, there is a clear female predominance in MS cases, with a 3:2 female-to-male ratio (Olek, 2000). Studies of MS incidence rates in migrants (Dean et al., 1976) and apparent epidemics of MS at geographical locations (Kurtzke et al., 1982), also discussed below, indicate a clear role for environmental factors.

### Genetic Factors

Studies in twins (Mackay and Myrianthopoulos, 1966; Williams et al., 1980; Heltberg and Holm, 1982; Ebers et al., 1986; Kinnunen et al., 1987; [No authors listed], 1992; Mumford et al., 1992) demonstrate shared genetic risk factors for MS. While the risk of developing MS in the general population is 1/750, our early understanding of the genetic factors linked to MS epidemiological studies and disease concordance within family members or twins. Such studies have demonstrated that approximately 15%–20% of the patients have a family history of MS and when both parents are affected with MS, 9% of the children develop the disease (Hogancamp et al., 1997; Sadovnick et al., 1997; Sadovnick, 2006). Twin studies have indicated that the monozygotic concordance rate is 30% versus the dizygotic rate of 5% (Holmes et al., 1967; Sadovnick et al., 1993). Nevertheless, large extended pedigrees are relatively uncommon.

Most recently, work involving genome-wide association studies (GWAS) using single nucleotide polymorphisms from the haplotype map (HapMap) project has provided insights into the genetic architecture of autoimmune diseases (Tishkoff and Verrelli, 2003; Frazer et al., 2007). Specifically, the sequencing of the human genome and the generation of the HapMap has finally allowed the identification of the genetic architecture underlying risk for developing autoimmune diseases by GWAS (Tishkoff and Verrelli, 2003). GWAS have afforded an unbiased and widespread approach in scanning the whole genome and identifying haplotypes associated with risk of developing human diseases. They provide an alternative approach to classic linkage analysis and have greater statistical power to detect variants conferring a modest disease risk (Risch and Merikangas, 1996; Yang et al., 2005).

In 2007, we performed among the first GWAS in patients with autoimmune diseases in subjects with MS and identified several gene regions associated with disease risk (Hafler et al., 2009). Over the past decade, we have performed a series of deeper investigations of MS genetic risk (Wellcome Trust Case Control Consortium et al., 2007; Aulchenko et al., 2008; Comabella et al., 2008; Australia and New Zealand Multiple Sclerosis Genetics Consortium, 2009; Baranzini et al., 2009; De Jager et al., 2009b; Jakkula et al., 2010; Nischwitz et al., 2010; Sanna et al., 2010; International Multiple Sclerosis Genetics Consortium et al., 2009).

In our most recent study, we assembled and analyzed genetic data of 47,351 MS patients and 68,284 control subjects. These data established a reference map of the genetic architecture of MS that includes 233 autosomal susceptibility variants outside the major histocompatibility complex (MHC), 1 chromosome X variant, and 32 independent associations within the extended MHC. We have used a number of different methods to map MS susceptibility genes onto cell types. These studies implicate multiple innate and adaptive pathways distributed across the cellular components of the immune system, particularly CD4 and B cells (Farh et al., 2015). Using expression profiles from purified human microglia, we found enrichment for MS genes in these brain-resident immune cells. Thus while MS is most likely initially triggered by perturbation of peripheral immune responses,

the functional responses of microglia and other brain cells are also altered and may have a role in targeting an autoimmune process to the CNS.

One of the additional aims of GWAS has been to refine our understanding of the genetic risk associated with the MHC through looking more closely at HLA types at six loci (A, B, C, DQA1, DQB1, and DRB1) (Sawcer et al., 2011). Prior to GWAS, our understanding of the association and linkage of MS with respect to MHC was limited to alleles and haplotypes on chromosome 6p21. Recently, studies have successfully established HLA DRB\*1501 as being the allele variant involved in MS as opposed to HLA DQA1 or DQB1 (Brynedal et al., 2007; Lincoln et al., 2009). Further work has implicated HLA-A2 as being negatively associated with MS, thereby potentially serving as a protective allele with consistent effects across cohorts.

Many of the alleles identified in MS are shared not only among other autoimmune diseases but also are strongly associated with immune pathways (Farh et al., 2015). Given these genetic commonalities, it is therefore not surprising that MS and other autoimmune diseases share related defects in immune function and regulation. Recent work aimed at uncovering the intricacies of the relationships between autoimmune diseases has confirmed commonality across seven autoimmune diseases through identifying shared genes among some but not all of the diseases (Cotsapas et al., 2011). A model addressing the overarching interconnectivity of various autoimmune disease mechanisms is likely to be elucidated in the future. As MS is a complex disease, understanding which combinations of genes within the population confer the greatest risk of developing autoimmune disease is a central goal of present genetic research efforts. Nevertheless, these studies have provided convincing evidence that MS fits into the autoimmune disease category and is caused by common allelic variants each with only subtle but important variations on immune function.

## Environmental Factors

Global maps of MS prevalence rates, constructed based on multiple descriptive epidemiological studies, reveal a nonrandom geographical distribution of the disease. A diminishing north to south gradient of MS prevalence was described in the Northern Hemisphere (Beebe et al., 1967; Kurtzke, 1977; Kurtzke et al., 1979; Hammond et al., 1987), with an opposite trend identified in the Southern Hemisphere (Hammond et al., 1988; Hogancamp et al., 1997; Kurtzke, 2000). Notably, there is a marked absence of MS cases directly near the equator. When taking continental differences into consideration, there is increased prevalence of MS with large dispersion in Western Europe and North America, both regions being highly populated by Caucasians, whereas areas in Central and Eastern Europe, Australia, and New Zealand have lower prevalence with the lowest prevalence occurring in Asia, the Middle East, and Africa. Such variation calls into question the possibility that ethnicity might be linked to the continental differences seen (Koch-Henriksen and Sorensen, 2010).

Previously, the study of latitudinal differences demonstrated only modest effect in Europe and North America (Lauer, 1995; Weinshenker, 1996), with the only clear trend of increased incidence attributed to the Southern Hemisphere where the majority of studies have come from New Zealand and Australia (Skegg et al., 1987; Mcleod et al., 1994). Descendants living New Zealand and Australia have a lower risk of MS than those descendants living in the United Kingdom. This general distribution likely reflects a combination of genetic and environmental influences particularly with respect to exposure to sunlight (Ebers, 2008). However, the aforementioned more recent study of populations in North America by the CDC did demonstrate a clear latitudinal gradient with higher prevalence of MS cases occurring farther from the equator, even when controlled for ethnic differences (Noonan et al., 2010).

Relatedly, environmental deficiencies have long been associated with MS, as indicated by the inverse correlation of the world prevalence of MS and environmental supply of vitamin D. Vitamin D may be supplied from the environment via sunlight exposure or via dietary intake of vitamin D3 (Vanamerongen et al., 2004; Ascherio et al., 2010). At higher latitudes, the exposure to sunlight is insufficient to produce vitamin D given the lower exposure to the sun in winter months. Vitamin D and its immunomodulatory effect have been established both in response to sunlight and in dietary vitamin D(3) intake (Smolders et al., 2008; Kragt et al., 2009). Subtle defects in vitamin D metabolism have suggested a possible genetic origin. Identification of a highly conserved vitamin D responsive element in the promoter region of the HLA-DRB\*1501 haplotype has sparked ongoing debate as to whether HLA-DRB\*1501 might be involved in the response to vitamin D particularly since studies suggest that the beneficial effect of vitamin D on MS may in fact be attenuated in those with the risk allele (Ramagopalan et al., 2009; Simon et al., 2011). Nevertheless, few genetic determinants have been identified.

Epstein–Barr virus (EBV) infection has been linked to MS risk since exposure to EBV is associated with 1.5 times greater risk of developing MS. Over 99% of the individuals with MS have evidence of prior infection with EBV in comparison to 90% in humans overall (Bagert, 2009). However, the role of EBV in the development of MS is not known. EBV generally infects resting B lymphocytes transforming them into memory cells that survive long term largely undetected by the immune system (Thorley-Lawson and Gross, 2004). Interestingly, serostatus in individuals with MS has demonstrated elevated titers to EBV prior to the development of any neurologic sequelae (Thacker et al., 2006).

Diet has been investigated as a potential environmental factor contributing to the development of MS. In particular, the marked increase in salt intake in the Western diet has been studied with interesting results. Based on evidence that development of EAE appears to be linked to pathogenic IL-23-dependent T<sub>H</sub>17 cells, a recent study demonstrated that elevated in vivo sodium chloride concentrations might increase the expression of pathogenic T<sub>H</sub>17 in murine and human cells, leading to increased production of proinflammatory cytokines. Researchers also showed that mice with high-salt diets developed greater expression of IL-17a-producing CD4<sup>+</sup> cells and more severe forms of EAE (Kleinewietfeld et al., 2013). Based on these results, another study looked at salt intake in the human population, demonstrating a 2.75-fold increase in exacerbation rate in RRMS patients with moderate-to-high salt diets when controlled for a number of factors including treatment, age, and disease duration (Farez et al., 2015). Of note, there was one study that found possible evidence to the contrary. Using estimates of 24-hour urine sodium extrapolated from spot urine samples over 5 years in a subanalyzed group of patients enrolled in the BENEFIT trial, researchers did not find an association between urinary sodium as a marker of dietary intake and progression clinically or radiographically of CIS or MS (Fitzgerald et al., 2017).

There has also been speculation about the role of childhood obesity and the risk of developing MS. A recent study looking at pediatric MS found an adjusted odds ratio of 3.76 for development of MS in extremely obese girls compared to healthy controls, but researchers found no effect in boys with obesity (Langer-Gould et al., 2013).

Finally, a major area of research for environmental factors is emerging from investigation of the role of the gut microbiome as a factor in mediating host immune responses and gene expression. A 2016 study used rRNA sequencing to analyze the microbiome in healthy, untreated, and treated MS cohorts. It characterized populations of the microbiome and found differences between healthy and MS populations at the phylum level. These results also suggested that certain microbiome populations might be considered proinflammatory, and treatment of MS might shift the population to a more normalized profile. In a more recent study, mice with EAE tended to have more severe disease when exposed to the microbiome from MS patients. Specific populations of gut bacteria were identified as either proinflammatory or antiinflammatory, specifically regulating expression of IL-10-positive T-cells and regulatory T cell (Treg) populations. Not surprisingly, the latter bacteria populations were decreased in the MS population, compared to healthy controls, and the former were increased (Cekanaviciute et al., 2017).

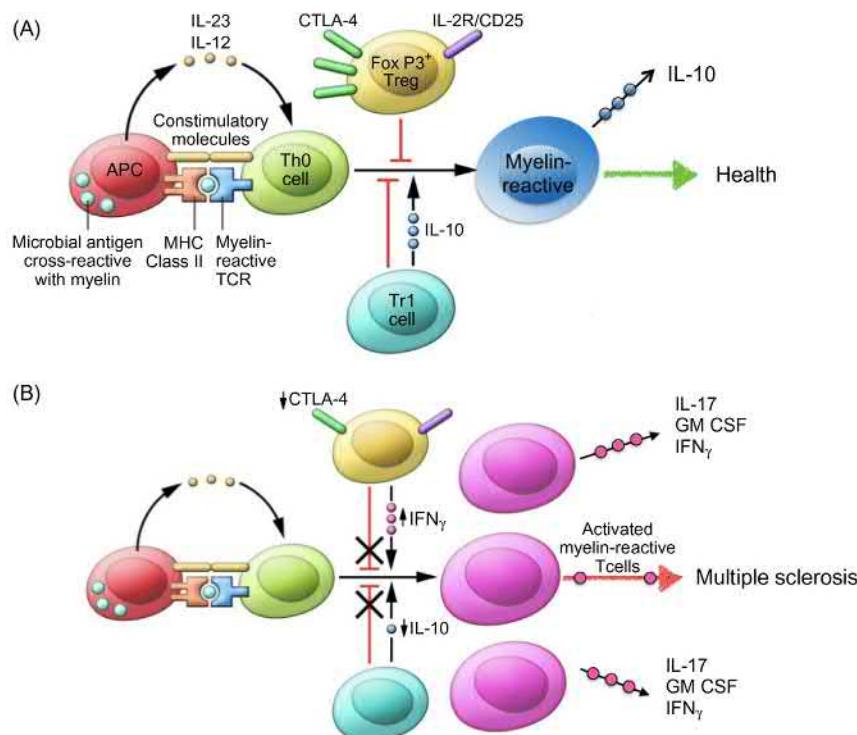

## IMMUNE PATHOGENESIS

Until recently, there were discussions as to whether MS is a primary degenerative disease with secondary inflammation or an autoimmune disease with immune-mediated destruction of the CNS. The sharing of almost half of the allelic variants between MS and other autoimmune disorders from the GWAS has, to a large extent, provided convincing evidence for an autoimmune pathophysiology for the disease (Hafler, 2012). Our current understanding of MS strongly implicates involvement of the immune system and autoreactive proinflammatory T cells that are critical to the propagation of CNS tissue injury. Elucidating the mechanism of disease initiation and how it contributes to the transition from physiologic immune-surveillance to pathologic cascade continues to be an area of ongoing investigation. Our foundation is based on the understanding that peripherally activated cross-reactive T cells migrate into the CNS of genetically susceptible hosts and mount proinflammatory responses to myelin epitopes. Myelin-reactive T cells appear to be both increased in frequency and activation state in individuals with MS (Raddassi et al., 2011; Cao et al., 2015), suggesting a peripheral breach of tolerance to CNS antigen. However, the presence of autoreactive cells in the periphery is an insufficient explanation for the development of autoimmune disease given that myelin-reactive T cells can be found in the peripheral blood of both healthy individuals and patients with MS.

## T-Cell Pathogenesis

Upon interaction of the T cell with the antigen-presenting cell (APC), the antigen-specific T cells proliferate and divide into subsets (see Fig. 51.1). Of specific interest to MS are the Th1, Th2, Th17, and Treg subsets. T cells have been classified according to the cytokine profiles that they produce upon activation (Abbas et al., 1996; O'Garra, 1998; O'Shea and Paul, 2010). MHC class II restricted CD4 T cells, producing IFN- $\gamma$ , GM-CSF, IL-2, and TNF- $\alpha$ , have been defined as Th1 (inflammatory) cells and have demonstrated pathogenicity in EAE models (Leonard et al., 1995; Segal et al., 1998; Severson and Hafler, 2010). The Th1 cytokines activate macrophages for cellular immunity with the assistance of IgG<sub>1</sub> secreted by B cells. In contrast, CD4 T cells producing IL-4, IL-5, IL-10, or IL-13 have been termed Th2 (antiinflammatory) cells and have demonstrated a protective role in EAE (Khoury et al., 1992; Owens et al., 1994; Begolka et al., 1998; Antel and Owens, 1999). Th2 cytokines promote humoral immune responses alongside IgG<sub>4</sub>. Th17 cells are thought to be proinflammatory in nature and secrete the cytokines IL-17A, IL-17F, IL-21, and IL-22, which have been strongly implicated in the pathogenesis of autoimmune diseases (Harrington et al., 2005). Tregs are a subset of T cells that are involved in the regulation of the immune system, maintenance of tolerance to self-antigens, and surveillance of autoimmune disease. They can secrete a variety of cytokines including transforming growth factor- $\beta$  (TGF- $\beta$ ), IL-10, and IFN- $\gamma$  in addition to utilizing FoxP3 as a transcription factor (Fontenot et al., 2003; Hori et al., 2003). Current work involving Tregs has linked this subset with immune dysregulation, a concept which will be discussed later.

Several lines of evidence support the hypothesis that Th1 cells may be pathogenic in MS. Th1 and Th2 cells express distinct profiles of chemokine receptors, including CXCR3/CCR5 and CCR3/CCR4, respectively

**FIGURE 51.1** Pathophysiology of MS. Defects in peripheral immune regulation lower the activation barrier for autoreactive T cells. (A) In normal homeostasis, APCs digest microbial antigens or self proteins and present them to naïve T cells in the context of costimulatory molecules. An appropriate cytokine milieu can drive differentiation of these naïve autoreactive T cells to a Th1 or Th17 cell phenotype; however, these potentially pathogenic T cells are not activated due to the actions of peripheral regulatory immune cell populations, such as FoxP3 Tregs and Tr1 cells. Via the actions of coinhibitory molecules and cytokines such as IL-10 and TGF- $\beta$ , autoreactive T cells become anergic and autoimmune disease is prevented. Other mechanisms, such as thymic deletion and lack of costimulatory molecules on APCs, are also involved in controlling autoreactive T cells. (B) MS patients have defects in peripheral immune regulation, including higher expression of costimulatory molecules on APCs, lower CTLA-4 levels, and lower IL-10 production. In addition, MS patients have an increased frequency of IFN- $\gamma$ -secreting Tregs relative to healthy controls. Thus the barrier for activation of autoreactive T cells is lowered for MS patients. Activated myelin-reactive T cells can then adhere to and extravasate across the choroid plexus and BBB, where they can initiate an inflammatory milieu that gives license to further waves of inflammation and eventual epitope spreading. APCs, Antigen-presenting cell; BBB, blood–brain barrier; MS, multiple sclerosis; TGF- $\beta$ , transforming growth factor- $\beta$ .

(Bonecchi et al., 2009). An increased proportion of T cells from MS patients was shown to express the characteristic Th1 chemokine receptor pattern and MS plaques were found to express increased levels of the corresponding chemokine (Siveke and Hamann, 1998; Balashov et al., 1999; Sorensen et al., 1999). The analysis of cytokine mRNA in CSF from MS patients showed a bias toward Th1 cytokines (Blain et al., 1994). Immunohistochemical studies of MS plaques *in situ* have demonstrated the presence of the proinflammatory cytokines TNF- $\alpha$  and IL-12 (Hofman et al., 1989; Selmaj et al., 1991; Windhagen et al., 1995). Markedly, MBP-reactive T cells derived from patients with MS secrete cytokines that are more consistent with Th1-mediated response, whereas MBP-reactive T cells from healthy individuals are more likely to produce cytokines that characterize a Th2-mediated response (Crawford et al., 2004). Interventions that shift or deviate the cytokine responses away from a Th1 and toward a Th2 profile have been deemed favorable.

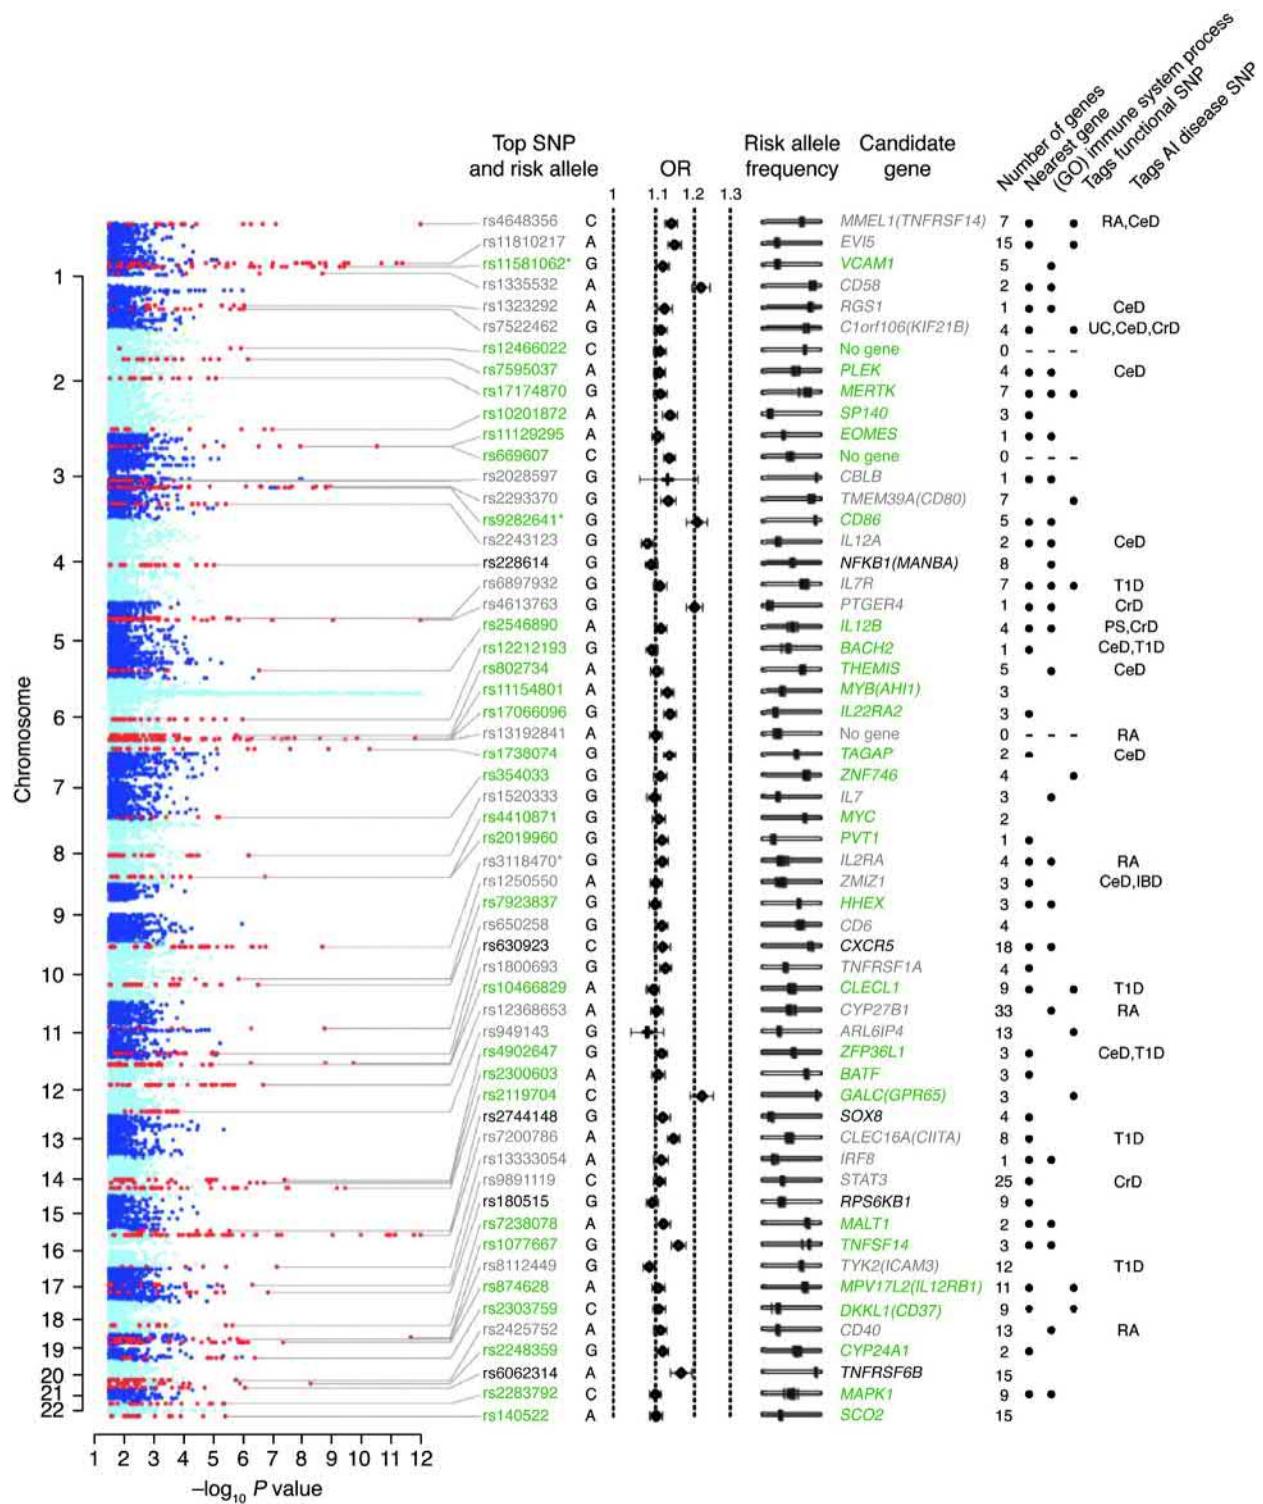

Despite the prior suggestion that Th1 cells are unique in driving the inflammatory response, recent work has characterized the putative role of proinflammatory Th17 cells in establishing the MS phenotype. Studies implicate pathogenic Th17 cells in gaining early access to the CNS (Steinman, 2007; Rebaldi et al., 2009). Entry to the CNS is mediated via the choroid plexus, which, in addition to producing CSF, spans the blood–CSF barrier and facilitates immune-surveillance. The Th17 mechanism implicates the CCR6/CCL20 axis in disease initiation as defined in the EAE model, with Th17 cells expressing CCR6 and choroid plexus endothelial cells expressing CCL20.

While myelin-specific autoreactive T cells are known to target myelin antigens, there was previously no characterization of the functional or transcriptional differences between these cells in healthy and MS populations. We recently compared responses of naïve CD4 $^{+}$  T cells, CCR6 $^{-}$  memory T cells, and CCR6 $^{+}$  memory T cells to various myelin peptides, including MBP, PLP, and MOG. It was found that naïve T cells and CCR6 $^{-}$  memory cells exhibited no response to the myelin epitopes. However, CCR6 $^{+}$  memory T cells produced GM-CSF, IFN- $\gamma$ , and IL-17 along with increasing their proliferation. Of note, in the absence of a myelin antigen, there was no difference in response amongst the populations. Moreover, this study found that CCR6 $^{+}$  memory cells were increased in number in MS patients (Cao et al., 2015). Finally, it was found that myelin-reactive T cells from healthy subjects secreted predominantly IL-10, explaining perhaps why healthy individuals have autoreactive T cells that we speculate may be involved in mediating responses to tissue damage.

In applying this information to human disease, it is likely that peripherally activated Th17 cells are able to bind to adhesion molecules and chemokine receptors expressed on the choroid plexus thereby migrating across the blood–CSF barrier and gaining access to circulating CSF. Dysregulated Th17 cells are subsequently able to access perivascular tissue, initiating a cascade of proinflammatory events. Th17 cells secrete IL-23, which, in EAE models, alongside the transcription factor ROR $\gamma$ t, promotes production of GM-CSF. This induces a positive feedback loop where further secretion of IL-23 occurs and is implicated in the encephalogenicity and incidence of axoglial damage (Codarri et al., 2011; El-Behi et al., 2011). In relating Th17 cells to the formation of perivascular infiltrates, it is possible that their secretion of IL-17 and IL-22 may increase BBB permeability and thus facilitate the influx of immune cells, such as autoreactive Th17 cells, Th1 (IFN- $\gamma$  secreting),  $\gamma\delta$  T cells, cytotoxic CD8 $^{+}$  cells, B cells, and immunoglobulin-secreting plasma cells (Kebir et al., 2007). This leads to the possibility of a two-step process for initiation of MS, one in which Th17 cells prime the entrance of other dysregulated immune cells and therefore creating the appropriate inflammatory environment containing infiltrates of cells that result in downstream damage of the CNS (Nylander and Hafler, 2012).

## Immune Dysregulation

In elaborating on the concept of immune dysregulation, GWAS have shed light on the likely involvement of allelic variants in diseases states (see Fig. 51.2) (Sawcer et al., 2011). A number of these variants involved genes for cytokine receptors and costimulatory molecules and have been associated with defects in Treg homeostasis. Costimulatory molecules have recently been found to function as negative regulators of the immune system. TIM-3 has been implicated in modulating Th1 and Th17 cytokine secretion and loss of TIM-3 functional T-cell regulation has been established in MS patients (Koguchi et al., 2006; Yang et al., 2008; Hastings et al., 2009). GWAS studies have linked CD226 to MS risk (Hafler et al., 2009), and recent work has implicated the CD226/TIGIT axis in regulating human T-cell function via a mechanism similar to that employed by CD28/CTLA4, in which binding to B7 induces coexpression of inhibitory and excitatory signals that modulate immune responses (Joller et al., 2011; Lozano et al., 2012). Costimulation between CD58/CD2 appears to be implicated in T-cell receptor signaling, including activation of Tregs, and has been suggested to provide a protective effect for MS (De Jager et al., 2009a).

**FIGURE 51.2** Regions of genome showing association to MS. Genome regions showing association with MS. Evidence for association from linear mixed model analysis of the discovery data (threshold at a  $2 \log_{10} P$  value of 12) is shown at left. Non-MHC regions containing associated SNPs are indicated in red and labeled with the rs number (green text for newly identified loci, black text for loci with strong evidence of association, and gray text for previously reported loci) and risk allele of the most significant SNP. Asterisks indicate that the locus contains a secondary SNP signal. ORs (diamonds) and 95% confidence intervals (whiskers) are estimated from a metaanalysis of discovery and replication data (1 indicates estimates for previously known loci from discovery data only). Risk allele frequency estimates in the control populations are indicated by vertical bars (scale of 0–1, left to right). A candidate gene and the number of genes are reported for each region of association. Black dots indicate that the candidate gene is physically the nearest gene included in the GO immune system process term. “Tags functional SNP” indicates whether the most significant SNP tags a SNP predicted to affect the function of the candidate gene. Where such an SNP exists, the gene is selected as the candidate gene; otherwise, the nearest gene is selected unless there are strong biological reasons for a different choice. The final column indicates whether SNPs are correlated ( $r^2 > 0.1$ ) with SNPs associated with other autoimmune diseases. CeD, Celiac disease; CrD, Crohn’s disease; PS, psoriasis; RA, rheumatoid arthritis; T1D, type 1 diabetes; UC, ulcerative colitis; OR, odds ratios; MHC, major histocompatibility complex; SNPs, single nucleotide polymorphisms; MS, multiple sclerosis. Genetic risk and a primary role for cell-mediated immune mechanisms in multiple sclerosis. *Nature* 476, 214–219.

Despite normal frequency of Tregs in MS patients, their suppressive ability is compromised and substantially decreased in response to autoreactive T cells in comparison to healthy individuals (Viglietta et al., 2004; Haas et al., 2005). Notably, Tregs have demonstrated great functional plasticity. Their ability to be reprogrammed suggests that Tregs may be able to function as a biomarker in MS (Nylander and Hafler, 2012). In the presence of IL-1 $\beta$  and IL-6, Tregs are able to produce the inflammatory cytokine IL-17, further implicating this subset in autoimmune disease (Koenen et al., 2008; Ayyoub et al., 2009; Beriou et al., 2009). Moreover, the notion of Treg reprogramming has arisen due to the observation that patients with RRMS have the ability to produce IFN- $\gamma$ -secreting Tregs, thereby characterizing a Th1-type Treg effector phenotype. This finding was observed in vitro under IL-12 stimulation of Tregs and recapitulated in ex vivo Tregs derived from patients with untreated RRMS. This role of Th1/Treg effector cells was suggested by the use of IFN- $\beta$ , a first-line therapy for RRMS, which has been shown to decrease IL-12 levels and normalize the ratio of IFN- $\gamma$ Foxp3 $^{+}$  Tregs to that of healthy controls (Dominguez-Villar et al., 2011). Costimulatory molecules and Treg plasticity in MS undoubtedly provide clues into disease pathogenesis.

## Autoantigens

Autoantigen-specific T cells have been identified both in healthy individuals and in patients with MS. Their entrance into the inflamed CNS environment is likely mediated by the immune mechanisms posited above, whereupon entering, the autoreactive T cells are able to subsequently contribute to myelin destruction and axonal damage in addition to secondary inflammation following activation by local APCs. Attention has been directed toward uncovering frequencies of autoantigen-specific T-cell binding to myelin proteins including MOG, MBP, and proteolipid in addition to heat shock protein  $\alpha$ B-crystallin and oligodendroglia-specific enzyme transaldolase in CD4 cells isolated from MS patients (Banki et al., 1994; Greer and Pender, 2008). Anti-MOG has previously been isolated from postmortem CNS tissue in MS patients (O'Connor et al., 2005). In an assay based on self-assembly of radiolabeled MHC tetramers, it was demonstrated that such tetramers were more sensitive for MOG autoantibody detection. Nevertheless, MOG-specific autoantibodies were found more so in patients with acute disseminated encephalomyelitis than in adults with MS (O'Connor et al., 2007). Likewise, the ability to detect and clone autoantigen-specific T cells from blood has allowed further quantification of MOG frequencies, work which demonstrated an increase in MOG-specific T cells in MS patients in comparison to healthy individuals (Raddassi et al., 2011).

Despite the inability to identify a putative role for environmental triggers, infectious factors, or microbial antigens in establishing MS risk, studies have suggested potential cross-reactivity between epitopes with microbial antigens. Finally, regardless of what antigen event initiates the self-reactive cascade, epitope spreading is likely to contribute to an array of activated immune cells that can respond to multiple antigens. Nevertheless, no single antigen has been clearly implicated in the pathogenesis of MS.

## The Role of B Cells

Given the marked presence of OCBs and increased intrathecal synthesis of IgG within the CSF of individuals with MS, in addition to the ongoing debate about the increased incidence of EBV and its ability to prime the immune system in individuals with MS, the notion of B-cell involvement has received great attention in playing a crucial role in MS pathogenesis. There appears to be great connectivity between the cell population in the CNS and CSF since clonally expanded B cells and plasmablast clones have been associated with the observed intrathecal immunoglobulin production (Lovato et al., 2011; Obermeier et al., 2011). There is evidence that B-cell clones populate the meninges, leading to the hypothesis that these aggregate structures can be related to the B-cell infiltrates found in MS lesions (Lovato et al., 2011). Likewise, ectopic lymphoid follicles, strongly resembling germinal centers, have been identified in the meninges of SPMS patients (Serafini et al., 2004). These follicles contain proliferating B cells, plasma cells, T cells, and dendritic cells with the corresponding diffuse meningeal inflammation being suggested to play a role in the manifestation of cerebral cortical gray matter pathology in MS. Follicles have been located more frequently in the deep sulci of the temporal cingulate, insula, and frontal cortex (Howell et al., 2011).

Moreover, the success of B-cell depleting agents in treating rapidly reducing inflammation and inducing remission (Hauser et al., 2008) suggests that B cells might be serving as APCs via MHC class II to autoreactive T cells and thus mediating the cascade of proinflammatory cytokine production within the CNS (Cross et al., 2006).

Furthermore, there is evidence from EAE mice that B cells might directly produce proinflammatory cytokines, such as IL-6 (Barr et al., 2012). Apart from being associated with cortical pathology, studies have implicated that meningeal B-cell follicles can be associated with early onset of disease in patients with SPMS (Maglizzi et al., 2007). Overall, such humoral activation within ectopic lymph tissue and CSF has been postulated to play an imperative role in disease progression secondary to the ongoing persistence of antigens driving a constitutive inflammatory and humoral response.

## TREATMENT

Therapeutic approaches in MS may be broadly divided into treatments that are symptomatic and/or supportive in nature and treatments that are directed at the underlying pathophysiology of the disorder. There are currently 15 agents approved by the United States FDA (see Table 51.1 for comparison of FDA-approved therapies) as disease-modifying therapies. They are expensive, with 10-year disease-related costs averaging US \$467,712 for patients on a single disease-modifying therapy (DMT) (Noyes et al., 2011). Immunotherapies as of 2017 are available in a number of administration forms: infusion-based, oral, and self-injection medications.

With only IFN- $\beta$  and glatiramer acetate, it was not uncommon for neurologists to take a “stepwise” approach to initiation of therapy, starting with the lower efficacy drugs first and then escalating care in conjunction with breakthrough disease to more immunosuppressive drugs such as cyclophosphamide. Now with the availability of more effective medications with similar risk profiles, it is no longer appropriate to allow patients to fail multiple agents before using an effective drug. Immunotherapies have shown the most efficacy in the RRMS, CIS, and early progressive forms of MS wherein there exists an inflammatory component. There is only one agent approved for PPMS; however, to date, there is no immunotherapy that has shown significant response in progressive forms of MS, such as SPMS and PPMS.

### Infusion-Based Therapies

The most effective FDA-approved immunotherapies for MS to date are the infusion-based medications, ocrelizumab (Ocrevus), alemtuzumab (Lemtrada), and natalizumab (Tysabri). Of note, mitoxantrone (Novantrone) is also an FDA-approved infusion which will be discussed, but given severe adverse effects, it is no longer used in modern practice.

#### **Natalizumab (Tysabri)**

Natalizumab is a monoclonal antibody to the very late activation antigen-4 (VLA-4), the  $\alpha 4\beta 7$  integrin expressed on activated T cells and monocytes, and is the ligand for vascular cell adhesion molecule (VCAM) expressed on CNS endothelial cells. Natalizumab, by preventing adhesion of activated T cells to endothelial cells, has been able to decrease influx of potentially autoreactive T cells into perivascular tissue. Natalizumab-treated patients have developed cases of progressive multifocal leukoencephalopathy, a rare and fatal disease caused by JC virus and characterized by progressive inflammatory damage of CNS white matter. This prompted both its manufacturer and the FDA to review its utility in treating MS. Patients must be screened for the JC virus in blood prior to initiating therapy. If negative, natalizumab can be safely started, and patients/prescribers are required to enroll in a REMS program (risk evaluation and mitigation strategy). JC virus is checked every 6 months, and if a patient converts to being JC virus positive, then the patient must transition to a new DMT. The timing of the transition is dependent on a number of factors. More recently, with the advent of JC virus index value testing using a two-step ELISA, the index value can risk-stratify patients for progressive multifocal leucoencephalopathy (PML).

Regardless, its clinical benefits have been deemed to outweigh the risks involved. Its use has been restricted to individuals with highly active disease. Two trials involving RRMS patients have demonstrated interesting clinical results. The AFFIRM study compared natalizumab alone to placebo and the SENTINEL study looked at adding natalizumab to ongoing IFN- $\beta 1a$  therapy. The AFFIRM trial demonstrated a 42% reduced risk of sustained progression of disability, a 68% reduction in rate of clinical relapse at 1 year, and an 83% reduction in accumulation of new or enlarging hyperintense lesions over 2 years (Polman et al., 2006). Results of the SENTINEL trial were similar to those of AFFIRM with the exception of a 64% decreased risk of sustained disability progression with natalizumab (Calabresi et al., 2007; Hutchinson et al., 2009).

**TABLE 51.1** Food and Drug Administration Approved Therapies for Multiple Sclerosis (MS) as of 2018

Brand name	Indications	Results	Mechanism of action
<b>T-CELL CYTOKINE DEVIATION</b>			
IFN- $\beta$ 1a (IM weekly)	Avonex	Treatment of RRMS	<p>Reduction of relapses and new MRI T2 lesions by about one-third and the volume of enlarging T2 lesions; reduction in the number and volume of Gd-enhancing lesions</p> <p>Slowing of brain atrophy</p> <ul style="list-style-type: none"> <li>• Acts on blood–brain barrier by interfering with T-cell adhesion to the endothelium by binding VLA-4 on T cells or by inhibiting the T-cell expression of MMP reduction in T-cell activation by interfering with HLA class II and costimulatory molecules B7/CD28 and CD40: CD40L</li> <li>• Immune deviation of Th2 over Th1 cytokine profile</li> <li>• Normalizing ratio of IFN-<math>\gamma</math> Foxp3 Tregs</li> </ul>
IFN- $\beta$ 1a (SC three times weekly)	Rebif	Treatment of RRMS	Same as IFN- $\beta$ 1a
Peginterferon- $\beta$ 1a (SC every 14 days)	Plegridy	Treatment of RRMS	Same as IFN- $\beta$ 1a
IFN- $\beta$ 1b (SC every other day)	Betaseron, Extavia	Treatment of RRMS	Same as IFN- $\beta$ 1a
<b>T-CELL RECEPTOR-MEDIATED CYTOKINE DEVIATION</b>			
Glatiramer acetate (SC daily)	Copaxone	Treatment of RRMS	<p>Reduction of relapses by one-third</p> <p>Reduction of 57% in the number and volume of Gd-enhancing lesions (Johnson et al., 1995)</p> <ul style="list-style-type: none"> <li>• Induces cytokine shift from one that is proinflammatory to one that is antiinflammatory and regulatory in nature (Duda et al., 2000)</li> </ul>
<b>BLOCK T-CELL TRAFFICKING</b>

<b>LYMPHOCYTE DEPLETION</b>			
Alemtuzumab	Lemtrada	Treatment of RRMS	<p>78% relapse free at 2 years compared to 59% IFN-<math>\beta</math>1a; ~1/3 develop autoimmune thyroid disease, ~2% develop idiopathic thrombocytopenia (Cohen et al., 2012; Coles et al., 2012)</p> <p>Humanized CD52-directed monoclonal antibody that causes depletion and repopulation of B lymphocytes and T lymphocytes</p>
Ocrelizumab	Ocrevus	Treatment of RRMS and PPMS	<p>RRMS: 47% ARR reduction compared to Rebif; 95% decrease in enhancing T1 lesions</p> <p>PPMS: 24% reduction in progression of EDSS compared to placebo at 12 weeks; 25% reduction in sustained 24-week disability (Hauser et al., 2017; Montalban et al., 2017)</p> <p>Fully humanized monoclonal antibody targeting CD20-positive B cells</p>

RRMS, Relapsing-remitting MS; Tregs, regulatory T cell; PPMS, primary progressive MS; CNS, central nervous system; APC, antigen-presenting cell; IFN, interferon; VLA-4, very late activation antigen-4; EDSS, Extended disability status scale; MMP, metalloproteinase.

### Alemtuzumab (Lemtrada)

Alemtuzumab is a humanized CD52-directed monoclonal antibody that causes depletion and repopulation of B lymphocytes and T lymphocytes. It was approved by the FDA in 2014 for use in RRMS, with a requirement that patients be enrolled in a REMS program due to its significant side-effect profile. It is given via infusion on 5 consecutive days at month 0 and then 3 consecutive days at month 12. In the CARE-MS I&II trials, it showed that 78% of the patients were relapse free at 2 years compared to 59% of the patients in an IFN- $\beta$ 1a group. About one-third of the patients develop autoimmune thyroid disease, with around 2% developing idiopathic thrombocytopenia, as well as other autoimmune conditions in lesser numbers (Cohen et al., 2012; Coles et al., 2012).

### Ocrelizumab (Ocrevus)

Ocrelizumab (Ocrevus) is fully humanized monoclonal antibody targeting CD20-positive B cells that was approved for both RRMS and PPMS in 2017. It was developed based on the success of the chimeric CD20 monoclonal antibody rituximab that has been used off-label for MS for several years. The OPERA I&II trials for RRMS showed a 47% ARR reduction compared to Rebif along with a 95% decrease in enhancing T1 lesions. These data suggest that at this time, Ocrelizumab should be considered as a first-line therapy for new onset RRMS.

The ORATORIO trial for PPMS showed a 24% reduction in progression of extended disability status scale (EDSS) compared to placebo at 12 weeks with a 25% reduction in sustained 24-week disability; however, the success in PPMS was strongly correlated with patients who were younger and still had evidence of inflammatory disease activity (Hauser et al., 2017; Montalban et al., 2017).

### Mitoxantrone (Novantrone)

Mitoxantrone, a small molecule chemotherapeutic agent able to cross the BBB, functions as a type II topoisomerase inhibitor, which disrupts DNA synthesis and DNA repair, both events which function in an immunosuppressant capacity thereby inhibiting T-cell, B-cell, and macrophage proliferation. Overall, this leads to enhanced T-cell suppressor function, inhibition of B-cell function and antibody production, decreased secretion of proinflammatory cytokines, and inhibition of macrophage-mediated myelin degradation (Fox, 2004). Mitoxantrone, administered intravenously, has been approved by the FDA as treatment for patients with worsening forms of MS including SPMS, worsening RRMS, and PRMS. The MIMS trial indicated a 44% reduction in time to first relapse; a 24% decrease in the expanded disability status scale, however, did not demonstrate a positive impact on MRI disease burden (Hartung et al., 2002; Krapf et al., 2005). Due to concerns related to increased incidence of systolic dysfunction and therapy-related acute leukemia, it is no longer used in modern MS treatment (Marriott et al., 2010).

## Oral Therapies

There are currently three FDA-approved oral medications for MS, starting with fingolimod (Gilenya) which was the first to be approved in 2010, followed by teriflunomide (Aubagio) and dimethyl fumarate, BG-12 (Tecfidera).

### Fingolimod (Gilenya)

Fingolimod's pharmacologic activity is targeted toward lymphocyte migration out of lymph nodes. This action is highly dependent on the engagement of a G-protein-coupled receptor, S1P<sub>1</sub>, present on the surface of the lymphocytes. Fingolimod is structurally similar to S1P and can function as an agonist by engaging four of the five known S1P receptors (S1P<sub>1</sub>, S1P<sub>3</sub>, S1P<sub>4</sub>, S1P<sub>5</sub>). This leads to a reduction in activated T cells that are able to exit the lymph node and subsequently cross the BBB to exert their potential pathogenic effects on perivascular tissue (Schwab and Cyster, 2007; Pham et al., 2008). Studies have indicated the potential for S1P receptors to be present on other cells, including neurons, microglial cells, oligodendrocytes, and astrocytes, suggesting a putative role for fingolimod in influencing myelin repair, modulating survival of oligodendrocyte progenitor cells, and directing astrocyte migration and proliferation (Yamagata et al., 2003; Miron et al., 2008, 2010).

In September 2010 fingolimod became the first FDA-approved first-line oral agent for the treatment of MS. The FREEDOMS trial demonstrated, after 2 years, an overall 54% decreased risk of relapse in the group treated with fingolimod versus those taking placebo. The risk of disability progression was 30% lower in patients receiving the lower dose (0.5 mg) as opposed to placebo. With regard to MRI disease burden, those taking fingolimod

presented with fewer new lesions and less brain tissue atrophy. The TRANSFORMS trial aimed at characterizing the efficacy of fingolimod versus intramuscular IFN- $\beta$ 1a (Avonex). The group taking fingolimod had a 52% lower risk of having a relapse than those taking IFN- $\beta$ 1a, with 82.5% of the fingolimod group and 70% of the IFN- $\beta$ 1a presenting with no relapses during the 1-year study period. Furthermore, the group taking fingolimod had fewer signs of MRI disease burden. There was no difference among the groups in the risk of disease progression (Cohen et al., 2010).

### **Teriflunomide (Aubagio)**

Teriflunomide is the active metabolite of leflunomide, an approved therapy for rheumatoid arthritis. It inhibits de novo pyrimidine nucleotide synthesis and therefore potently decreases T-cell and B-cell proliferation (Hartung et al., 2010). Reports also indicate that teriflunomide may interrupt T cell and APC interactions in addition to possessing antiinflammatory properties (Zeyda et al., 2005; Gold and Wolinsky, 2011). The TEMSO trial demonstrated a 31% reduction in annual relapse rate, a 21% reduction in disability progression, and a 76% reduction in number of new or enlarging T2 lesions on MRI in the higher dose cohort (O'Connor et al., 2011). Although FDA pregnancy categories A–X have been rendered obsolete, it was initially designated as Category X due to severe teratogenicity concerns. Main side effects include alopecia, transaminitis, and reactivation of viral infections including varicella zoster virus (VZV). Teriflunomide was approved by the FDA in September 2012 for patients with RRMS.

### **Dimethyl Fumarate, BG-12 (Tecfidera)**

BG-12 is an oral formulation of fumaric acid, which is metabolized to monomethyl fumarate. It was approved to be a second-line agent in 2013. Other oral formulations of fumaric acid have previously been used to treat psoriasis. Both dimethyl fumarate and the active metabolite induce activation of the nuclear factor E2-related factor-2 pathway, which exerts neuroprotective effects and decreases myelin damage in the CNS (Kappos et al., 2008; Fontoura and Garren, 2010; Linker et al., 2011). Antiinflammatory mechanisms have also been attributed to dimethyl fumarate (Gold, 2011). The DEFINE trial was completed in 2011. As a randomized, double-blind, placebo-controlled phase III study, patients with RRMS were assigned to receive either oral BG-12 at a dose of 240 mg twice or thrice daily, or placebo. The primary end point was the proportion of patients who had a relapse 2 years later in addition to disability progression and MRI disease burden. The study demonstrated positive results with a significant reduction in relapse rate (27% with BG-12 twice daily and 26% with BG-12 thrice daily versus 46% with placebo), in the rate of disability progression, in the number of new or enlarging T2 lesions, and in new gadolinium-enhancing lesions (Gold et al., 2012). The CONFIRM trial was also completed in 2011. In a phase III, randomized study, it aimed to ascertain the efficacy and safety of BG-12 at a dose of 240 twice or thrice daily in comparison to both placebo and glatiramer acetate in patients with RRMS. Similar to the DEFINE trial, both BG-12 and glatiramer acetate significantly reduced relapse rates and MRI disease burden in relation to the placebo group (Fox et al., 2012). In early 2013, BG-12 was approved as a first-line therapy for adults with RRMS.

## **Injection-Based Therapies**

The injection-based therapies are the oldest FDA-approved treatments for MS, with the exception of daclizumab (Zinbryta) which was recently approved in 2016 for both RRMS and early SPMS. This group includes the interferons, glatiramer acetate, and daclizumab.

### **Interferons**

Compared to placebo-treated RRMS controls, treatment with alternate-day subcutaneous injections of 8 million units of IFN- $\beta$ 1b (Betaseron) was shown to decrease the primary efficacy outcome measure of frequency of relapses by 34% after 2 years ([No authors listed], 1993). A significant decrease in the accumulation of MRI lesions was observed with treatment (Paty and Li, 1993) and 5-year follow-up data reported that disease progression in the IFN- $\beta$ 1b-treated group was 35%, compared with 46% progression in the placebo group ([No authors listed], 1995). A 30% decrease in the annual exacerbation rate in the treated group was maintained. IFN- $\beta$ 1a (Avonex, weekly IM injections), a glycosylated recombinant beta-interferon, was evaluated in a 2-year study of weekly intramuscular injections of six million units (30  $\mu$ g). The proportion of patients progressing by the end of the trial was 21.9% in the treated group compared to 34.9% in the placebo group. The annual exacerbation rate

was decreased by 32% in the treated group versus the placebo group. Treatment was also associated with a 40% reduction in mean MRI lesion load (Jacobs et al., 1995, 1996). Clinical and MRI benefits of IFN- $\beta$ 1a (Rebif, subcutaneous, three times weekly) doses for up to 4 years were demonstrated in PRISMS-4, thereby suggesting that early treatment with IFN- $\beta$ 1a was of increased benefit to patients with RRMS as compared with those treated later in disease course (PRISMS, 2001).

$\beta$ -Interferon therapy utilizes recombinant forms of naturally occurring cytokines intrinsically possessing a wide range of properties. The mechanism of action involving  $\beta$ -interferons appears to be quite complex with the DMT exerting its effects on the pathophysiology of MS at several sites. Studies have suggested that  $\beta$ -interferons inhibit the migration of activated inflammatory cells across the BBB and into the CNS parenchyma through decreasing the function of the VCAM-1/very late activation antigen-4 cell adhesion axis (see natalizumab). IFN- $\beta$  may potentially intercept inflammatory cell adhesion and subsequent migration across the BBB (Calabresi et al., 1997; Gruber et al., 2005). The rapid effect of  $\beta$ -interferons on the gadolinium-enhancing lesions of MS represents a biological marker of treatment response and establishes the BBB as an important site of action of  $\beta$ -interferon therapy (Stone et al., 1997).

Studies have also suggested that the  $\beta$ -interferons may exert their pharmacologic effects by shifting cytokines and immune cell profiles in MS patients toward one that is antiinflammatory and protective (Brod et al., 1996). IFN- $\beta$  has also demonstrated ability to upregulate expression of costimulatory molecules needed for antigen presentation (CD80, CD86, and CD40) on monocytes, thus decreasing the generation of autoreactive T cells and limiting T-cell activation. As addressed earlier, IFN- $\beta$  has been implicated in normalizing the ratio of IFN- $\gamma$ <sup>1</sup>Foxp3<sup>1</sup> Tregs to that of healthy controls and in decreasing IL-12 levels, thereby potentially restoring the ability of Tregs to regulate immune cells (Dominguez-Villar et al., 2011).

### **Glatiramer Acetate (Copaxone)**

Treatment with glatiramer acetate/copolymer 1 (Copaxone, GA, subcutaneous, daily) was associated with a 2-year relapse rate reduction of 29% compared to placebo control (Johnson et al., 1995). The clinical benefit of GA for relapse rate in comparison to placebo was sustained following an 11-month extension period utilizing the same study design (Johnson et al., 1998). Subsequent studies revealed a beneficial effect of GA in MRI with a 35% reduction in total gadolinium-enhancing lesions and 57% reduction in new gadolinium-enhancing lesions, with an overall decrease in T2 disease burden (Mancardi et al., 1998; Comi et al., 2001).

GA is a random sequence polypeptide of the four amino acids alanine (A), lysine (K), glutamate (E), and tyrosine (Y). As a sequence of amino acids, GA has been proposed to function as a T-cell receptor antagonist to MBP/MHC at MBP-specific T-cell receptors and operate as an altered peptide ligand to the MBP (Aharoni et al., 1999; Duda et al., 2000). Thus research suggests that GA elicits its effect on the immune system by inducing deviation of cytokine production in response to MBP from Th1 cytokines to Th2 cytokines, a change that is characterized by increased secretion of antiinflammatory cytokines, with prolonged GA treatment leading to a Th2 bias in MS patients (Miller et al., 1998; Duda et al., 2000; Gran et al., 2000; Neuhaus et al., 2000; Valenzuela et al., 2007). In addition, GA has been implicated in altering the cytokine profile to one that is more consistent with a regulatory population (Hong et al., 2005). Furthermore, increases in FoxP3<sup>1</sup> expression in Tregs have been demonstrated following GA, also supporting theories that GA facilitates a regulatory population (Hong et al., 2005).

## **CONCLUDING REMARKS**

Over the past decade, major strides have been made in our understanding of the immunopathogenesis underlying the development and course of MS, an autoimmune disease that predominantly impacts the CNS with white matter damage and demyelination of neurons thought to be primarily driven by T-cell dysregulation, inflammation, and immune dysfunction. Nevertheless, our ever-growing fund of knowledge continues to inspire future directions. Novel insights are providing hints for future prospects related to early cortical demyelination, gray matter pathology, imaging, and B-cell involvement in MS further establishing this disease as a multifocal entity. Overall, our increasing knowledge pertaining to MS continues to be multifactorial. The ability for clinicians and researchers to utilize our understanding of the immunopathogenesis in relation to known pharmacologic mechanisms, clinical findings, and imaging modalities will be paramount in taking the necessary steps toward eradicating MS.

### INTRODUCTION

Autoimmunity is implicated in a small but important group of peripheral nerve diseases. These include the acute inflammatory neuropathies eponymously referred to as the Guillain–Barré syndrome (GBS) and Fisher syndrome (FS), and the chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), both idiopathic and associated with a serum paraprotein. Substantial evidence exists for an autoimmune pathogenesis in GBS and its subtypes. The evidence is still gathering to support similar processes in the chronic inflammatory neuropathies including the demyelinating neuropathy associated with antibodies to myelin-associated glycoprotein (MAG). Although the most current evidence supports an antibody-driven pathogenesis triggered by infection for GBS and FS, T-cell mechanisms predominate in CIDP and other cellular immune components are crucial effectors of disease. Experimental allergic neuritis (EAN), an inflammatory model of neuropathy, has been instructive in the detailed study of the pathogenesis of immune-mediated neuropathies and will be discussed.

## ACUTE NEUROPATHIES: THE GUILAIN–BARRÉ SYNDROME

### Historical Background

Guillain, Barré, and Strohl described a rapidly evolving flaccid paralysis with areflexia and albuminocytological dissociation in the cerebrospinal fluid (CSF) in 1916 (Guillain et al., 1916). Early autopsies demonstrated both T-cell inflammation and demyelination in peripheral nerves (Asbury et al., 1969; Haymaker and Kernohan, 1949) leading to the notion of GBS being a single pathophysiological entity synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP). AIDP is by far the most common variant of GBS in the developed world. Variants such as the FS (Fisher, 1956) and the axonal variants (1986) (Feasby et al., 1986), acute motor axonal neuropathy (AMAN), and acute motor and sensory axonal neuropathy (AMSAN) (Yuki et al., 1990; McKhann et al., 1991, 1993) are now part of a spectrum of disease with variable worldwide occurrence (see later and Box 52.1).

### Epidemiology

Since the near eradication of poliomyelitis, GBS has become the commonest cause of acute flaccid neuromuscular paralysis in the world. The incidence of GBS is 0.81–1.89 per 100,000 (Hughes and Rees, 1997; Sejvar et al., 2011). The incidence increases steadily with advancing age (0.62 per 100,000 in 0–9 year olds and 2.99 per 100,000 in 80–89 year olds) and males are affected more than females by 1.25:1 (Hadden and Gregson, 2001; Sejvar et al., 2011). Case-control studies implicate infections as precipitating events (see later).

Severity may vary from mild with full recovery in 10% of the patients only, to bedbound in 40%, to complete paralysis with ventilatory dependence in 20%. Death occurs in 3.5%–12% of the patients (Guillain-Barre Syndrome Study Group, 1985; Rees et al., 1998; Cornblath, 2005).

### Clinical Features and Subtypes of Guillain–Barré Syndrome

#### **Acute Inflammatory Demyelinating Polyradiculoneuropathy**

The diagnosis of GBS remains clinical. Electrophysiological studies help to subtype patients into diagnostic categories. AIDP accounts for over 95% of the patients with GBS in Europe and North America. Patients present with a rapidly evolving neuropathic (sensory-)motor paralysis, usually ascending, in two or more limbs over less than 4 weeks. The illness is monophasic. Most patients have numbness, tingling, or pain and many complain of bladder disturbance, facial weakness, or swallowing difficulty (Hughes, 1990). The autonomic disturbance is common with arrhythmia and fluctuating blood pressures. Tendon reflexes are absent or reduced. The CSF contains less than 50 leukocytes per  $\mu\text{L}$  (Asbury and Cornblath, 1990) and CSF protein is raised in 80% of the cases. Antiganglioside antibodies may be detected in the serum (see below) by enzyme-linked immunosorbent assay (ELISA), often with thin-layer chromatography confirmation, but novel solid-phase multiplex and combinatorial ganglioside assays have emerged and are being increasingly used (Rinaldi et al., 2009). Electrophysiological studies typically show slowed motor conduction velocities, delayed F-waves, and preserved compound muscle action potential (CMAP) amplitudes consistent with demyelination, and a “spared” sural nerve but conduction failure and axonal degeneration may complicate the picture.

Multifocal perivascular T-cell infiltration with demyelination, typically patchy with the involvement of proximal and terminal nerve segments, characterizes the pathology of AIDP (Asbury et al., 1969; Hall et al., 1992).

#### BOX 52.1

#### THE DIVERSITY OF GUILAIN–BARRÉ VARIANTS

- Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)
- Regional variants, e.g., pharyngo-cervical-brachial
- Acute motor axonal neuropathy (AMAN)
- Acute motor and sensory axonal neuropathy (AMSAN)
- (Miller) Fisher syndrome (ataxia, ophthalmoplegia, and areflexia)
- Acute panautonomic neuropathy
- Acute pure sensory neuropathy
- Acute motor conduction block neuropathy

Indications of blood–nerve barrier (BNB) breakdown and deposition of activated complement components can be seen in some but not all cases of AIDP (Hafer-Macko et al., 1996b). These observations raise the possibility that T cell- or antibody-mediated immune injury can predominate in an individual case, although the evidence is increasingly in favor of an antibody-driven process in humans.

### **Acute Motor Axonal Neuropathy**

AMAN is a pure motor variant of GBS seen most commonly in China, Japan, and Mexico (McKhann et al., 1991, 1993; Ogawara et al., 2000). Here, it accounts for almost half of the cases, but in Europe and North America, it accounts for only 5%–20% (Rees et al., 1995b; Visser et al., 1995), clinically probably nearer 5%. In China, AMAN occurs in seasonal epidemics, affects more children (McKhann et al., 1991), and is strongly associated with *Campylobacter jejuni* infection. Sensory impairment is minimal and autonomic involvement less common. Electrophysiological studies are characterized by reduced CMAP amplitudes, absent F-waves with normal distal motor latencies, and conduction velocity (Kuwabara et al., 2000) but many feel criteria of this sort misclassify AMAN as AIDP and the prevalence is higher (Uncini and Kuwabara, 2012). Sensory involvement is absent.

The pathology of axonal GBS has largely been described from AMAN cases in northern China. The pathological changes indicate an antibody-mediated immune attack directed preferentially against the motor axons causing primary axonal degeneration in the absence of prominent T-cell inflammation (Griffin et al., 1995, 1996a; Hafer-Macko et al., 1996a). Macrophages may be found in the periaxonal space suggesting that the antigen of interest is on the axolemma (Fig. 52.1). Animal models of AMAN have disrupted nodal sodium channel clusters and detachment of paranodal myelin terminal loops. This would significantly reduce the safety factor for impulse transmission and might be responsible for the rapidly reversible conduction block frequently present in human AMAN (Yuki and Kuwabara, 2007). However, since in some patients little pathology is found (Griffin et al., 1996b) and in others recovery is too rapid for nerve fiber degeneration and regeneration (Ho et al., 1997; Kuwabara et al., 1998), axonal conduction failure and distal neuromuscular terminal failure must also make a prominent contribution to clinical weakness in AMAN.

### **Acute Motor and Sensory Neuropathy**

AMSAN is a more severe form of AMAN with a more severe course, sensory involvement, and delayed recovery (Feasby et al., 1986; Griffin et al., 1995). Sensory as well as motor nerve roots are involved. The pathology is similar to that of AMAN.

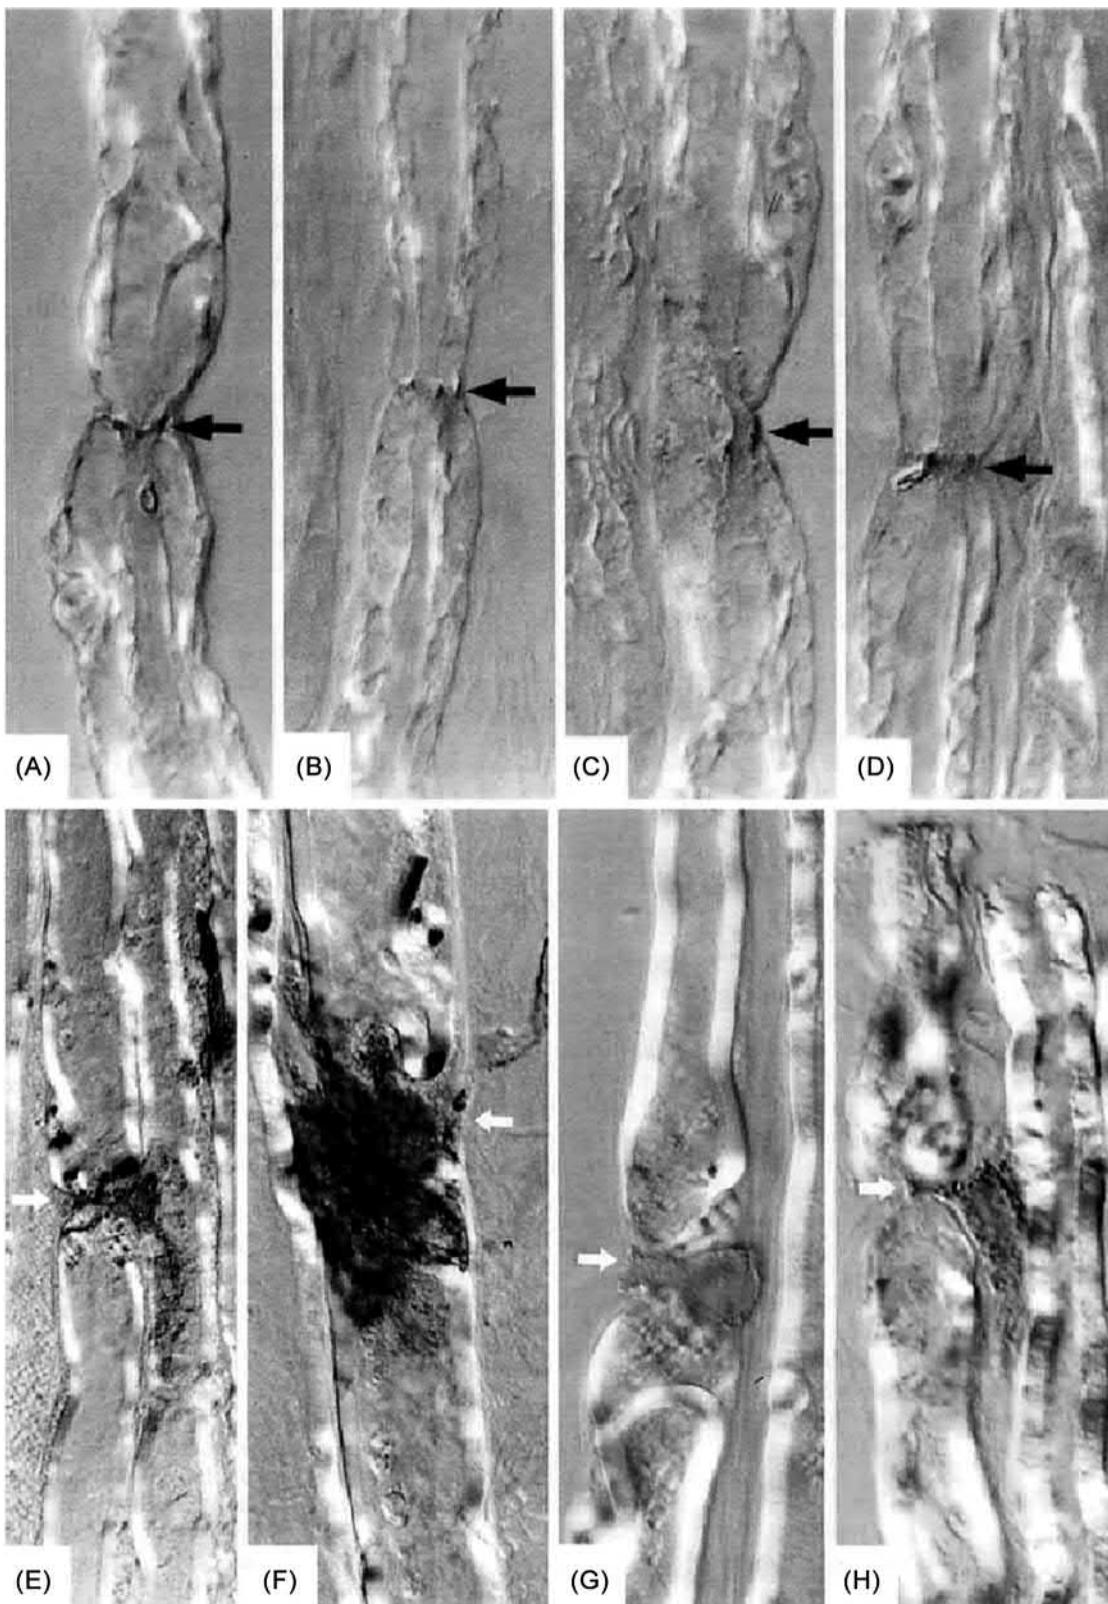

### **Miller Fisher Syndrome**

The Miller Fisher or FS (Fisher, 1956) accounts for approximately 5% of GBS cases and comprises ophthalmoplegia, ataxia, and areflexia without limb weakness. In common usage, facial and bulbar weakness have been included as part of the syndrome. Overlapping forms with AIDP are not uncommon. This syndrome is strongly associated with preceding *C. jejuni* infection, and more than 90% of the patients have antibodies to the ganglioside GQ1b that are almost certainly pathogenic (see below) (Mizoguchi, 1998; O'Hanlon et al., 2001). Anti-GQ1b antibodies are also found in GBS patients with ophthalmoplegia. The pathophysiological and structural basis of the clinical manifestations in FS are still not completely resolved, although complement has been shown to be important in models of disease (Willison et al., 2008).

## **Autoimmune Features**

### **Molecular Mimicry**

Molecular mimicry has been invoked as a mechanism in a variety of autoimmune diseases. AMAN and FS provide some of the best available evidence to support the hypothesis of molecular mimicry as a pathogenic mechanism underlying postinfectious autoimmune disorders. AIDP may be very similar and as more evidence of complex ganglioside antigen associations emerges, AIDP may be resolved into the same pathogenic category as AMAN and FS. AMAN and FS fulfill some of the Koch–Witebsky postulates supporting autoantibody as pathogenic (Witebsky et al., 1957; Rose and Bona, 1993). Antiganglioside antibodies can be demonstrated in patient serum. They have cognate antigens (gangliosides) enriched in peripheral nerve. It is possible to immunize animals (see below) with ganglioside antigens either purified or as whole bacteria to produce autoantibody and disease albeit with difficulty. The transfer of antibody from patient/model animal to a normal subject can sometimes transfer disease. Furthermore, mechanisms of antibody action are now starting to be understood.

**FIGURE 52.1** Immunostained teased ventral root fibers from a case of AMAN 4 days after the onset of neurologic symptoms. (A–D) The complement activation product C3d was localized discretely at nodes of Ranvier (black arrows) of large myelinated motor fibers. The golden-brown immunoreaction product is at the nodes. (E–H) Many motor fibers had macrophages overlying, and extending processes into, the nodes of Ranvier (white arrows designate nodes of Ranvier). [(E) and (F) were immunostained with the macrophage marker HAM-56; (G) and (H) for HLA-DR (major histocompatibility locus class II)]. AMAN, Acute motor axonal neuropathy. Acute motor axonal neuropathy: an antibody-mediated attack on axolemma. *Ann. Neurol.* 40, 635–644.

### **Antiganglioside Antibodies in Guillain–Barré Syndrome Variants**

Antibodies to ganglioside species are found in the serum of patients with GBS (both AMAN and AIDP). They are polyclonal, predominantly IgG, and generally complement-fixing IgG1 and IgG3 (Willison and Veitch, 1994; Ogino et al., 1995; Yuki et al., 1995; Ho et al., 1999). This implies class switching usually with T-cell help, both atypical of human anticerbohydrate responses (see below). Antibodies to single gangliosides GM1, GM1(NeuGc), GM1b, GalNAc-GM1b, GD1a, GalNAc-GD1a, GD1b, 9-O-acetyl GD1b, GD3, GT1b, GQ1b, GQ1b $\alpha$ , LM1, galactocerebroside, and sulfated glucuronyl paragloboside (SGPG) have been reported in more than 200 papers on inflammatory neuropathies (Willison and Yuki, 2002). Clinico-serological correlations between GBS subtypes and serum antibodies to putative ganglioside antigens have been drawn (Ho et al., 1999; Ogawara et al., 2000; Rees et al., 1995a). Antibodies to gangliosides GM1 and GD1a, implicated as the major target antigens in AMAN (Hadden et al., 1998; Ho et al., 1999), can be detected in 50%–60% of AMAN patients in the Far East (Ho et al., 1999; Ogawara et al., 2000). Antibodies to GalNAc-GD1a and GM1b are found in motor predominant GBS in about 10%–15% of the cases (Ang et al., 1999; Yuki et al., 2000). Anti-GQ1b antibodies, frequently cross-reactive with structurally related gangliosides, are present in 80%–90% of the patients with FS (Willison et al., 1993; Yuki et al., 1993; Carpo et al., 1998). This correlation provides the strongest association between antibodies to a specific ganglioside and a clinical phenotype.

More recently, the serendipitous identification of antibodies to complex gangliosides has led to a resurgence of interest in antibodies (Kusunoki's first reference) (Greenshields et al., 2009; Kusunoki and Kaida, 2011). Antibody activity to a ganglioside species can be enhanced or entirely abrogated by the close association of a second species of ganglioside presumably making a complex epitope. Antibodies to ganglioside complexes may explain the lack of antibodies found in sera when only single ganglioside activities were sought, the difficulties of consistent identification of clinic-serological phenotypes, and the apparent inconsistency in the spatial distribution of single gangliosides and antibody binding.

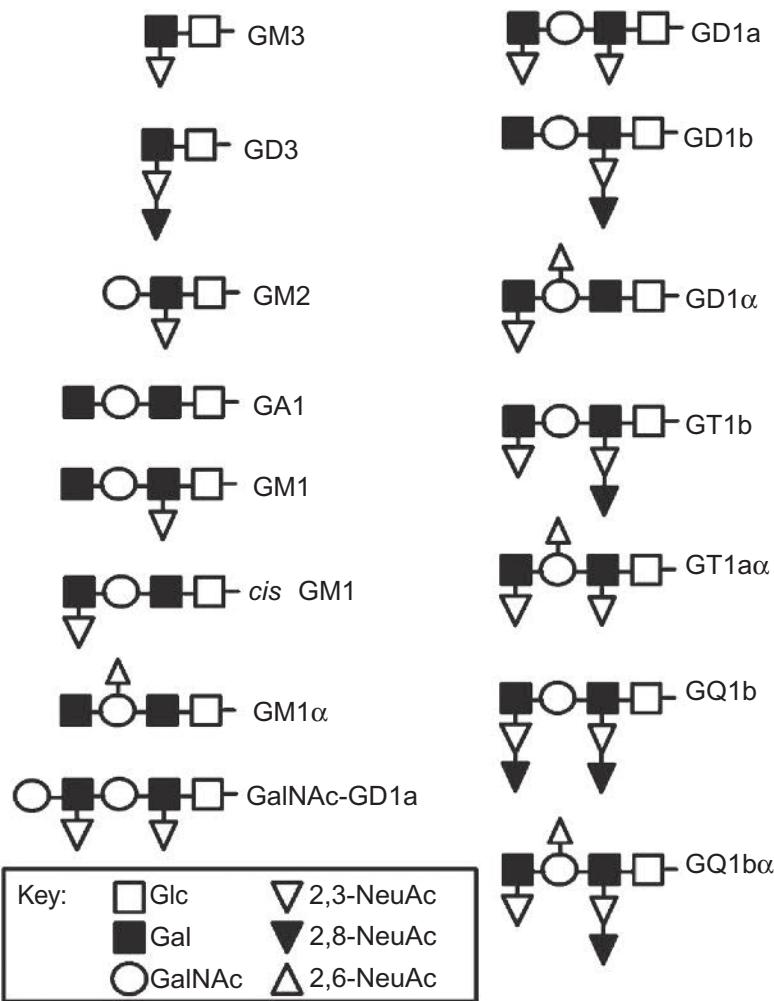

The serological studies have also identified associations of specific antiganglioside or ganglioside complex antibodies with poor recovery (reviewed in Lopez et al., 2010; Sheikh and Zhang, 2010). These association studies imply that specific antiganglioside antibodies can not only injure intact nerve fibers to induce neuropathy but can also adversely affect recovery by either inducing more severe neuropathic disease or interfering with the nerve repair process required for recovery. Experimental studies with antiganglioside antibodies support the latter hypothesis (Lehmann et al., 2007; Lopez et al., 2010).

### **Gangliosides in Peripheral Nerve**

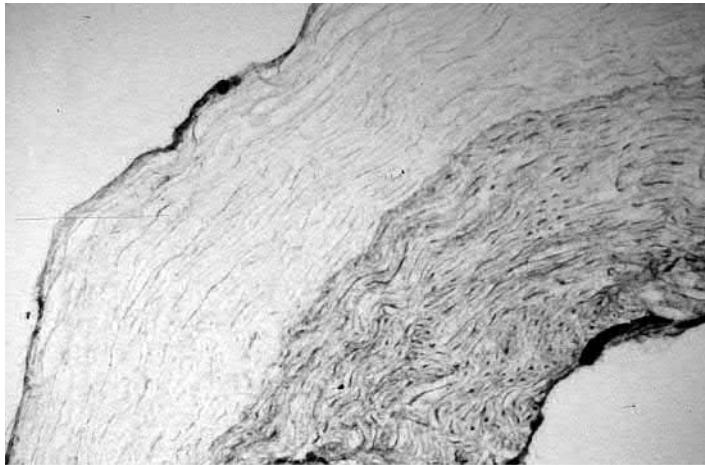

Gangliosides are sialic acid containing glycolipids (see Fig. 52.2), widely distributed in mammalian tissues, but enriched in the nervous system. GM1, GD1b, GD1a, and GT1b are most abundant. A simple hypothesis to explain the differences between GBS variants is based on the premise that target gangliosides have differential distribution in the peripheral nervous system (PNS), but this hypothesis is being modified in response to the discovery of complex ganglioside epitopes. In relation to FS, GQ1b is relatively enriched in the oculomotor cranial nerves (Chiba et al., 1993, 1997) although anti-GQ1b antibodies may bind elsewhere (Goodyear et al., 1999). Although ganglioside immunolocalization studies are technically difficult, the AMAN-associated gangliosides GM1 and GD1a are localized at the nodes of Ranvier and in motor nerve terminals (MNTs) (Sheikh et al., 1999; Gong et al., 2002). Furthermore, preferential staining of motor nerve fibers has been demonstrated with monoclonal anti-GD1a antibodies in rats (Fig. 52.3) and also with human anti-GD1a antibodies from a patient with AMAN (De Angelis et al., 2001). The distribution of ganglioside complexes in vivo will be even more difficult. Other factors such as variations in permeability of the BNB, density and accessibility of target gangliosides, and relationship to functional components of the axolemma, such as ion channels, are likely to be relevant.

### **Functional Effects of Antibodies**

Antibodies bind to nerves at nodes of Ranvier where gangliosides (especially GM1) and channels are enriched. Early studies indicated that anti-GM1 antibodies possibly blocked or altered channel function, although the exact mechanism was unclear (Sheikh et al., 1999). Intraneuronal injection of GBS patient serum, purified immunoglobulin, or specific antiganglioside antibodies has produced mixed results (Saida et al., 1979; Winer et al., 1988; Sumner et al., 1992). Powerful models developed over the last 10 years have demonstrated clear binding of antibodies and complement to nodal structures, dissolution of the axonal cytoskeletal architecture, and disruption of nodal and paranodal channels (Susuki et al., 2007). The electrical effect of this is to destabilize the membrane resulting in trains of uncontrolled miniature end-plate potentials identifiable in models.

**FIGURE 52.2** Some of the ganglioside species in peripheral nerve, potentially targets for neuropathy-associated antibodies. Note the similarity in structures between species, which allows for some cross-reactivity. *Glc*, Glucose; *Gal*, galactose; *GalNAc*, 5 *N*-acetylgalactosamine; *NeuAc*, 5 neuraminic (sialic) acid.

**FIGURE 52.3** Unfixed fresh-frozen rat motor-sensory nerve root stained with a monospecific murine IgG anti-GD1a antibody. There is preferential strong staining of the motor axons of the ventral root (below) compared to the sensory axons of the adjacent dorsal root (above). Magnification  $\times 320$ .

An alternative site of the attack is at the roots and MNTs where the BNB is relatively deficient. MNTs degenerate in AMAN (Ho et al., 1997) and are disturbed electrophysiologically in FS (Uncini and Lugaresi, 1999). In an ex vivo phrenic nerve-diaphragm preparation, Willison et al. showed that anti-GQ1b antibodies bind to nerve terminals, cause complement-dependent quantal acetylcholine release resulting in neuromuscular blockade and a calcium-dependent disruption of the terminal bouton (Goodear et al., 1999; Plomp et al., 1999; O'Hanlon et al., 2001). The same effects were shown with anti-GD1a antibodies dependent upon GD1a antigen density (Goodfellow et al., 2005).

In a parallel series of patch-clamp experiments, IgG GQ1b, GD1a, GD1b, and GM1 antibodies have been shown to cause reversible complement independent pre- and postsynaptic blockade depending upon the antibody used (Buchwald et al., 2002).

The clinical, pathological, and electrical effects are almost entirely abrogated by the application of an inhibitor of the C5 component of complement (eculizumab) which results in a failure of formation of the membrane attack complex (Halstead et al., 2008). This pathophysiological understanding and subsequent proof of concept in an animal model have led to the design of human trials.

Antiganglioside antibodies can inhibit neurite growth and growth cone extension in primary neuronal cultures consistent with the notion that these antibodies can adversely affect axon and nerve regeneration (Zhang et al., 2011b). Small GTPase RhoA is part of the downstream inhibitory intracellular signaling that mediates antiganglioside antibody-induced inhibition of axon growth (Zhang et al., 2011b). At the cellular level, antiganglioside antibody-mediated inhibition of axon regeneration requires the engagement of activating Fc-gamma receptors on macrophage lineage cells.

A recent study has shown that pleiotropic cytokine erythropoietin (EPO) with neurotrophic properties reverses the inhibitory effects of antiganglioside antibodies via EPO receptors and the Janus kinase 2/Signal transducer and activator of transcription 5 pathway (Zhang et al., 2011a).

## Environmental Effects

*C. jejuni* is a Gram-negative, nonspore-forming enteropathogen and is one of the most common causes of bacterial gastroenteritis worldwide (Friedman et al., 2000; Oberhelman and Taylor, 2000). Infection with *C. jejuni* is found in 13%–72% of the patients with AMAN or GBS (Hughes and Rees, 1997; Hadden and Gregson, 2001) with an overall prevalence estimated around 30% (Moran et al., 2002). Only 1 in 1000 cases of *C. jejuni* infection is complicated by GBS. The exact characteristics of *C. jejuni* that determine whether GBS follows infection are still unclear. However, a relationship of GBS with a number of Penner serotypes is recognized (Prendergast and Moran, 2000). Penner serotyping distinguishes *C. jejuni* strains on the basis of strain-specific, heat-stable extractable capsular lipopolysaccharide (LPS) and lipooligosaccharide (LOS). Penner strains HS:19 (Rees et al., 1995b; Sheikh et al., 1998) and HS:41 (Goddard et al., 1997) are particularly overrepresented in GBS and uncommon in patients with uncomplicated gastroenteritis. The LPS and LOS of *C. jejuni* carry ganglioside-like moieties. Several studies have characterized these in GBS- and diarrhea-associated *C. jejuni* strains. GM1-, GD1a-, GalNAc-GD1a-, GM1b-, GT1a-, GD2-, GD3-, and GM2-like structures have all been identified (Aspinall et al., 1993; Yuki et al., 1994; Nachamkin et al., 2002). Although no GQ1b-like structure exists, antibody-binding assays have shown the presence of GQ1b- and GT1a-cross-reactive moieties in *C. jejuni* LPS/LOSs (Yuki et al., 1994; Jacobs et al., 1995, 1997). It is these structures that are likely to provide the initial stimulus to autoimmune activation.

Upper respiratory tract infection or other febrile episodes caused by cytomegalovirus (5%–22%), Epstein–Barr virus (2%–10%), *Mycoplasma pneumoniae* (5%), and *Haemophilus influenzae* have all been identified as potentially causative (Hadden and Gregson, 2001). *H. influenzae* carries ganglioside-like moieties. Swine flu and rabies vaccinations have also been causatively implicated, but recent surveillance for an association with swine flu vaccination failed to demonstrate any conclusive link (Crawford et al., 2012).

More recently, Zika virus, a mosquito-borne RNA flavivirus, has been identified as a potential trigger for GBS. During a Zika virus outbreak in 2013–14 in French Polynesia, an increase of GBS cases was observed. Notably, these post-Zika virus infection GBS cases were mostly AMAN but negative for antiganglioside antibodies typically associated with this variant of GBS. However, 31% of the patients had antiglycolipid antibodies detected by ELISA and 46% detected by glycoarray antibodies. A temporal association between increased rates of GBS cases and Zika virus infection was also observed during the major Zika virus outbreak in 2015–16 in South America. A detailed description of a cohort of GBS cases in Colombia during Zika virus outbreak revealed that in contrast to the classic clinical course of GBS, many patients (20%) showed a parainfectious, rapid disease onset.

## Animal Models of Disease

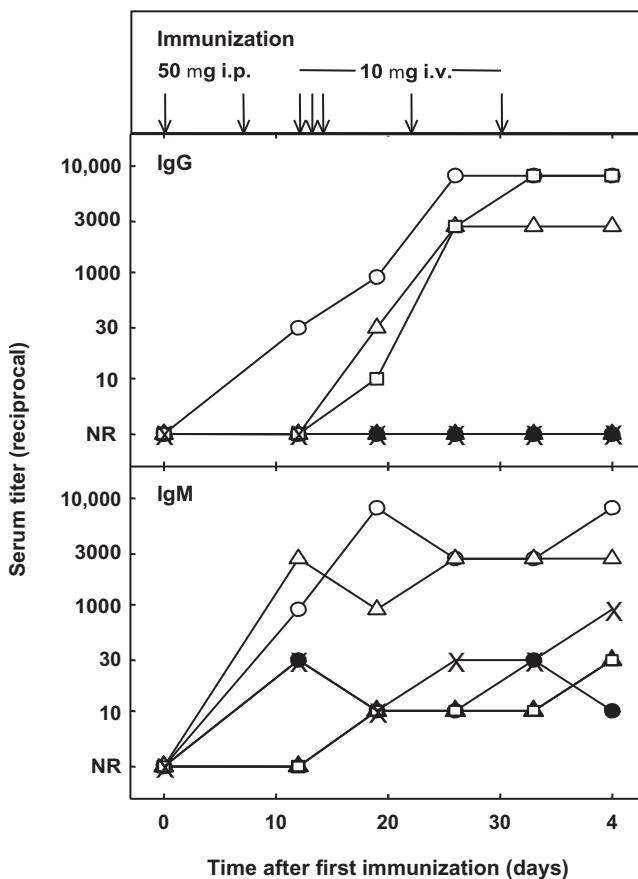

Attempts to generate either IgG antiganglioside antibodies or neuropathy in animals by immunization with *C. jejuni* were for a long while either unforthcoming or not reproducible. Immunization of mice with *C. jejuni* LPSs/LOSs generates mainly low-titer IgM antibodies (Wirguin et al., 1997; Goodey et al., 1999) reflecting a

high level of tolerance to self-gangliosides (Bowes et al., 2002). Tolerance to self-gangliosides can be overcome by immunization with gangliosides or *C. jejuni* LPSs conjugated to adjuvant in transgenic animals lacking complex gangliosides (Lunn et al., 2000) (see Fig. 52.4). This model illustrates that where tolerance is circumvented, potentially pathogenic antibodies can be generated.

A sensory ataxic neuropathy with pathological changes in the nerve and the cord has been induced in rabbits by GD1b immunization and passive antibody transfer (Kusunoki et al., 1999). Immunization with mixed bovine brain gangliosides or GM1 alone produced an acute flaccid paralysis in rabbits reminiscent of human disease (Susuki et al., 2003). The implantation of a murine IgG anti-GD1a secreting hybridoma into mice but not passive transfer of the same antibody led to an axonal neuropathy (Sheikh et al., 2004). Additional cytokine factors may be required to initiate the neuropathy.

The combined research in GBS models has clearly demonstrated that antibodies bind to ganglioside targets on the nerve, fix complement, destroy the nodal, and cytoskeletal architecture through complement and calcium-dependent mechanisms and result in electrophysiological instability and axonal dissolution (Willison et al., 2008).

A passive transfer animal model has been established to examine the effects of antiganglioside antibodies on peripheral nerve repair/axon regeneration (Lehmann et al., 2007). These passive transfer studies show that patient and experimental antibodies inhibit axon regeneration in a nerve crush model mimicking the regenerative response of degenerating/injured axons in GBS (Lehmann et al., 2007; Lopez et al., 2010). The impaired regenerative responses and ultrastructure of injured peripheral axons mimicked dystrophic and stalled the growth cones

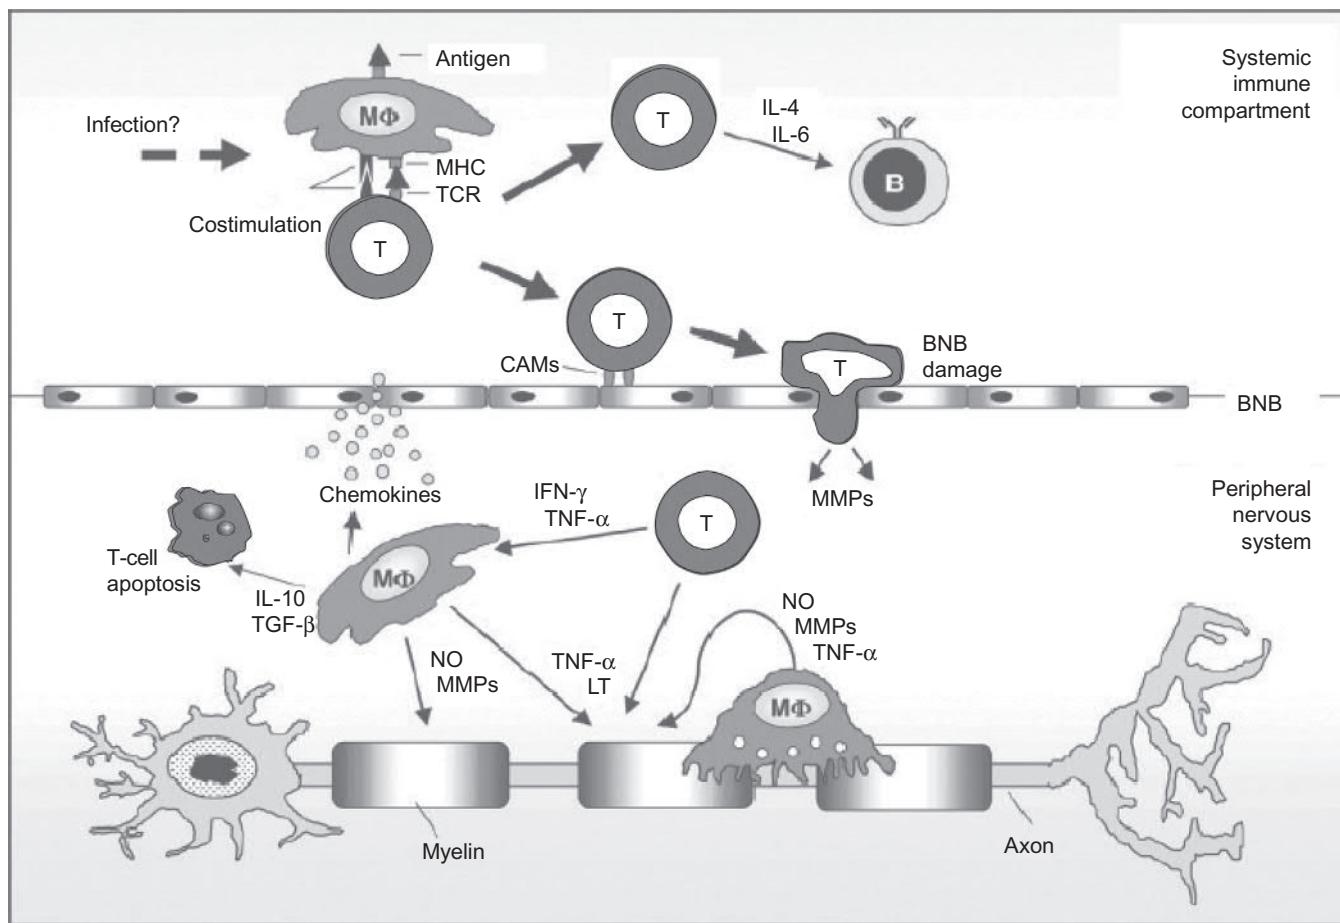

**FIGURE 52.4** Mice lacking complex ganglioside species (*GalNAcT*) are able to class switch to complement-fixing IgG production when immunized with KLH-conjugated ganglioside. The figure shows serological responses of *GalNAcT*<sup>-/-</sup> and wild-type mice immunized with GD1a-KLH or KLH alone. Sera collected at the indicated times were tested for IgG and IgM anti-GD1a antibody titers by ELISA. Open symbols, individual *GalNAcT* mice immunized with GD1a-KLH; filled symbols, individual wild-type mice immunized with GD1a-KLH; X, *GalNAcT*<sup>-/-</sup> mouse immunized with unconjugated KLH. Titer values are presented as the greatest dilution resulting in a signal which exceeded 3 SD above the control mean. *i.p.*, Intraperitoneal; *i.v.*, intravenous; *KLH*, keyhole limpet hemocyanin. High-affinity anti-ganglioside IgG antibodies raised in complex ganglioside knockout mice: reexamination of GD1a immunolocalization. *J. Neurochem.* 75, 404–412. ©2000 Blackwell Publishing Ltd.

typically seen after central nervous system (CNS) injury. Such dystrophic/stalled growth cones can also be seen in nerve biopsies of GBS patients with poor recovery (Sheikh and Zhang, 2010). These observations support the notion that inhibition of axon regeneration is one mechanism of poor recovery in GBS patients with antiganglioside antibodies. Further, this antibody-induced nerve injury model was used to show beneficial proregenerative effects of EPO (Zhang et al., 2011a).

## Cellular Mechanisms

Comprehensive evidence of T-cell involvement in GBS has not been so forthcoming despite the central role of T cells in the pathogenesis of EAN. Studies of animal models and predominantly human AIDP have generated a complex multistep pathogenesis for cellular involvement in the autoimmune neuropathies (see Fig. 52.5).

Multifocal lymphocytic infiltration was established as the hallmark of the pathology of GBS in early postmortem studies (Asbury et al., 1969) but it is not always seen (Cornblath et al., 1990; Honavar et al., 1991).

**FIGURE 52.5** Schematic illustration of the immune responses in the inflamed peripheral nervous system. Basic principles of the cellular immune responses: autoreactive T cells (T) recognize a specific autoantigen presented by MHC class II molecules and the simultaneous delivery of costimulatory signals on the cell surface of antigen-presenting cells, such as macrophages (MΦ), in the systemic immune compartment. Activated T lymphocytes can cross the BNB in order to enter the PNS. Within the PNS, T cells activate macrophages that enhance phagocytic activity, production of cytokines, and the release of toxic mediators, such as NO, MMPs, and proinflammatory cytokines, propagating demyelination and axonal loss. The termination of the inflammatory response is mediated, in part, by macrophages by the induction of T-cell apoptosis and the release of antiinflammatory Th2/Th3 cytokines, such as IL-10 and TGF- $\beta$ . BNB, Blood–nerve barrier; IL-10, interleukin-10; TGF- $\beta$ , transforming growth factor- $\beta$ ; MMPs, matrix metalloproteinases; MHC, major histocompatibility complex; PNS, peripheral nervous system; NO, nitric oxide. Circulating-activated T cells are found early in the course of GBS (Taylor and Hughes, 1989; Hartung and Toyka, 1990).  $\alpha\beta$ T cells with CD4 and CD8 ratios in similar proportions to peripheral blood (Cornblath et al., 1990) are the predominant cells found in nerve. The restricted usage of  $V\beta$  genes, especially  $V\beta 15$ , suggests activation by a common antigen or superantigen (Khalili-Shirazi et al., 1997). Furthermore,  $\gamma\delta$ T cells have also been found in, and isolated from, GBS-affected nerves (Khalili-Shirazi et al., 1998; Winer et al., 2002).  $\gamma\delta$ T cells are capable of recognizing nonprotein antigen and are thus candidates for responding to putative carbohydrate and ganglioside antigens (see above) (Bukowski et al., 1998). They proliferate in vitro in response to *C. jejuni* sonicates but require either  $\alpha\beta$ T cells or interleukin (IL)-2/IL-15 to do so. The predominant use of  $V\gamma 8\delta 1$  suggests the activation of epithelial (possibly gut) resident  $\gamma\delta$ T cells (Cooper et al., 2000).  $\alpha\beta$  and  $\gamma\delta$ T cells also probably provide the necessary help to orchestrate class switching of antiganglioside antibodies to IgG1 and IgG3.

Autoantigen in the systemic compartment is processed and presented by antigen-presenting cells. EAN can be initiated with neuritogenic epitopes of peripheral nerve proteins P0, P2, and PMP22 (Hughes et al., 1999) or by adoptive transfer of sensitized T cells. Disease severity depends upon the cell or antigen dosage (Hartung et al., 1996). Disease is dependent on the presence of T cells, their normal function (Holmdahl et al., 1985; Hartung et al., 1987; Jung et al., 1992), and normal function of the costimulatory partners B7.1/CD80 or B7.2/CD86 and CTLA-4/CD28 (Kiefer et al., 2000; Zhu et al., 2001; Zehntner et al., 2003).

Lymphocyte activation is revealed by greater numbers of circulating T cells—bearing activation markers and increased concentrations of Th1 cytokines such as IFN- $\gamma$ , IL-2, IL-2 receptor, and tumor necrosis factor (TNF)- $\alpha$  (Taylor and Hughes, 1989; Hartung et al., 1991; Exley et al., 1994; Creange et al., 1996). Levels of transforming growth factor (TGF)- $\beta 1$  are depressed (Creange et al., 1998). In EAN, levels of IFN- $\gamma$ , IL-1 $\beta$ , IL-6, TNF- $\alpha$ , TNF- $\beta$ , and IL-12 are raised during the development of disease (Zhu et al., 1997).

Homing and migration of activated T cells to the peripheral nerve are modulated by E-selectin and mucins binding L-selectin and sialyl Lewis antigens (Hartung et al., 2002) and then VCAM-1 and ICAM-1, both upregulated early in GBS and EAN progression (Enders et al., 1998; Creange et al., 2001). Blockade of VCAM-1 or its ligand VLA-4/ $\alpha 4\beta 1$  integrin ameliorates EAN (Enders et al., 1998). Selectin and integrin released into the circulation may downregulate inflammation (Hartung et al., 1988). Chemokines assist in leukocyte recruitment localization and trafficking (Bagnolini, 1998; Campbell et al., 1998). The chemokine receptors CCR1, CCR2, CCR4, CCR5, and CXCR3 have been characterized in AIDP-affected nerves, differentially upregulated by infiltrating cell populations (Kieseier et al., 2002).

Diapedesis through the vascular endothelium and the basal lamina is facilitated by the matrix metalloproteinases (MMPs). MMP-2, MMP-3, MMP-7, and especially MMP-9 have been implicated in the pathogenesis of EAN and GBS (Kieseier et al., 1998; Creange et al., 1999) and correlate with GBS severity.

Macrophages, both resident and recruited from the circulation (Hartung et al., 2002), remain the key component in perpetuating endoneurial inflammatory damage through the release of specific immune mediators. Under inflammatory conditions, they continue to express antigen and induce Schwann cells to do so also (Gold et al., 1995). Depletion of macrophages abrogates the development of EAN, indicating their central role in the final common pathway of nerve damage. A recent study used a function-neutralizing monoclonal antibody against CD11b to ameliorate disease onset and severity in murine EAN to reduce leukocyte trafficking in the inflamed nerve. Activated macrophages target normal looking nerves and Schwann cells in EAN and AIDP (Hartung et al., 1996; Hughes et al., 1999) probably by antibody-targeted cellular cytotoxicity and complement-dependent mechanisms (Hafer-Macko et al., 1996a,b). Macrophage processes insinuate themselves between myelin lamellae and strip the myelin in AIDP (Hughes et al., 1999) or directly attack the axon in AMAN (see Fig. 52.1) (Hafer-Macko et al., 1996a). In the endoneurium, macrophages secrete a host of inflammatory mediators including MMPs, TNF- $\alpha$ , nitric oxide, eicosanoids, neutral proteases, lipases, and phospholipases, all contributing to nerve damage (Gregson and Hall, 1973; Redford et al., 1997; Smith et al., 1999).

Macrophages may also influence recovery from GBS. They direct T-cell apoptosis reducing the ongoing response. During recovery, the T-cell response shifts toward Th2 with rises in IL-4 in patients (Dahle et al., 1997) and upregulation of TGF- $\beta 1$ , IL-10, and catolysin in models of disease (Kiefer et al., 1996). TGF- $\beta 1$  favors recovery (Vriesendorp et al., 1996; Zhu et al., 1997) and levels are correlated to the severity of GBS (Creange et al., 1998).

A recent study (Mausberg et al., 2011) showed that EPO reduced disease severity and also shortened the recovery phase of EAN. The clinical improvement in this model correlated with decreased T-cell inflammation within the peripheral nerve and produced less nerve fiber injury. In contrast, EPO increased the number of macrophages in the recovery phase of EAN. The beneficial effects of macrophages and the modulation of the

immune system toward antiinflammatory responses in the PNS were associated with the upregulation of anti-inflammatory cytokine TGF-beta.

## Cellular and Humoral Immune Elements Are Synergistic

Understanding of the pathomechanisms of the acute inflammatory neuropathies is incomplete. Neither antibodies nor T cells generate disease in isolation and immunization with any antigen which induces responses in both cellular and humoral arms of the immune system. The apparent absence of T cells in some biopsies, and hence their possible nonnecessity, is discussed above. Arguments against the early and significant involvement of antibodies include the absence of detectable antiganglioside antibodies, using the current methodology, in a significant proportion of GBS (usually AIDP) cases, and the onset of adoptive transfer-EAN (AT-EAN) 4 days after transfer, before antibodies could be synthesized. However, recent advances have reduced the strength of these arguments. First, disease severity in AT-EAN is usually enhanced by cotransferring antibodies recognizing myelin or oligodendrocytes/Schwann cell epitopes ([Spies et al., 1995](#)), although this was not confirmed when pretreatment AIDP GBS sera were coadministered to rats with mild EAN ([Hadden et al., 2001](#)). Gangliosides are not necessarily targeted by antibodies as single entities explaining why many sera were apparently negative for antiganglioside antibodies. Combinatorial epitopes made from adjacent but differing molecules that enhance or reduce antibody affinity in vitro and probably in vivo are recognized as targets ([Kusunoki and Kaida, 2011](#)).

## Genetic Aspects of Guillain–Barré Syndrome

The role of host genetics in susceptibility to GBS is still in its infancy. No strong correlations have been established between disease susceptibility or GBS subtypes and host major histocompatibility complex (MHC) class I or class II haplotypes in several studies ([Magira et al., 2003](#); [Gelejns et al., 2005a](#)). The study of single nucleotide polymorphisms in genes for various components of the immune response has not identified any significant contributors ([Gelejns et al., 2005a,b](#)). One Dutch study identified that GBS patients homozygous for the Fc $\gamma$  receptor IIa-H131 had a higher chance of developing severe disease than patients with other genotypes ([van der Pol et al., 2000](#)). Polymorphisms in CD1 molecules which present ganglioside to T cells were associated with GBS in two studies but the largest study to date failed to confirm this ([Kuijf et al., 2008](#)). Metaanalysis focusing on TNF- $\alpha$ , CD1, and Fc $\gamma$ R suggests that the TNF- $\alpha$  308A allele may be a moderate risk factor for GBS ([Wu et al., 2012](#)), but this awaits the confirmation in directed larger studies.

## Treatment and Outcomes

The effectiveness of other immunotherapies for GBS is supported by good evidence ([Hughes et al., 2003](#)). Two to five sessions of plasma exchange (PEx) hasten recovery in nonambulant patients preferably started within 2 weeks of disease onset ([Chevret et al., 2017](#)). Intravenous immunoglobulin (ivIg) is as effective as PEx and is still probably the intervention of choice ([Hughes et al., 2014](#)). The concern about possible contamination of ivIg with prions means that the written informed consent is essential before administration, although advances in ivIg purification technology and prion detection may reduce this concern. The drive to search for new, more effective, and safer therapies is stronger than ever.

A large randomized controlled trial, previous smaller trials, and a Cochrane metaanalysis have shown steroids to be at best ineffective and in some cases harmful. There is no indication for their use in GBS.

Complement inhibitors such as eculizumab are effective in other complement-mediated conditions such as paroxysmal nocturnal hemoglobinuria and possibly effective in multifocal motor neuropathy. Two phase-II trials explored the safety of eculizumab in GBS. In the ICA-GBS trial, five patients with GBS received eculizumab in addition to standard ivIg treatment. The combination treatment was not associated with an increased frequency of severe adverse events. Similarly, in the Japanese Eculizumab Trial, GBS patients safely received eculizumab in conjunction with ivIg and although the primary outcome was not reached, secondary outcomes were positive, and further, larger studies are awaited. Immunoabsorption of pathogenic antiganglioside antibodies has been infrequently used ([Willison et al., 2004](#)). Preclinical studies in antibody and T cell–induced models of GBS suggest that EPO is a viable candidate drug to develop further for neuroprotection and enhancing nerve repair in patients with GBS ([Zhang et al., 2011a](#)).

## CHRONIC NEUROPATHIES: CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

CIDP is an acquired PNS disease characterized by progressive or relapsing proximal and distal weakness with or without sensory loss. There is good evidence to indicate that CIDP is autoimmune.

### History

Osler recognized a chronic relapsing or progressive form of "multiple neuritis" in 1892. Austin (1958) described a slowly progressive or recurrent "steroid responsive polyneuropathy" with histology indistinguishable from that seen in GBS. The term "chronic inflammatory demyelinating polyradiculoneuropathy" was coined in 1975 (Dyck et al., 1975).

### Epidemiology and Clinical Features

The prevalence of CIDP is 1.25–7 per 100,000 (Lunn et al., 1998; Mygland and Monstad, 2001). Symmetrical sensory and motor deficits both proximal and distal reach their nadir over more than 8 weeks. The clinical course is commonly chronic and progressive particularly in untreated patients but some patients have a relapsing-remitting pattern of disease. Some case series have shown that up to 15% of the patients with CIDP can start acutely with GBS-like onset (Dionne et al., 2010). Cranial nerve and the diaphragm are infrequently involved. CSF examination demonstrates albuminocytological dissociation with raised protein in more than 90% of the cases (Bouchard et al., 1999), and the cell count is <10 mm<sup>3</sup> unless complicated by human immunodeficiency virus. Electrophysiology typically demonstrates multifocal motor conduction slowing, temporal dispersion, and block with delayed or absent F-waves. Half of the patients require treatment at any one time and 13% require long-term aid to walk (Lunn et al., 1999). In a single study, 6 of 21 patients were shown to have serum antibodies to the peripheral myelin protein P0 (Yan et al., 2001) but this remains unconfirmed. Morphological examination demonstrates macrophage-associated demyelination in nerve roots, plexuses, and nerve trunks with T cells in the endoneurium. The edema, Schwann cell proliferation, and inflammatory infiltrates testify to the ongoing inflammation. Axonal degeneration occurs in severe or late cases or in distal sensory nerve biopsies (Hadden and Hughes, 2003).

As with GBS, CIDP is heterogeneous, and a number of subtypes or related conditions have emerged.

### Multifocal Motor Neuropathy With Conduction Block

Multifocal motor neuropathy with conduction block (MMNCB) (Pestronk et al., 1988) is a rare but treatable condition sometimes misdiagnosed as motor neuron disease. Wasting and weakness begin asymmetrically in the distribution of a motor nerve usually more distal than proximal, most commonly in the upper limb. Fasciculations and cramps occur. Males account for 70% of the cases. Sensory symptoms are reported in 20% of the patients. Depending upon assay methods, between 30% and 80% of the patients have anti-GM1 antibodies in the serum (Sander and Latov, 2003), some as a paraprotein. Rarely, anti-GD1a antibodies are described (Carpo et al., 1996). Electrophysiological studies demonstrate multifocal conduction blocks in two or more nerves with normal sensory conduction. Many studies demonstrate the evidence of more widespread slowing or axonal degeneration.

The etiology of MMNCB remains unresolved, as it is seldom fatal, and neuropathological material is seldom sought. Perivascular CIDP-like inflammation has been described in a motor nerve biopsy (Kaji et al., 1993), and there are minimal findings in sensory nerves (Corse et al., 1996). Inflammatory cellular infiltration and immunoglobulin deposition were described in the motor roots of an autopsy case (Oh et al., 1995). The therapeutic response to immunomodulation supports an autoimmune pathogenesis (Umapathi et al., 2005).

### Multifocal-Acquired Demyelinating Sensory and Motor Neuropathy

Lewis and Sumner described the entity now referred to as multifocal-acquired demyelinating sensory and motor neuropathy in 1982 (Lewis et al., 1982). Electrophysiological examination demonstrates multifocal sensory and motor involvement with conduction block.

### Multifocal-Acquired Sensory and Motor Neuropathy

This group of patients has only been recently described (Alaedini et al., 2003). Antiganglioside antibodies are found in the serum of 48%, and there is a beneficial response to immunomodulation. The nerve conduction

studies do not suggest demyelination and are more consistent with axonal degeneration. These findings require confirmation.

### **Paraproteinemic Demyelinating Peripheral Neuropathy**

Ten percent of the patients with a peripheral neuropathy will have a paraprotein in the serum. Although this should initiate a search for a malignant source, such as multiple or solitary myeloma, most are monoclonal gammopathies of undetermined significance (MGUS). A number of MGUS-neuropathy syndromes are described.

The commonest is a progressive sensory ataxic neuropathy with unsteadiness and tremor associated with an IgM<sub>k</sub> paraprotein that reacts with the HNK-1 epitope of the peripheral nerve antigen MAG. Up to 80% of the patients with an IgM paraprotein and a demyelinating neuropathy have anti-MAG antibodies. Nerve conduction studies reveal motor conduction slowing, particularly distally (Cocito et al., 2001). Electron microscopic examination of myelin in sural nerve biopsies reveals the characteristic widening of the intraperiod line not seen in other conditions (see Fig. 52.6).

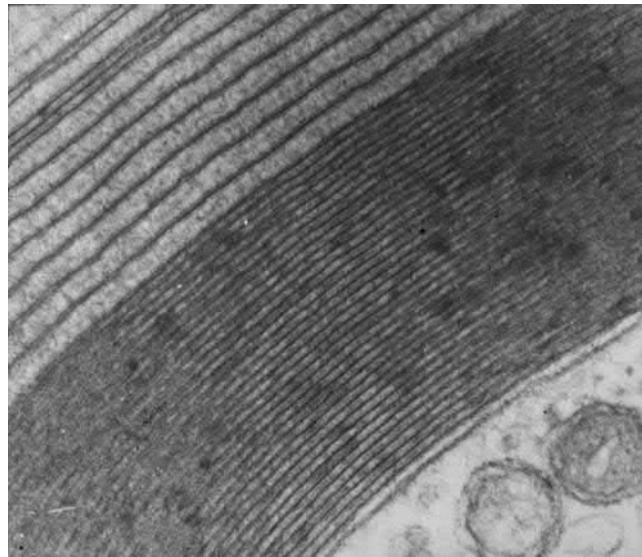

Neuropathies associated with IgG or IgA paraproteins are found in a diverse group of patients with axonal and demyelinating forms of the disease. No consistent pathogenesis has yet emerged. The demyelinating cases have a similar therapeutic response to CIDP (Stork et al., 2015).

Chronic ataxic neuropathy with ophthalmoplegia, M-protein, and antidisialosyl antibodies (CANOMAD) is a rare paraproteinemic syndrome rather like a chronic FS. Its pathogenesis is not yet resolved.

The POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes) is a rare condition associated with both osteosclerotic myeloma and Castleman's disease. The paraprotein required to make the diagnosis does not seem to participate in the pathogenesis as it is often still found after successful treatment. Furthermore, cytokines (especially IL-6 and IL-1 $\beta$ ) and vascular growth endothelial factor are implicated in causation (Lagueny et al., 2004; Dispenzieri, 2012).

### **Autoimmune Features**

Many of the features of autoimmunity displayed in the acute neuropathies are also seen in CIDP. Cellular and humoral responses are both important to the pathogenesis. Raised circulating levels of IL-2 and TNF- $\alpha$  correlate with disease activity (Misawa et al., 2001). A TH-17 response is active with raised levels of IL-17 detectable (Chi et al., 2010), and reduced levels of CD25/CD4 and FoxP3 cells indicate reduced regulatory T cell (Treg) capacity (Chi et al., 2008). Cytokines that affect B-cell responses such as B cell-activating factor are also elevated in sera

**FIGURE 52.6 Widely spaced myelin.** The normal myelin lamellae are tightly compacted and have a periodicity in electron microscope preparations of 12–15 nm. In the demyelinating neuropathy associated with IgM paraprotein that has activity against MAG (anti-MAG PDPN), the intraperiod line becomes split giving an overall periodicity of 30–40 nm. Note the suggestion of material within the widened spaces, possibly immunoglobulin M. Electron micrograph  $\times 100,000$ . MAG, Myelin-associated glycoprotein; MAG PDPN, myelin-associated glycoprotein paraproteinemic demyelinating peripheral neuropathy.

of CIDP patients. T-lymphocyte migration into the endoneurium is facilitated by the increased levels of chemokines, cell adhesion molecules, and MMPs (Previtali et al., 2001; Kieseier et al., 2004). The expression of the BNB constituents claudin-5 and ZO-1 is altered in CIDP perhaps contributing to increased BNB permeability (Kanda et al., 2004). Within the endoneurium, T cells secrete IFN- $\gamma$ , IL-2, and TNF- $\alpha$  (Mathey et al., 1999) and probably others, contributing to inflammatory upregulation of effectors such as macrophages, continued recruitment, and direct nerve damage. The expression of downregulatory cytokines IL-4, IL-10, and TGF- $\beta$  is also found, and in CIDP, expression of nerve growth factor (NGF), glial cell derived neurotrophic factor (GDNF), Leukemia inhibitory factor (LIF), and their receptors may contribute to nerve regeneration (Yamamoto et al., 2002). Clear evidence of Fas deficiency gives support to an inability to halt the ongoing response as effectively as in a monophasic disease (Comi et al., 2009).

Macrophage and Schwann cells in the endoneurium express the costimulatory molecules CD80 (B7-1) and CD86 (B7-2) and their cognate partners CTLA-4 and CD28 are found on endoneurial T cells (Hu et al., 2007).

Antibodies to the glycopeptides P0 and P2, and glycolipids and gangliosides LM1 and GD1b, and LM1 ganglioside complexes have been described but remain unconfirmed, or difficult to confirm, in other studies (Yan et al., 2001; Sanvito et al., 2009; Nobile-Orazio et al., 2010).

More recently, several groups independently reported the occurrence of autoantibodies against nodal-complex proteins in CIDP. These autoantibodies are infrequent and found in 3%–18% of CIDP cases and directed against the neurofascins (predominantly NF155), contactin-1, and/or contactin-associated protein-1 (Caspr). They belong predominantly to the IgG4 subtype and are associated with distinct clinical phenotypes. Patients with anti-NF155 antibodies tend to be younger and have prominent tremor, sensory ataxia, and distal demyelinating symmetric features. CIDP patients with contactin-1 antibodies are older and show a predominant motor involvement and axonal damage. In common, they show a poor response to ivIg treatment and may respond to anti-CD20 treatments.

Pathological studies in nerve samples from these patients demonstrated segmental demyelination with detachment of terminal myelin loops from the axolemma in the paranodal region of the affected nerve fibers.

Unlike GBS or CIDP, in the anti-MAG paraproteinemic demyelinating peripheral neuropathy (anti-MAG PDPN), there is evidence of only antibody-mediated immunity. There is no evidence of macrophage-associated demyelination, T-cell infiltration into the endoneurium, or upregulation of T-cell costimulatory molecules. There is quite strong evidence that anti-MAG antibodies may fulfill the Koch–Witebsky postulates. Anti-MAG antibodies can be found in the serum of patients with characteristic clinical presentation. MAG is expressed at the Schmidt-Lanterman incisures, the paranodes, and on the periaxonal myelin (Gabriel et al., 1998). It displays the HNK-1 carbohydrate epitope shared by several other peripheral nerve antigens. Histological studies demonstrate IgM anti-MAG deposits on Schwann cells that colocalize with MAG (Takatsu et al., 1985). Electron-dense material seen between widened lamellae is consistent with anti-MAG IgM insinuated between the layers (Mendell et al., 1985) (see Fig. 52.6). Activated complement components have been described by some researchers (Monaco et al., 1990). The disruption of MAG functions and complement-mediated damage may result in alterations in the axonal neurofilament cytoskeleton (Lunn et al., 2002), and these, in turn, may lead to slowing of nerve conduction and axonal degeneration.

## Immunogenetic Features

Restricted usage of T-cell receptor (TCR) genes has been demonstrated in CIDP. The predominant TCR in CIDP is  $\alpha\beta$  but  $\gamma\delta$  T cells are found in the majority of nerve biopsy specimens (Winer et al., 2002), again implying a possible nonprotein immune response. No clonality has been demonstrated in isolated T cells. However, significant numbers of highly Th1 inflammatory natural killer T cells identified by expression of V $\alpha$ 24J $\alpha$ Q invariant TCR chain are found (Illes et al., 2000).

A number of putative immunogenetic modifiers have been proposed. Polymorphisms in TAG-1 are not associated with treatment response or outcome (Pang et al., 2012), and no association has been found with CD1 in small studies (Uncini et al., 2011). Recently, studies to suggest that homozygous genotype for a low number of GA repeats in SH2D2A (Uncini et al., 2011) and defective AIRE-mediated central tolerance to P0 (Su et al., 2012a) may be implicated in disease have been presented.

## Environmental Influences

A preceding illness, infection, or vaccination has been identified in patients with CIDP in 32% in the 6 months and 16% in the 6 weeks preceding their illness. Others have found no convincing evidence of vaccination being a trigger (Pritchard et al., 2002). No specific provoking environmental events have so far been recognized for CIDP or the paraproteinemic peripheral neuropathies.

## Animal Models

The pathogenesis of CIDP is not completely defined. Widely accepted animal models that recapitulate all the clinical aspects of CIDP are not available. However, recently developed spontaneous autoimmune polyneuropathy (SAP) models have provided useful insights into pathogenic mechanisms involved in inflammatory demyelinating nerve injury relevant to CIDP. SAP can be seen in transgenic mice expressing the MHC class II  $\text{I}\alpha^b$  molecule. This MHC presents a single peptide, E $\alpha$ 52-68, in mice overexpressing IL-10 under the control of human VMD2 promoter, and in nonobese diabetic (NOD) mice alongside modulations of the costimulatory molecule B7-2 (CD86) and the autoimmune regulator Aire. The subsequent pathogenic mechanisms in NOD mice are fairly well characterized. Elimination of B7-2 in NOD mice induces protection against diabetes mellitus in these animals but triggers the onset of a CIDP-like illness at 6–7 months of age that is almost 100% penetrant in female mice (Salomon et al., 2001; Ubogu et al., 2012). These mice develop a chronic progressive neuropathic disorder that has overlapping clinical, electrodiagnostic, and morphological features with CIDP (Ubogu et al., 2012). B7-2 knockout NOD mice point to the pathogenic role of costimulatory pathways such as B7-1/B7-2:CD28/CTLA-4 molecules in the development of SAP due to disruption of the balance between pathogenic and Tregs maintained by this pathway. Nerve injury in these animals is mediated by Th1 cells that are reactive against myelin P0, the most prominent PNS myelin protein (Bour-Jordan et al., 2005; Louvet et al., 2009). Sera from these animals also contain antibodies to P0, which may contribute to peripheral nerve injury (Kim et al., 2008; Su et al., 2012a).

The importance of the immunogenetic repertoire in the development of SAP is suggested by the absence of neuropathic disorder in B7-2 knockout mice on C57BL/6 or 129/Sv nonautoimmune mouse background (Salomon et al., 2001). How the immunogenetic repertoire contributes to the development of immune neuropathies was exemplified by the development of SAP in transgenic NOD mice with hypomorphic Aire gene function (NOD. Aire $^{GW/+}$  mice) (Su et al., 2012a). Aire is critical to central tolerance. Aire functions by upregulating the ectopic expression of a variety of tissue-specific self-Ags in medullary thymic epithelial cells (mTECs) (Anderson et al., 2002) and increasing the probability of negative selection of antigen-specific high affinity (developing) thymocytes (Anderson et al., 2005). Interestingly, NOD. Aire $^{GW/+}$  mice have increased immune cell and autoantibody reactivity toward P0 in the peripheral immune compartment (Su et al., 2012a). These observations support P0 being an Aire-regulated Ag in mTECs and that decreased P0 expression in mTECs is linked to the development of antigen-specific autoimmunity. Further, CD4 $^+$  T cells from NOD. Aire $^{GW/+}$  mice are sufficient to transfer neuropathy, and Th1 effector cells are dominant in the peripheral nerves in this model (Su et al., 2012a). The clinical relevance of these experimental findings was supported by the following observation. The patients with autoimmune polyendocrinopathy syndrome type 1 (APS-1) have genetic mutations in Aire and develop multior gan autoimmunity. Recently, a CIDP-like neuropathy was recognized as a potential novel component of APS-1 in two unrelated children in whom there were confirmed Aire mutations (Valenzise et al., 2009). These patients have evidence of defective tolerance to P0 and harbor anti-P0 antibodies in their sera (Su et al., 2012a). Overall, these studies show defective tolerance to P0 and antigen-specific dysregulated cellular and humoral immune responses in both Aire-deficient mice and APS-1 patients with CIDP-like neuropathy.

Findings of autoantibodies against nodal proteins in CIDP have prompted animal studies demonstrating pathogenicity of these antibodies. Passive transfer studies with antibodies against neurofascin-155 and Caspr suggest that these antibodies bind corresponding paranodal protein and destroy the nodal architecture in motor nerve fibers, resulting in conduction deficits. These effects were not observed in neurofascin-deficient mice which indicate that specific binding to the target paranodal proteins is required for the pathological effects. In contrast, the relevance of myelin P0 as a potential antigenic target in CIDP remains contentious; however, Yan et al. demonstrated that 6/21 sera (28%) from patients with CIDP responsive to PEx contained IgG anti-P0 antibodies. Four of these sera containing IgG anti-P0 antibodies produced conduction block and demyelination by passive transfer when the BNB was breached, either by direct injection or by preceding passive T-cell transfer (Yan et al., 2000).

Animal models of MMNCB are lacking, and animal studies that explored passive transfer of IgM GM1 antibodies failed to demonstrate pathogenicity. However, *in vitro* studies showed that anti-GM1 IgM antibodies in sera from multifocal motor neuropathy (MMN) patient activate complement.

In anti-MAG PDPN, passive transfer of antibodies results in complement-mediated demyelination in cats and rabbits (Hays et al., 1987; Willison et al., 1988) although the pathological features were not similar to those seen in human disease. Widened myelin lamellae, almost pathognomonic of the condition, were demonstrated after passive transfer to chicks (Tatum, 1993). Induction of high-titer IgM antibodies cross-reactive with human MAG by immunization with the peripheral nerve glycolipid SGPG has been achieved in rats, rabbits, and cats. However, no convincing neuropathy, as a result, has been demonstrated.

## Pathogenic Mechanisms

The final common path of macrophage-mediated demyelination in CIDP is thought to be similar to that seen in GBS (see above).

## Treatment and Outcome

Steroids, ivIg, PEx, and immunosuppressive drugs have all been used in the treatment of CIDP. PEx and ivIg are both very potent (Mehndiratta et al., 2015; Eftimov et al., 2013). There was no statistically significant difference between steroids and ivIg in an early comparative trial (Hughes et al., 2001, 2017), and even though steroid is cheaper in the short term, ivIg was the treatment of choice. More recent evidence suggests that steroids may have a disease-modifying effect, driving patients into remission more frequently and effectively than ivIg (Nobile-Orazio et al., 2012). Interferon- $\beta$ 1a was shown to be ineffective in otherwise treatment-resistant patients (Hadden et al., 1999). Campath-1H (alemtuzumab) and fingolimod, both designed to severely reduce circulating numbers of pathogenic T cells, are currently under trial. There is inadequate evidence to properly assess anecdotally beneficial drugs such as azathioprine, cyclosporin, and mycophenolate mofetil.

In MMNCB, a dramatic therapeutic response is sometimes seen to ivIg demonstrated in controlled trials, and cyclophosphamide may have a place in primary treatment (Umapathi et al., 2015). Many other agents including interferon- $\beta$ 1a, rituximab, mycophenolate, azathioprine, and cyclosporin have been used with evidence for no effect for mycophenolate and only anecdotal evidence of partial benefit for the others (Umapathi et al., 2015). PEx has no effect, and interestingly steroids often worsen the condition by an unknown mechanism. Predictors of favorable outcome are anti-GM1 antibodies, younger age, the presence of conduction block, a normal creatine kinase (CK), and less severe disease at outset (Hadden and Hughes, 2003). Despite the treatment, conduction blocks are dynamic, and weakness probably progresses slowly overtime (Taylor et al., 2000).

In anti-MAG PDPN, patients only need treatment for their neuropathy if it becomes severe and disabling. Randomized controlled evidence of benefit is available for ivIg in the short term (Lunn and Nobile-Orazio, 2016; Su et al., 2012a). Rituximab (an anti-CD20 monoclonal) was promising in case series but had disappointing benefit in individual randomized control trials (RCTs). However, a metaanalysis of the trial outcomes demonstrates meaningful benefits in a number of outcome domains (Lunn and Nobile-Orazio, 2016).

## CONCLUDING REMARKS AND FUTURE PROSPECTS

The last decade has witnessed huge advances in the understanding of the pathogenesis of both acute and chronic inflammatory peripheral neuropathies. GBS and CIDP are heterogeneous clinical conditions in which humoral and cellular mechanisms conspire to cause disabling diseases. Although there are still innumerable advances to be made, our greater understanding of pathomechanisms is inspiring trials of novel agents for the treatment which will transform treatment in the next decade. Our understanding of disease with the emergence of further exciting discoveries will reduce significantly death and disability from GBS and CIDP.

## INTRODUCTION

In recent years, the recognition and ability to detect antibodies directed against receptors, ion channels, and relevant proteins within both the peripheral and central nervous system has continued to evolve. Nevertheless, myasthenia gravis (MG) and related autoimmune disorders of the neuromuscular junction remain the paradigm diseases, serving to highlight those features which help define an antibody mediated disorder. The history of the discoveries in this archetypal autoimmune disease is summarized in [Table 53.1](#).

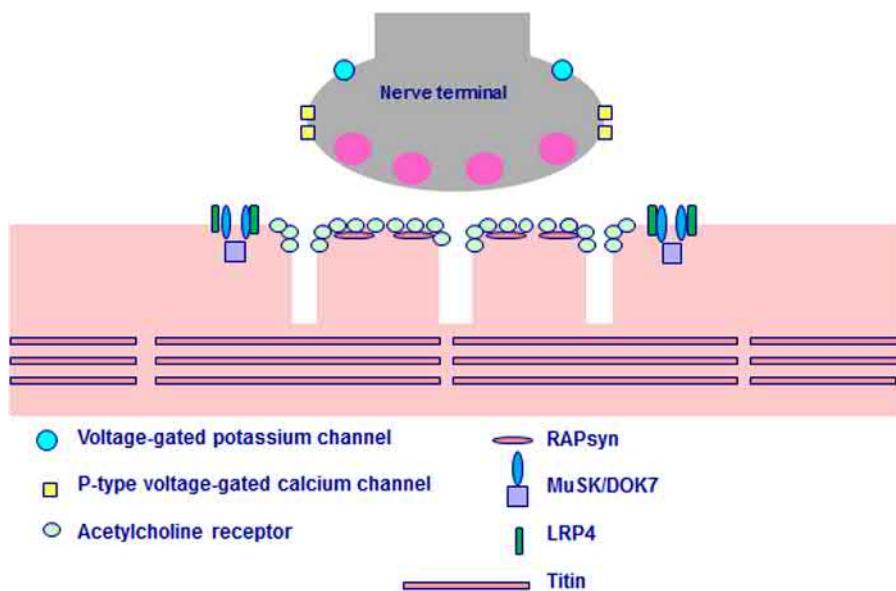

### The Neuromuscular Junction

The neuromuscular junction (NMJ) consists of the presynaptic motor nerve terminal and the postsynaptic motor “endplate.” At the NMJ, the distal motor axon loses its myelin sheath and expands to form the boutons of the presynaptic nerve terminal. These contain mitochondria and the synaptic vesicles that store the acetylcholine (ACh). The vesicles are organized within specialized active zones alongside voltage-gated calcium channels

**TABLE 53.1** A History of Myasthenia Gravis Research

Date	Key observation	Reference
1672	Thomas Willis publishes what is arguably the first clinical description of MG	Willis
1895	Jolly shows that defect is at the neuromuscular junction	Jolly
1913	Thymectomy appears to produce clinical improvement in patients with thymoma or nonthymomatous MG	Sauerbruch
1939		Blalock
1934	Mary Walker demonstrates the effectiveness of cholinesterase inhibitors as treatment	<a href="#">Walker (1934)</a>
1960	Simpson proposes that MG is caused by antibodies to an “endplate” protein	<a href="#">Simpson(1960)</a>
1962	The snake toxin, $\alpha$ -Bungarotoxin, can be used as a label for AChRs at the neuromuscular junction	<a href="#">Chang and Lee (1963)</a>
1964	Elmqvist and colleagues show that the miniature endplate potentials are reduced in MG	<a href="#">Elmqvist et al. (1964)</a>
1971	Several groups begin to purify AChRs from electric organs of electric rays using affinity chromatography on neurotoxin columns	
1973	Immunization against purified electric ray AChR leads to an EAMG in rabbits	<a href="#">Patrick and Lindstrom (1973)</a>
1973	AChRs are reduced in number at neuromuscular junctions, as determined by $^{125}\text{I}$ - $\alpha$ -Bungarotoxin binding	<a href="#">Fambrough et al. (1973)</a>
1975	MG can be passively transferred to mice by injection of patients’ IgG	<a href="#">Toyka et al. (1975)</a>
1976	MG patients have AChR antibodies as shown by radioimmunoprecipitation of $^{125}\text{I}$ - $\alpha$ -Bungarotoxin-tagged AChRs	<a href="#">Lindstrom et al. (1976)</a>
1976–78	Plasma exchange produces striking clinical improvement in MG, which correlates inversely with AChR antibody levels	<a href="#">Newsom-Davis et al. (1978)</a>
1977	IgG and complement are present at the neuromuscular junctions in MG patients and in mice with EAMG	<a href="#">Engel et al. (1977)</a>
1980	MG can present with different HLA, thymic pathology, age at onset, and muscle antibodies	<a href="#">Compston et al. (1980)</a>
1981	The MG thymus contains plasma cells making AChR antibody	<a href="#">Scadding et al. (1981)</a>
1977–Present	Experimental autoimmune model used to determine pathogenic and immunological mechanisms	on-going
1984–Present	Study of T cells from MG patients and their responses to the AChR epitopes	on-going
1995–Present	Study of immune mechanisms in the MG thymus	on-going
2001–Present	Discovery of MuSK antibodies and their distinctive mechanisms	on-going
2010–present	Development of new biologics and benefits of Rituximab and Eculizumab demonstrated in MG	on-going

MG, Myasthenia gravis; AChR, acetylcholine receptor; MuSK, muscle-specific kinase; EAMG, experimental autoimmune myasthenia gravis.

**FIGURE 53.1** Ion channel targets for autoantibodies at the neuromuscular junction.

Neuromuscular transmission depends on the calcium-dependent release of vesicles of ACh. ACh binds to the AChRs on the postsynaptic membrane resulting in a depolarization which, if it reaches a critical threshold, initiates an action potential in the muscle leading to contraction. ACh is immediately destroyed by acetylcholinesterase. AChRs, VGCCs, and VGKCs are all targets for the antibody mediated neurological diseases. The receptor tyrosine kinase MuSK and the protein that activates it, LRP4, have been found to be targets for antibodies in a proportion of patients with MG without AChR antibodies.

(VGCCs). In addition, voltage-gated potassium channels (VGKCs) are also present on the presynaptic nerve terminal (Fig. 53.1).

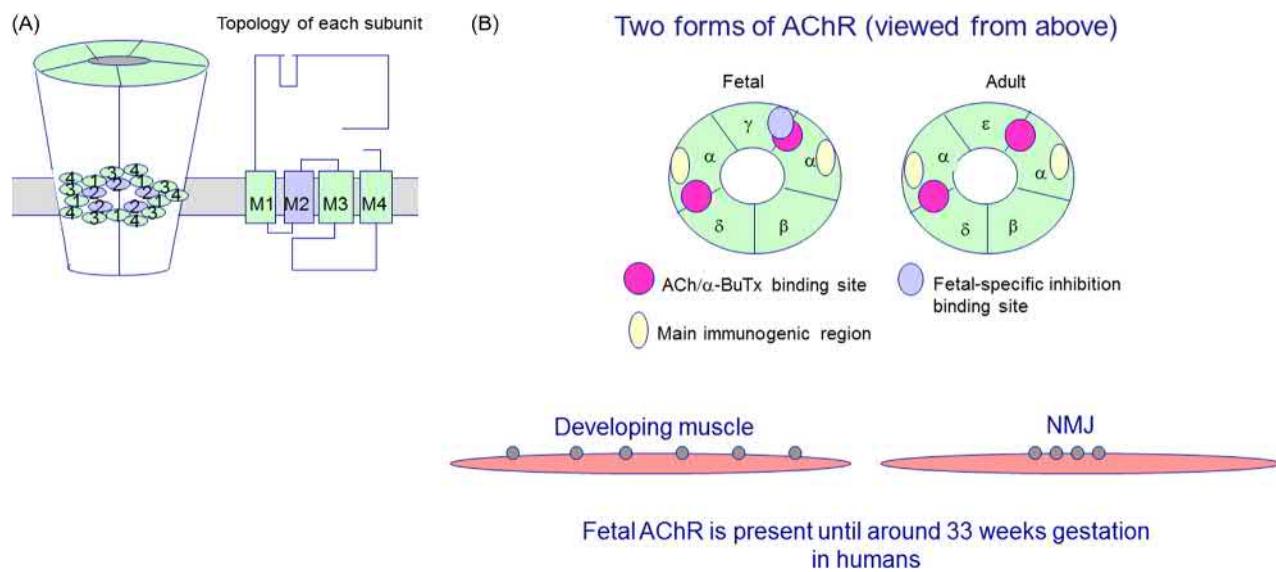

The postsynaptic membrane is deeply infolded to create “junctional” folds. The crests of these, lying in close alignment to the presynaptic active zones, contain the highest density of acetylcholine receptors (AChR). At the depths of these folds, there are relatively few AChRs, but an abundance of voltage-gated sodium channels (VGSC). The synaptic cleft between the presynaptic and postsynaptic membranes contains the basal lamina composed of collagen IV, heparan sulfate and laminin, and many other proteins. The enzyme acetylcholinesterase is anchored to the basal lamina through its collagen-like tail (ColQ).

The clustering of the AChRs is critical for efficient neurotransmission. As will be discussed below, the development and maintenance of the NMJ structure are dependent on a number of key proteins: agrin, low-density lipoprotein receptor related protein 4 (LRP4), muscle-specific kinase (MuSK), docking protein 7 (DOK7), and rapsyn (Singhal and Martin, 2011) (see Fig. 53.1) in addition to other intracellular proteins that are less well characterized.

## Neuromuscular Transmission

Neuromuscular transmission in mature muscle begins with propagation of the action potential into the motor nerve terminal. This depolarization causes opening of the VGCCs and the resulting calcium influx results in the fusion of the ACh containing vesicles and release of ACh. This is terminated by the closing of VGCCs and the opening of the VGKCs with subsequent repolarization of the nerve terminal. ACh binding to the AChR results in the opening of the AChR central ion pore and a localized depolarization of the motor endplate. If sufficient, this will cause the opening of the VGSCs and propagation of the action potential along the muscle fiber to initiate contraction.

The amount of ACh released by a single vesicle is termed a quantum. The spontaneous release of a single quantum is responsible for the generation of a local depolarization, termed a miniature endplate potential (MEPP); a nerve impulse releases multiple vesicles (around 25–30 in humans) leading to a greater depolarization, termed the endplate potential (EPP). It is possible to calculate the number of quanta released, the quantal content, from these parameters (Wood and Slater, 2001). An inherent safety factor exists in normal muscles, whereby more ACh is released than is required to reach the activation threshold for the opening of the VGSCs.

**FIGURE 53.2** The AChR (A,B). The AChR is a transmembrane protein with  $(\alpha)_2$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  subunits in the fetal form and  $(\alpha)_2$ ,  $\beta$ ,  $\delta$ , and  $\epsilon$  subunits in the adult form. A high proportion of antibodies in MG bind to the main immunogenic regions that are on both the  $\alpha$  subunits. In addition, many patients' antibodies bind to the fetal-specific  $\gamma$  subunit. In some cases, antibodies that inhibit the function of the fetal form, selectively, cross the placenta causing fetal muscle paralysis with severe and often fatal deformities. MG, Myasthenia gravis; AChR, acetylcholine receptor; MuSK, muscle-specific kinase; VGCC, voltage-gated calcium channel; VGKC, voltage-gated potassium channel; Ach, acetylcholine.

At the neuromuscular junction, as described above, the AChRs are clustered by the agrin/LRP4/Musk/DOK7 pathway but this clustering process is balanced by binding of ACh that stimulates AChR dispersal. Any defect in the clustering process, as occurs in patients with MuSK antibodies, will be followed by dispersal of the AChRs.

### Acetylcholine Receptor and Muscle-Specific Kinase, the Main Antigenic Targets

The nicotinic AChR remains the major antigenic target in MG. The AChR is a pentameric ligand-gated ion channel that exists in adult and fetal isoforms. The adult form consists of two  $\alpha$ -subunits and one each of the  $\beta$ -,  $\delta$ -, and  $\epsilon$ -subunits, with each subunit being composed of a large extracellular domain, glycosylation sites, and four transmembrane domains. During development, the fetal-specific  $\gamma$  subunit is replaced by the  $\epsilon$ -subunit to form the adult isoform. If the muscle is denervated by nerve injury, the fetal isoform expressing the  $\gamma$  subunit is expressed throughout the muscle until reinnervation occurs.

The AChR subunits are organized around a central ion channel (Fig. 53.2). The two ACh binding sites are between the  $\alpha$ - and  $\epsilon$ - or  $\gamma$ -subunits and between the  $\alpha$ - and the  $\delta$ -subunits, respectively. Both sites need to be occupied for the ion channel to be in the open state. The main immunogenic region is a conformation dependent region on the extracellular component of each of the  $\alpha$ -subunits (Lindstrom, 2000).

MuSK is a receptor tyrosine kinase. The extracellular portion consists of three immunoglobulin-like domains and a cysteine-rich domain. The intracellular portion consists of a juxtamembrane domain, followed by a tyrosine kinase catalytic domain. MuSK is critical both for the development (DeChiara et al., 1996) and ongoing maintenance (Kong et al., 2004) of the NMJ. The role of MuSK and its coreceptor LRP4 is described in detail below (see MuSK antibodies).

## MYASTHENIA GRAVIS

### Epidemiology

Myasthenia affects all races and can occur at any age from the first year of life to the age of ninety. In the Western countries, MG with AChR antibodies (AChR-MG) typically shows two age peaks, in the third decade in

females and in the sixth and seventh decades in males. While the frequency of the early-onset disease has remained unchanged, an increased incidence in the elderly has been consistently reported in the last two decades. The explanation could be the increased longevity of the population and the improvement in diagnosis but these factors only do not appear to be responsible. A metaanalysis of 55 published studies calculated a pooled incidence rate of 5.3 per million person-years (CI 4.4–6.1) and a pooled prevalence rate of 77.7 per million (CI 64–93) (Carr et al., 2010), but a prevalence approaching 150 per million was suggested in a recent study (Andersen et al., 2014).

Interestingly, in Asian populations, particularly the Chinese, there is a high prevalence of limited forms of the disease with childhood onset (Zhang et al., 2007). The incidence and prevalence is difficult to evaluate because of different healthcare systems but it is possible that there is a specific genetic predisposition to childhood MG in these populations or that there is an environmental contribution.

The incidence of MuSK and LRP4 antibody forms of MG is much lower and difficult to assess. For MuSK-MG, it appears to vary with latitude with the highest rates in Italy, Spain, and Turkey—all Mediterranean countries—compared with much lower rates in northern Europe. It is not uncommon in Japan but relatively infrequent in the Chinese (Yeh et al., 2004).

## Etiology of Myasthenia

In the majority of cases, no single cause is identifiable. There is genetic predisposition, which most likely reflects the contribution of polymorphic MHC class I and II loci. Other possible genetic susceptibility markers include the AChR alpha subunit (Garchon et al., 1994; Giraud et al., 2007), Immunoglobulin G (IgG) heavy and light chains (Dondi et al., 1994), Fc gamma receptor IIa (Amdahl et al., 2007), TAP (Hjelmstrom et al., 1997), CTLA4 (Wang et al., 2008), and PTPN22 (Provenzano et al., 2012). Molecular mimicry between AChR subunits and microbial proteins has been proposed as a possible initiating process with autosensitization against muscle AChR occurring as a result of determinant spreading, but there is little robust evidence. Certain drugs, notably penicillamine, may also trigger the development of a reversible form of MG in genetically susceptible individuals (Drosos et al., 1993) but changes in clinical practice means that these cases are seldom seen now.

## General Clinical Aspects

MG is an autoimmune disorder characterized by fatigable muscle weakness. It often involves the extraocular muscles at onset causing diplopia and/or ptosis. If it remains confined to these muscles, it is termed ocular MG. If other muscle groups are involved, often facial, axial, limb, bulbar, and respiratory muscles, it is termed generalized MG. Bulbar and respiratory involvement can be life-threatening.

The diagnosis rests on a compatible clinical presentation supported by serological confirmation (see below) and/or electromyographic evidence (with repetitive nerve stimulation and/or single fiber electromyography) of a defect in neurotransmission. MG is commonly associated with thymic abnormalities, notably thymic hyperplasia and thymoma, and appropriate imaging of the thymus is therefore recommended at presentation.

Symptomatic treatment includes the use of cholinesterase inhibitors but the majority of cases will also require immunosuppressive agents including the corticosteroids and steroid sparing agents (azathioprine, mycophenolate mofetil, methotrexate, and cyclosporine). Thymectomy is a therapeutic option in younger patients with detectable AChR antibodies and a recent study has shown its beneficial effect (Wolfe et al., 2016). Intravenous immunoglobulin and plasma exchange may be employed in severe, life-threatening, or refractory disease. Newer biological agents, such as the monoclonal anti-CD20 agent, Rituximab (RTX) have shown promise in refractory cases (Maddison et al., 2011). Most of these aspects are discussed in more detail below. The treatment modalities available for MG are more fully reviewed elsewhere (Sanders and Evoli, 2010).

## CLINICAL HETEROGENEITY OF MYASTHENIA

### Different Forms Related to Antibodies and Thymic Pathology

MG is not a single disease entity but can be classified into different groups. Defined serologically, it is possible to delineate five main subgroups of MG (see Table 53.2) that differ also by means of age of onset, HLA association, thymic pathology (Compston et al., 1980), and presence of antibodies directed against non-AChR

**TABLE 53.2** MG (Myasthenia Gravis) Patients Divided on the Basis of Antibody Status, Age at Onset, Thymic Pathology and HLA Association

Subtype of MG	Age at onset	Sex M:F	Typical thymic pathology	HLA association	Associated autoantibodies
Early-onset	<51 years	1:3	Thymitis or hyperplasia	B8, DR3	AChR. May have other tissue antibodies, e.g., thyroid
Thymoma associated	Mainly 40–60 years	1:1	Epithelial tumor containing many lymphocytes	No clear association	AChR. Titin and ryanodine receptor antibodies very common. Also cytokine antibodies
Late-onset	>50 years	1.5:1	Normal or atrophied	B7, DR2 in males	AChR. Titin and ryanodine receptor antibodies common, particularly after age 60 years
AChR antibody negative MuSK antibody positive	2–70 years	1:3	Normal or atrophied in most	Not known	MuSK. Other antibodies very uncommon
AChR antibody negative MuSK antibody negative	1–80 years	2:3	Mild thymitis/hyperplasia in some	DR14.DQ5	Cell-based assays can demonstrate antibodies to clustered AChR, MuSK, and/or LRP4 in a proportion

These subgroups are not appropriate in patients with purely ocular MG and in other ethnic populations. *AChR*, Acetylcholine receptor; *MuSK*, muscle-specific kinase.

proteins. The latter group includes MuSK, LRP4 and the striational muscle proteins, titin and ryanodine receptor (RyR).

### Early-Onset Acetylcholine Receptor-Antibody Positive Myasthenia Gravis

These patients are usually defined as presenting before the age of the 50 years. There is a marked female predominance and an incidence that has remained relatively stable for many years. There is an association with HLA A1, B8, DR3, DR2, and DR52 amongst Northern Europeans (Compston et al., 1980; Janer et al., 1999; Hill et al., 1999) and HLA DPB1, DQB1, and DR9 amongst the Japanese (Horiki et al., 1994). Childhood onset AChR-Ab MG is relatively rare in North Europeans but more prevalent amongst Oriental populations as mentioned above (Vincent et al., 2001).

Clinically, the MG often involves extraocular muscles at onset before generalizing, although a proportion will remain purely ocular. The early response to cholinesterase inhibitors is usually good but the majority of patients will still require some form of immunosuppressive therapy. The thymus is typically hyperplastic and thymectomy is a therapeutic option in early-onset generalized AChR-Ab MG, with current available evidence suggestive of benefit in over half of cases (see below). Antibodies (Abs) against titin and RyR are rarely found in the early-onset cases and should raise concerns regarding a thymic tumor.

### Late-Onset Acetylcholine Receptor-Antibody Myasthenia Gravis

By conventional definition, these patients present after 50 years of age and males exceed females by 3:2 ratio. Employing a registry to identify all individuals with positive AChR antibody levels, it has been found that the age specific incidence rises between 45 and 75 years before rapidly falling (Vincent et al., 2003). There is a weak association with HLA B7, DR2 (Compston et al., 1980) and DR4, DQw8 (Carlsson et al., 1990).

Clinically, these patients have a similar phenotype to the early-onset form, although ocular MG may be more common (Zivkovic et al., 2012). The overall response to immunosuppressive treatment is similar to early-onset disease but a greater proportion of patients will encounter side effects, presumably due to comorbid disease (Sanders and Evoli, 2010). However, the thymus is typically atrophic unlike the hyperplastic early-onset thymus. The response to thymectomy is poorer and it is not routinely offered to patients over 60 years of age.

Over half of these late-onset cases have detectable Abs against titin and RyR (Buckley et al., 2001) whilst 25% have Abs against the cytokines, interferon- $\alpha$ , or interleukin-12 (Meager et al., 2003). Titin and RyR Abs are more prevalent in thymoma cases and some authors have speculated that their presence in late-onset MG may represent an immune response against occult thymomas that are subsequently destroyed (Marx et al., 2010).

## Thymoma Associated Myasthenia Gravis

Thymomas are tumors derived from thymic epithelial cells, thereby distinguishing them from lymphoma, neuroendocrine, and germ cell tumors. These are conventionally classified by means of the WHO classification (A, AB, B, and C). A coexisting thymoma is identified in 10% of the MG patients. It can occur at any age but is most common amongst the 40–60 age group. There is no gender difference or consistent HLA association.

Clinically, MG is generalized with detectable AChR antibodies, although ocular and seronegative cases have been reported (Maggi et al., 2008). Myasthenia may be more refractory to treatment than other forms of MG (Sanders and Evoli, 2010). Following thymectomy, AChR Ab levels do not necessarily fall without additional treatments but in contrast to early-onset disease, myasthenia rarely improves without further immunotherapies (Somnier, 1994).

Serum Abs against striated muscle were recognized first in the 1960s. Their major targets are two intracellular proteins, titin and the RyR, both of which are expressed in thymoma (Skeie et al., 1997; Mygland et al., 1995). These antibodies are typically observed in >90% of the thymoma associated MG cases but there are no convincing data supporting their pathogenic role and Abs against the AChR are invariably identified. Neutralizing Abs against interferon- $\alpha$  and interleukin-12 are observed in approximately 70% and 50% of the cases, respectively (Buckley et al., 2001; Meager et al., 2003). These are useful markers for identification of recurrence which occurs in about 10% of the thymomas.

## Muscle-Specific Kinase Antibody Positive Myasthenia Gravis

These patients can present at any age, peaking in the 30s with a female predominance. There is significant worldwide variation with a correlation with geographical latitude, suggesting potential environmental influences (Vincent et al., 2008). On the other hand, despite the small numbers in individual studies, a significant association with HLA DR14 and DQ5 in a Dutch cohort (Niks et al., 2006) and DRB16 and DQB5 in an Italian cohort (Bartoccioni et al., 2009) have been identified suggesting genetic susceptibility. It is not yet clear whether environmental or genetic factors or both predispose to this form of MG.

Clinically, the phenotype is often different from AChR-MG with prominent ocular, bulbar, neck, and respiratory weakness (Evoli et al., 2003; Sanders et al., 2003). Muscle wasting and atrophy of the tongue and facial muscles may be evident both clinically and radiologically (Farrugia et al., 2006). The response to treatment can also differ with a comparatively poorer response (and frequent intolerance) to cholinesterase inhibitors (Evoli et al., 2003; Pasnoor et al., 2010). A proportion can be refractory to conventional immunosuppressive treatment (Evoli et al., 2003). In such cases, plasma exchange may be more effective than intravenous immunoglobulin (Pasnoor et al., 2010) but interestingly, rituximab (RTX) may be more effective in MuSK patients than in those with AChR antibodies (Maddison et al., 2011; Diaz-Manera et al., 2012). The thymus is typically normal or atrophic (Evoli et al., 2008; Leite et al., 2005) in direct comparison to that seen in AChR-Ab MG, and most centers do not perform thymectomy. Thymoma is very rare in MuSK-MG (Saka et al., 2005).

## Neonatal Myasthenia Gravis

This is caused by passive transfer of maternal antibodies across the placenta. It may occur in up to 10% of the female patients with AChR antibodies (Vincent et al., 2001). The affected newborn babies exhibit transient symptomatic weakness, requiring the use of cholinesterase inhibitors for a few weeks. Rarely, it can occur in women who are symptom free but have AChR antibodies.

Arthrogryposis multiplex congenita is a condition where the newborn have multiple joint contractures as a consequence of absent fetal movement in the uterus. It can occur if there are high levels of maternal antibodies directed against the fetal isoform (see Fig. 53.2) of the AChR (Barnes et al., 1995). These antibodies can block the ion channel function of the fetal isoform leading to paralysis during development. The adult isoform takes over during the third trimester and thus, although the condition is not usually reversible, it does not progress after birth. The pathogenic mechanisms were examined in a mouse model of maternal-to-fetal transfer (Jacobson et al., 1999b). There are also rare case reports of neonatal MG occurring in MuSK MG with both transient (Niks et al., 2008) and more persistent disease (Behin et al., 2008) described.

## ANTIBODIES IN MYASTHENIA

### Evidence for Pathogenicity of Acetylcholine Receptor and Muscle-Specific Kinase Antibodies

Both AChR and MuSK antibodies are pathogenic, satisfying the strict criteria required for establishing causation in autoimmune disease (Rose and Bona, 1993). Both are directed against autoantigens that are highly relevant to a disorder of neurotransmission and are highly specific for MG.

The main criteria in these diseases are the passive transfer of MG from man to animal (usually mice or rats) and the response to treatments that reduce Ab levels. Passive transfer models involve injection of IgG from MG patients into animals and lead either to objective weakness or at least to neurophysiological evidence of impaired neurotransmission. Plasma exchange dramatically reduces antibody levels within a few days and leads to striking clinical improvement even in patients with long-standing disease. In addition, maternal–fetal transfer of the disease has been reported in both serological forms of MG.

Further *in vivo* evidence comes from replication of the human disease in animals that have been immunized with the relevant antigen, termed experimental autoimmune MG (EAMG). This active immunization model has been used extensively to study the immune biology of MG, as will be mentioned below.

### Acetylcholine Receptor Antibodies

AChR Abs were first detected by means of a radioimmunoprecipitation assay (RIA) employing  $^{125}\text{I}$   $\alpha$ -bungarotoxin that binds strongly to AChRs and labels AChRs in detergent extracts of human muscle (Lindstrom et al., 1976). Modern RIAs employ AChR extracted from muscle cell lines expressing mixtures of fetal and adult AChRs (Beeson et al., 1996). Directly radiolabeled recombinant MuSK are used for detection of MuSK antibodies (Matthews et al., 2004). Enzyme linked immunosorbent assays are not found to be as sensitive or as specific in our hands. AChR antibodies belong to variable IgG subclasses, although IgG1 and IgG3 predominate (Rodgaard et al., 1987; Vincent et al., 1987). A significant proportion of Abs are directed against the MIR on  $\alpha$ -subunits, although other sites (Whiting et al., 1986) and other AChR subunits (Jacobson et al., 1999a) can also be targets. These Abs have a high affinity (around 100 pM) and are highly specific for the intact receptor with limited binding to recombinant polypeptides or denatured AChR subunits; the Abs bind predominantly to the extracellular portion of the receptor.

The diagnostic sensitivity of the RIA is high in adult-onset generalized MG (80%–85%) but quite low in ocular MG (around 50%) (Wong et al., 2014) and in prepubertal-onset disease (50%–70%) (Finnis and Jayawant, 2011). Between patients, there is variation in the Ab specificity, isoelectric heterogeneity, and avidity for the AChR and no clear correlation with disease activity is observed. Although some reports indicate a poor correlation between Ab levels and clinical severity in MG, the Ab titer can be useful in monitoring disease activity in individual patients (Vincent and Newsom Davis, 1980). This association has been reported after thymectomy, plasma exchange, or immunotherapies (Heldal et al., 2014). Moreover, in a recent study including 223 patients with ocular presentation, AChR antibodies were detected in 71% of the cases and an increased antibody titer predicted the risk for MG generalization (Peeler et al., 2015).

In generalized MG, 85% have AChR Abs and 0%–10% have MuSK Abs; a rather variable but usually low percentage may have LRP4 Abs, although there are few systematic studies at present and assays are not well standardized. There are very rare case reports of patients with both AChR and MuSK Abs (Saulat et al., 2007; Rajakulendran et al., 2012) and LRP4 Abs may coexist with much higher levels of MuSK Abs (Higuchi et al., 2011) raising questions about their importance.

Cell-based assays (CBAs) have now been developed that use human embryonic kidney (HEK) cells transfected with DNA for the antigen of interest that is then expressed on the cell surface. Indirect immunofluorescence can be used to detect the binding of patients' Abs. This method is sensitive and, importantly, measures potentially pathogenic Abs that only bind to extracellular determinants of the antigen (Leite et al., 2010). This was demonstrated in previously seronegative cases using cells transfected with AChR subunits which were clustered with the scaffold protein, rapsyn (Leite et al., 2008). CBAs have also been developed to detect MuSK or LRP4 Abs (Higuchi et al., 2011) as mentioned below.

The "clustered AChR" Abs were found in 38% of the RIA-seronegative MG patients and were useful in confirming the MG diagnosis especially in childhood, ocular, and mild disease forms (Rodriguez Cruz et al., 2015). More recently, a French study reported the presence of clustered AChR Abs in 16% of the adult patients with generalized MG with a phenotype resembling those positive on standard RIA but with a milder disease course

as shown previously. Interestingly, thymectomy was performed in a proportion of patients with evidence of thymoma in one case (Devic et al., 2014). In future, these results will need confirmation by larger, multicenter studies. Of relevance, experimental studies of passive transfer with purified patients' IgG into mice resulted in the reduction of MEPP amplitudes indicating the loss of postsynaptic AChR that mirrors that found in typical MG patients (Jacob et al., 2012) confirming the pathogenicity of the clustered AChR Abs (Vincent and Newsom Davis, 1980).

## Characteristics and Mechanisms

AChR Abs cause loss of AChR through three principal mechanisms. These include complement mediated destruction, crosslinking and accelerated degradation, and functional blockade. AChR Abs belong predominantly to the complement fixing IgG1 and IgG3 subclasses (Rodgaard et al., 1987) that are divalent for the AChR and can therefore cause neuromuscular transmission failure by internalizing the AChRs or activating complement (Rodgaard et al., 1987; Toyka et al., 1975). Internalization or antigenic modulation is an increase in the normal rate of turnover of the AChRs that is observed in both MG patients (Drachman et al., 1978) and EAMG (Lindstrom and Einarson, 1979). It is most prominent when Abs are directed against the MIR (Tzartos et al., 1991) and lead to reduced AChR expression on the postsynaptic membrane without membrane damage. The activation of complement results in the generation of the membrane activation complex that is responsible for lysis and destruction of the postsynaptic membrane, loss of postsynaptic folding, and ultimately loss of AChR and related proteins. IgG colocalizing with activated complement was shown both in EAMG (Sahashi et al., 1978) and MG (Engel et al., 1977) muscle biopsies. The importance of complement in the pathogenesis of this form of MG came from several lines of evidence. Depletion (Lennon et al., 1978), inhibition (Biesecker and Gomez, 1989), or blockade (Piddlesden et al., 1996) of complement all resulted in resistance to developing the disease in EAMG. Further evidence was provided by the study of transgenic mice lacking components of the classical complement cascade (Tuzun et al., 2003) and complement (Morgan et al., 2006) and recently anticomplement therapy has been found effective in severe cases (see Biologics below). By contrast, direct block of ACh binding to the AChR or of the ion channel itself appears to be uncommon in majority of the patients.

Whatever the mechanisms, failure of neuromuscular transmission results from the loss of AChRs, which leads to reduced MEPP and EPP amplitudes. The reduced EPP amplitude falls below the required threshold to initiate an action potential, leading to blocking of neurotransmission. There is partial compensation for this through an increase in AChR synthesis by the muscle and in the number of quanta of ACh released, which appears to be a compensatory mechanism in both MG and EAMG (Plomp et al., 1995).

## Muscle-Specific Kinase Antibodies

MuSK is a receptor tyrosine kinase critical for the formation and maintenance of the neuromuscular junction. The extracellular portion consists of three immunoglobulin-like domains and a cysteine-rich domain. MuSK-Abs are detected by RIA in 40% of the AChR-negative patients with variable frequency across populations.

CBA techniques can be applied to the detection of MuSK-Abs and may improve the diagnosis in RIA-negative patients. A multicenter study investigating seronegative sera from 13 countries searching for MuSK-Abs by CBA achieved positive results in 13% of the samples (Tsonis et al., 2015) but many of the Abs detected were of the IgM type and their specificity is still uncertain. Recently, a study from the Oxford group found that 8% of the RIA-negative MG samples bound MuSK antigen expressed on HEK cells. Their pathogenic role on AChR clustering was confirmed in vitro in C2C12 myotubes (Huda et al., 2017). Interestingly, in this study, the patients with MuSK-Abs only on CBA had a milder phenotype than those positive on standard RIA.

## The Role of Muscle-Specific Kinase in Neuromuscular Junction Development and Maintenance

To understand the effects of antibodies in MuSK-MG, it is necessary to appreciate the complex mechanism of neuromuscular junction formation and maintenance, for which MuSK has a critical role (Kong et al., 2004). During development, a large soluble protein N-agrin is released from the motor nerve and binds to the MuSK coreceptor, LRP4; this binds to and activates MuSK phosphorylation. Phosphorylated MuSK recruits the intracellular protein DOK7 that is also phosphorylated and together they initiate the complex pathway that results in the clustering of rapsyn and AChRs on top of the postsynaptic folds under the nerve terminals. This process can be

studied to a large extent in cultured mouse C2C12 myotubes. The C2C12 myoblasts can be induced by serum deprivation to fuse and become myotubes with high AChR expression throughout the membrane. When agrin is added to the myotubes, the LRP4/MuSK/DOK7 pathway is activated and AChRs form high density clusters ( $>3\text{ }\mu\text{m}$ ) on the myotube surface. These clusters can be observed and quantified using fluorescently labeled alpha-bungarotoxin, the snake toxin that is used extensively to measure muscle AChRs and for the RIA. If DOK7 is virally transduced into the C2C12 cells, the AChR clusters occur without the requirement of agrin, LRP4, or MuSK, showing that DOK7 is the ultimate initiator of the clustering process. These phenomena can be used to study the effects of MuSK and LRP4 Abs.

MuSK Abs belong predominantly to the noncomplement fixing IgG4 subclass (McConville et al., 2004). These Abs are able to undergo Fab arm exchange to produce bispecific Abs that do not cross-link identical antigens (van der Zee et al., 1986), and which therefore function monovalently (Schuurman et al., 1999). This suggests that the effector mechanisms are unlikely to be the same as those in AChR mediated disease. MuSK Abs have been shown to be monovalent for MuSK but they can interfere with protein–protein interactions (Koneczny et al., 2017). MuSK-Abs bind to an epitope within the first Ig-like MuSK domain, preventing its interaction with LRP4, which results in the impairment of the AChR clustering pathway (Huijbers et al., 2013; Koneczny et al., 2013). A recent study showed that the level of IgG4 directed against the first Ig-like MuSK domain correlates better with disease severity than the total MuSK Ab titer (Huijbers et al., 2016) while no correlation was found with Abs directed to the other MuSK epitopes (e.g., Frizzled-like domain). Some studies have also found that MuSK interacts with ColQ, a collagen-like protein that anchors AChE to the basal lamina in the synaptic cleft.

MuSK Abs inhibit the binding of LRP4 to MuSK and thus interfere with the agrin induced clustering pathway. The divalent IgG1-3 Abs do not block LRP4 binding to MuSK. Nevertheless, both IgG4 and IgG1-3 MuSK Abs inhibit agrin induced AChR clustering in the C2C12 myotubes, suggesting that the IgG1-3 antibodies alter MuSK function in an LRP4-independent manner (Koneczny et al., 2013). Since the IgG1-3 antibodies are less frequent, their functional roles, which could include complement mediated damage, have not been explored adequately in animal models.

There are very little data from human muscle, and the only published pathological study has demonstrated normal motor endplates, normal AChR numbers, and little evidence of complement deposition (Shiraishi et al., 2005). By contrast, both active immunization against MuSK (Shigemoto et al., 2006; Viegas et al., 2012) and passive transfer of human MuSK Ab IgG (Cole et al., 2008) models have demonstrated AChR loss in clinically affected animals, although complement deposition has not been observed and complement deficient mice remain susceptible to the disease (Mori et al., 2012).

Of particular interest, combined pre- and postsynaptic morphological changes have been observed in animal models (Cole et al., 2008; Richman et al., 2012) and may explain the severe phenotype that is observed in the mice and in patients. There is also electrophysiological evidence of both pre- and postsynaptic defects (Viegas et al., 2012; Klooster et al., 2012) with the failure of the presynaptic compensatory mechanism (Plomp et al., 1995) further impacting on underlying neurotransmission.

## LRP4 Antibodies

The proportion of LRP4-positive patients among the AChR/MuSK seronegative cases varies widely from 0% to 50% in different reports, probably due to the different techniques applied, such as luciferase reporter immunoprecipitation (Higuchi et al., 2011), ELISA (Zhang et al., 2012), and CBA (Pevzner et al., 2012; Marino et al., 2015). In a recent European multicenter study, LRP4 Abs were detected in 18.7% of the 635 seronegative patients, with a difference in the frequency among different countries, suggesting a possible role of ethnicity in disease susceptibility (Zisimopoulou et al., 2014). A recent Chinese study reported a frequency of LRP4 antibodies of only 4%, associated with AChR and MuSK-Abs in a proportion of cases (Li Y, Muscle Nerve, 2017).

LRP4 Abs were predominantly of the IgG1 subclass and their potential pathogenicity has been demonstrated in active immunization models by disrupting agrin–LRP4 binding to MuSK and by complement–activation (Shen et al., 2013). However, there have been no reports on passive transfer models from human LRP4 Abs. Moreover, somewhat worryingly, LRP4 Abs have been reported in a significant proportion of other neurological diseases including neuromyelitis optica (NMO) (Zhang et al., 2012) and amyotrophic lateral sclerosis (Tzartos et al., 2014). Future studies are needed in order to standardize the assays and clarify the pathogenicity potential of LRP4.

Most of the positive patients have a mild generalized disease. In some of the patients, a double association with MuSK (predominantly) or AChR Abs were considered responsible for a more severe disease course

(Higuchi et al., 2011; Zhang et al., 2012; Pevzner et al., 2012; Marino et al., 2015). There is a female and early-onset preponderance (only 16% were >50 years). Thymic hyperplasia can occur but there are no reports of thymoma.

## Novel Targets

While the search for novel antigens in MG is keenly pursued, there are still some patients without detectable Abs. The frequency of the so-called triple-negative cases is variable. Abs to agrin, ColQ, and cortactin have recently been described in MG patients (Zhang et al., 2014; Zoltowska Katarzyna et al., 2015; Gallardo et al., 2014; Cortes-Vicente et al., 2016) but their role in the disease pathogenesis has not been proved and they are not currently used in routine diagnostic assays. Antibodies against rapsyn have also been described (Agius et al., 1998), but as the antigen is intracellular, the Abs are unlikely to be pathogenic.

One of the problems with many studies on triple negative cases is that the sera are seldom taken at the onset of symptoms and most patients have been treated with immunotherapies. In addition, it is possible that some of the antibodies that are found are secondary to the disease process and not the primary pathogenic entity.

## THE THYMUS AND CELLULAR IMMUNITY IN MYASTHENIA GRAVIS

### Role of T Lymphocytes in Myasthenia Gravis

High affinity AChR Abs are thought to be dependent on CD4+ T lymphocytes but as these are rarely observed in myasthenic muscle and almost never found at the neuromuscular junction; they are not thought to be effector cells in MG. Nevertheless, their critical role in the autoimmune pathogenesis is demonstrated through several lines of evidence in both MG and EAMG. EAMG was first described following the immunization of rabbits with AChR purified from the electric organ of *Torpedo californica* (Patrick and Lindstrom, 1973) and later reproduced in a number of other species. In the murine model, there are both disease sensitive and resistant strains, related to their different H-2 alleles (Berman and Patrick, 1980).

AChR-specific CD4+ T lymphocytes occur in both the peripheral blood and thymuses of MG patients. They may also be observed in the healthy controls but the clinical improvement observed following their removal with anti-CD4 monoclonal Abs (Ahlberg et al., 1994) and in HIV (Nath et al., 1990) supports a pathogenic role for these lymphocytes. These isolated CD4+ T lymphocytes may respond to stimulation with the intact AChR, recombinant subunits or AChR peptides (Conti-Fine et al., 1998; Wang et al., 1998), and T cell lines or clones propagated from MG patients will respond more vigorously to stimulation in vitro than those derived from the healthy controls. The epitopes are most commonly found on the  $\alpha$ -subunit of the AChR (e.g., Ong et al., 1991). In EAMG, a dominant epitope within the  $\alpha$ 146-162 activates MHC class II restricted CD4+ T lymphocytes, leading to pathogenic antibody production (Christadoss et al., 2000). No clearly immunodominant epitope has been identified reproducibly in a high proportion of MG patients, although an epsilon subunit epitope was identified in some (Hill et al., 1999). The TCR V $\beta$  families show preferential expansion of the V $\beta$  4 and 6 amongst MG patients (Navaneetham et al., 1998) whilst mice lacking V $\beta$  6 respond poorly to immunization with AChR (Krcio et al., 1991; Ahlberg et al., 1994).

Mice genetically deficient in functioning CD4+ T lymphocytes don't develop EAMG (Kaul et al., 1994) whilst severe combined immunodeficient mice will only produce AChR Abs and develop myasthenic symptoms if the human grafted cells contain CD4+ T lymphocytes (Wang et al., 1999).

CD4+ T lymphocytes and the cytokines they secrete will influence the type of autoimmune response generated in both MG and EAMG. Analysis of blood from MG patients has confirmed the presence of T helper 1 (Th1), Th2, Th17, and T regulatory (Treg; Foxp $^+$ ) cells (Li et al., 2008) but the role of these T lymphocyte subsets in the development of the disease is best examined using transgenic mice. Interleukin-12 (IL-12) is essential for promoting development of Th1 cells and IL-12 - / - mice are resistant to the development of EAMG despite a significant Ab response (Karachunski et al., 2000). The role of IFN- $\gamma$  remains unclear with conflicting reports of EAMG susceptibility (Balasa et al., 1997; Wang et al., 2007). IL-4 appears to be either neutral (Balasa et al., 1998) or confer a protective effect (Karachunski et al., 1999). There is an apparent increase in Th17 and decrease in Tregs during development of EAMG in rats (Mu et al., 2009) and administration of Tregs to myasthenic rats inhibited progression of EAMG (Aricha et al., 2008). Initial studies identified no change in Treg numbers in MG subjects compared with the healthy controls (Huang et al., 2004), although a specific functional impairment in those Foxp3+ Tregs (Balandina et al., 2005) was subsequently identified.

T cell activation requires the interaction of TCR/MHC peptide in addition to the interaction between CD28/CTLA4 on the T lymphocytes and CD80 (B7) on antigen presenting cells (the CD28–CD80 interaction). It also requires the crosslinking of the CD40 ligand (CD40–CD40L interaction). Using transgenic mice, it has been demonstrated that both interactions are essential for the primary immune response (Shi et al., 1998), although their contribution to the secondary response is thought to be less prominent. Here, the CD278 (inducible T-cell costimulator) is thought to be important for the secondary response (Scott et al., 2004).

### Advances in the Cellular Immunology of Acetylcholine Receptor Myasthenia Gravis

The breakdown of central and peripheral tolerance checkpoints is an important aspect involved in the pathogenesis of MG. A recent study showed that the frequency of autoreactive B cell receptors was higher in patients with AChR and MuSK MG than in the healthy controls (Lee et al., 2016). In addition, studies on regulatory B and T cells provide new insights into the involvement of defective immune regulatory pathways in the immunopathogenic mechanisms likely responsible for MG. The understanding of the mechanisms that account for B-cell shift from a proinflammatory to a regulatory phenotype and defective B cell tolerance has important therapeutic implications in terms of developing durable B and T cell–targeted therapies for MG.

The B-cell population is functionally heterogeneous and B cells can be divided into different subsets according to the cytokine that they produce. One functional B cell subset, regulatory B cells (Bregs), has recently been shown to downregulate the immune response through the production of IL-10, IL-35, and TGF- $\beta$  (Fillatreau et al., 2008; Shen et al., 2014). In particular, IL-10 appears to inhibit dendritic cell production of IL-12 and to suppress Th1 and Th17 cell responses in several models of autoimmune diseases (Li et al., 2012; Quan et al., 2013).

The most accepted cell markers to identify Bregs are considered CD1d + CD5 + and CD24 + CD38 + B cells, which are phenotypically indistinguishable from transitional immature B cells and which have been shown to produce the highest percentage of IL-10. The involvement of CD19 + CD24 + CD38 + immature Bregs in autoimmunity was first described in studies on RTX-treated Systemic lupus erythematosus patients, in which the disease remission was associated with a reconstituted B cell population predominantly characterized by immature Bregs (Blair et al., 2010). This led to the hypothesis that after the B cell depletion therapy, the newly repopulated B cells are constituted by competent Bregs that can efficiently suppress the immune response and restore the immune balance in favor of tolerance (Palanichamy et al., 2009).

Both frequency and function of Bregs were reduced in MG patients compared with the healthy controls and were associated with disease activity (Sheng et al., 2016; Karim et al., 2017; Yi et al., 2017) and response to RTX (Sun et al., 2014). These findings were confirmed in a recent study showing a lower percentage of Bregs in patients with MuSK MG (Guptill et al., 2015). From these findings, Bregs may serve as a marker for disease activity in MG patients and as a promising therapeutic target.

Early studies searching for AChR-specific T cells were technically demanding and have not proven to be particularly helpful in understanding the disease etiology or providing new targets for therapies. More recently the emphasis has been on the regulatory T cells. Thymic T CD4 + lymphocytes include Tregs involved in self-tolerance mechanisms and follicular T helper cells (ThF) that play a critical role in B lymphocyte differentiation and affinity maturation. Treg lymphocytes play important immunosuppressive functions (Sakaguchi et al., 2010; Campbell and Koch, 2011) and both quantitative and functional alterations of CD4 + CD25 + FoxP3 + Tregs have been described in several autoimmune pathologies (Long and Buckner, 2011; Noack and Miossec, 2014) but with contradictory results. In MG, where it is well known that thymus pathology is implicated in the pathogenesis, Treg should be even more relevant. Reduced Tregs were found in a recent study on AChR-MG patients, in which different subpopulations of Treg were significantly reduced after the thymectomy and immunosuppression and were, in general, lower than in healthy subjects (Kohler et al., 2017). Therapies focused on ameliorating Treg function through enhancing (Long and Buckner, 2011) their suppressive activity or their migration appeared to be promising in preclinical models of MG (Sheng et al., 2006) because of the adoptive transfer of ex vivo generated Treg (Aricha et al., 2008).

A subpopulation of Treg, called follicular regulatory T (Tfr) cells, are thought to control the function of ThF that promote B cell maturation and high affinity Ab production in germinal centers. An abnormal production of thymus derived ThF might be involved in the development of several autoimmune diseases including MG. A recent study showed an increased frequency of ThF and a decreased rate of Tfr in the peripheral blood of MG patients compared to the healthy control that inversely correlated with the disease severity (Wen et al., 2016). These results were confirmed in the patients with generalized MG in a study which showed a correlation between ThF, plasma cell frequency, and AChR-Ab titer (Zhang et al., 2016).

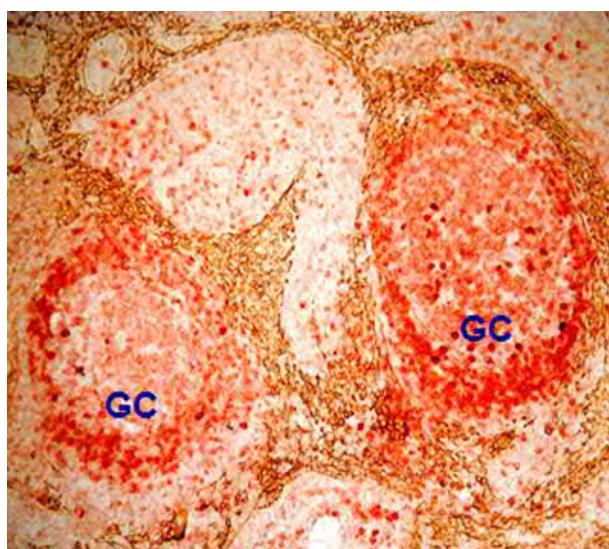

## The Thymus in Myasthenia Gravis

Thymus is involved in the maintenance of self-tolerance. While MuSK-MG is rarely associated with thymus alterations, in AChR-MG thymus changes are common, especially in the early-onset subtype. In case of thymoma, thymectomy is always mandatory while the rationale for thymectomy in nonthymomatous patients is related to the role of the thymus follicular hyperplasia (TFH) in the pathogenesis of the disease. Several studies showed that the TFH includes infiltrates of lymphocytes- and AChR-specific germinal centers that can be targeted by complement factors (Leite et al., 2007).

The thymus is an epithelial organ that can be morphologically divided into a distinct cortex, medulla and corticomedullary zone. The cortex contains densely packed immature lymphocytes alongside a sparse population of epithelial cells and bone marrow derived macrophages. The medulla is less cellular containing more mature T lymphocytes, more prominent epithelial cells, dendritic cells, B lymphocytes, and rare myoid cells (Pearse, 2006). The thymus has a critical role in self-tolerance with a fine balance between the generation of protective T lymphocytes and deletion of autoreactive T lymphocytes required. Relevant autoantigens including the  $\alpha$ -subunit of the AChR are expressed on medullary thymic epithelial cells (mTECs) under the control of the autoimmune regulator gene (AIRE) (Giraud et al., 2007). Central T cell tolerance relies on the close interaction between these mTECs and the nearby dendritic cells and their effect on the T lymphocyte development and subsequent differentiation.

The thymus is thought to have a critical role in the development of early-onset AChR antibody-positive MG. The cortex is typically normal but the medulla contains lymphocytic infiltrates and germinal centers with distinct areas of B lymphocyte proliferation, differentiation, somatic hyper-mutation, and immunoglobulin class switching. A typical pathological section of an MG thymus is shown in Fig. 53.3. These B lymphocytes, when cultured in vitro, are capable of secreting AChR Abs spontaneously (Vincent et al., 1978; Scadding et al., 1981). It is, therefore, to be expected that antibody levels fall post thymectomy (Vincent et al., 1983) but they seldom disappear.

Whether early-onset AChR antibody-positive MG begins in the thymus, or whether these changes are a reflection of a systemic process, remains unresolved. Individual AChR subunits are expressed on mTECs (Salmon et al., 1998), presumably as part of a self-tolerance mechanism, and these are targeted by both autoantibodies (Safar et al., 1991) and complement (Leite et al., 2007). Native AChR is also expressed by the muscle-like myoid cells, which whilst comparatively rare, are more abundant in the hyperplastic thymus (Kirchner et al., 1986). The germinal centers appear to be focused around these myoid cells. Given that they lack MHC class II or costimulatory molecules, they rely on the antigen presenting dendritic cells to prime the CD4<sup>+</sup> T lymphocytes. One proposed multistep hypothesis is that the mTECs first present epitopes from isolated AChR subunits to CD4<sup>+</sup> T lymphocytes, evoking the production of early antibodies capable of attacking the thymic myoid cells

**FIGURE 53.3** Hyperplastic thymus with the presence of GC in an early-onset MG patient with AChR antibodies. Double CD79a (red)/CK19 (brown) immunostaining. Intense CD79a<sup>+</sup> staining marks the periphery of germinal centers, CK19 is specific for the thymic epithelial tissue. Original magnifications,  $\times 250$ . that express the intact AChR. As the immune response continues to proliferate, germinal centers are formed that allow these antibodies to diversify allowing recognition of native AChRs (Willcox et al., 2008).

The thymus is typically involuted and atrophic in older patients. The aging thymus is gradually replaced with fat, although residual foci of mTECs may persist and myoid cells are only rarely encountered. The histological analysis of the thymus tissue from the late-onset MG cases previously suggested no differences from normal controls (Myking et al., 1998). Nevertheless, a more recent study looking at young and late-onset MG cases identified residual lymphocyte accumulation amongst the older cohort and no qualitative differences between the two groups (Ishii et al., 2007).

## Thymoma

Thymomas are heterogenous neoplasms of thymic epithelial cells (TEC) with mixed cortical and medullary markers. They may develop from either early TEC progenitors or from more mature cortical or medullary TECs (Hasserjian et al., 2005). They are responsible for the generation of numerous maturing polyclonal T lymphocytes (thymocytes) capable of maturing into CD4 + or CD8 + T lymphocytes. The degree of thymopoiesis is known to vary according to the thymoma subtype (Nenninger et al., 1998). The B2 subtype is the most common type associated with MG (accounting for ~50% of the cases) and contains an abundance of mature CD4 + T lymphocytes ready for export (Strobel et al., 2004). It should be noted that corticosteroids can deplete the immature T lymphocytes and thereby modify the histological subtype.

There are certain features in thymomas that are likely to promote inefficient self-tolerance including defective AIRE and HLA class II expression, an absence of myoid cells, failure to generate Foxp3 + Treg cells as well as defective T lymphocyte signaling (Marx et al., 2010). Other antigenic targets are also recognized which is unsurprising given the wide range of systemic, hematological, endocrine, cutaneous, gastrointestinal, and renal disorders associated with thymoma (Marx et al., 2010). A lower production of Treg was observed in thymoma and confirmed by immunohistochemistry (Scarpino et al., 2007).

Genetic aberrations and polymorphisms may also be identified in thymoma. These include HLA genes (notably loci at 6p21) which may affect MHC class II expression and non-HLA genes (including CTLA4 and PTPN22) which influence T-cell receptor signaling.

## TREATMENTS IN MYASTHENIA GRAVIS

### General Approach

The current treatment for MG consists of symptomatic therapy with acetylcholinesterase inhibitors and generalized immunosuppression with corticosteroids, azathioprine, mycophenolate, and immunomodulation with intravenous immunoglobulin and plasmapheresis. Thymectomy is common in early-onset MG. In response to the need for more effective or more rapid treatments in some patients, biologics have been applied to MG management as described below.

The efficacy of thymectomy in early AChR-MG was suggested in several small case series but results from the thymectomy trial (MGTX) have been recently published (Wolfe et al., 2016). This multicenter (40 centers included) trial was conducted between 2006 and 2012 and recruited 126 nonthymomatous AChR-MG patients comparing prednisone alone versus prednisone with transsternal thymectomy. Patients who underwent thymectomy had a lower time-weighted average Quantitative myasthenia gravis (QMG) score over a 3-year period and required lower average alternate-day prednisone than those who received prednisone alone. Moreover, immunosuppressive treatment, need for hospitalization, and treatment side effects were less in the thymectomy group. The MGTX trial represents a milestone in the management of MG patients even if it leaves some open questions, such as the efficacy of thymectomy in late-onset AChR-MG, where the thymus is normally atrophic or in other MG types and the benefit from less invasive surgical approaches (Keijzers et al., 2015).

### Biologics

Several recent studies have demonstrated the benefits of Rituximab (RTX)-mediated B cell depletion in refractory MG, especially in MuSK MG (Iorio et al., 2015). RTX, a monoclonal antibody targeting CD20 on B cells, led

to a sustained clinical improvement in parallel to a reduction or discontinuation of corticosteroid and plasma exchange treatments.

The expression of the CD20 antigen is restricted to the late pre-B-cell stage and is maintained until their differentiation to plasma cells when expression is usually lost. Interestingly RTX targeting the precursor of plasma cells depletes the niche of short-lived plasma cells while it has no effect on the long-lived plasma cell subset (Winter et al., 2012).

It has been hypothesized that MuSK IgG4 Abs are produced almost exclusively by short-lived plasma cells (Diaz-Manera et al., 2012), which may explain why RTX is particularly effective in MuSK-MG and why MuSK antibody titer markedly decreases after RTX treatment. On the other hand, this finding might be related to a modification of the B-cell repertoire induced by RTX with the disappearance of the initially expanded populations and the reconstitution of a diverse B-cell repertoire that might account for its long-lasting effect.

RTX appeared to be safe and effective even in patients with refractory AChR-MG, who were observed to have a long-lasting response after treatment and a significant decrease of the Ab titers that correlated with the clinical improvement (Robeson et al., 2017). The ongoing trial in AChR-MG will provide more definite conclusions on the efficacy and safety of this treatment but one of the main concerns regards the number of reinfusions needed to prevent a relapse. Based on evidences from NMO studies, the reemerging of CD27+ memory B cells to 0.05% of the peripheral blood cells has been recommended as target value to repeat RTX in MG (Lebrun et al., 2016).

Eculizumab, a humanized monoclonal antibody, inhibits the formation of terminal complement complex by preventing the enzymatic cleavage of complement 5 (C5). It was tried for the first time in MG in a small trial involving 14 refractory AChR-MG patients with promising results (Howard et al., 2013). Currently, a phase III study is assessing the efficacy of eculizumab in refractory AChR-MG.

Belimumab, a human monoclonal antibody that prevents B-cell activating factor (BAFF) from binding to B cells provoking the inhibition of B cells proliferation and survival, has not been shown to be effective in a phase II trial in patients with AChR-MG and MuSK-MG (clinicaltrialgov.com: NCT01480596).

## LAMBERT-EATON MYASTHENIC SYNDROME

### Introduction

The Lambert–Eaton Myasthenic Syndrome (Wirtz et al.) is clinically and electrophysiologically distinct from MG. Approximately 50% of the LEMS cases are paraneoplastic, typically associated with small cell lung carcinoma (SCLC). There are certain features that make it possible to distinguish paraneoplastic and nonparaneoplastic forms.

### Epidemiology and Etiology

LEMS is less common than MG with an annual incidence of 0.48 per million in a Dutch study (Wirtz et al., 2003). The median age of onset is 60 years in both the paraneoplastic and nonparaneoplastic forms (O'Neill et al., 1988) although there is another smaller peak at 35 years in the nonparaneoplastic forms (Titulaer et al., 2011a). There is a male predominance in the paraneoplastic form and a slight female predominance in the nonparaneoplastic form. In the latter, similar to early-onset MG, there is an association with HLA B8 and DR3.

### Clinical Features

The cardinal clinical features of LEMS include muscle weakness, autonomic dysfunction, and areflexia. Typical findings include proximal muscle weakness that is more marked in the lower limbs. Ocular and bulbar symptoms may occur later in the disease course. The speed of progression is often more rapid in the paraneoplastic form (Titulaer et al., 2008). Autonomic involvement is seen in over 80% of the cases. Commonly encountered symptoms include dry mouth, erectile dysfunction, and constipation. Micturition difficulties and orthostatic syncope are less common. In contrast to MG, the muscle strength in LEMS will improve after a period of maximal voluntary contraction. A recent update on the clinical features (Titulaer et al., 2011a) and a clinical method predicting the presence of a small cell cancer can be found elsewhere (Titulaer et al., 2011b).

## Investigation and Treatment

Electromyography will confirm a disorder of neurotransmission although a significant increase in the compound muscle action potential following a period of exercise or high frequency stimulation allows electrophysiological differentiation from MG. Serological confirmation involves detection of antibodies against the P/Q type voltage-gated calcium channels which are found in approximately 90% of the LEMS cases and are invariably present in paraneoplastic SCLC cases (see below).

To detect the antibodies, the P/Q type VGCCs are extracted from mammalian brain, labeled with  $^{125}\text{I}$   $\omega$ -conotoxin which binds specifically to these VGCCs and used in an RIA. In addition, antibodies against N type (30%–40%) and L type (25%) VGCCs may be present (Motomura et al., 1997; Johnston et al., 1994). Other antibodies which have been identified include those against Synaptotagmin (Takamori et al., 1995) and more recently against SOX-1 in 65% of the paraneoplastic cases and around 5% of the nonparaneoplastic cases (Sabater et al., 2008; Titulaer et al., 2009).

Symptomatic treatment requires 3,4-diaminopyridine (3-4-DAP). If additional treatment is required, the corticosteroids and other immunosuppressive agents are used. Intravenous immunoglobulin, plasma exchange, and RTX may be used in severe and refractory cases. Any underlying SCLC should be treated in appropriate manner. Treatment options are reviewed in more detail (Titulaer et al., 2011a).

## Pathophysiology

VGCC contains several subunits but the  $\alpha_1$ -subunit is primarily responsible for the biochemical and electrophysiological functions of the protein. Similar to the MIR on the  $\alpha$ -subunit of the AChR, there may be particularly immunogenic sequences; 50% of the LEMS patients have antibodies against linker domains on the  $\alpha_1$ -subunit (Takamori et al., 1997).

Freeze fracture electron microscope studies of the presynaptic motor nerve terminal have demonstrated an ordered array of intramembranous particles. These are located close to the site of transmitter exocytosis. There is some evidence that VGCC constitutes at least some of the intramembranous particles in the active zone (Robitaille et al., 1990). LEMS patients have both a reduction in the total number of active zone particles and the number of particles per active zone (Nagel et al., 1988).

The evidence for the pathogenic nature of VGCC comes from both clinical and experimental studies. Patients respond to plasma exchange (Newsom-Davis et al., 1982) and cases of maternal-to-fetal transfer of the disease have also been reported (Lecky, 2006). Passive transfer with LEMS plasma or IgG produces the same neurophysiological abnormalities in mice (Lang et al., 1983; Fukunaga et al., 1983), although no weakness was observed. Further studies confirmed the localization of IgG close to the presynaptic active zones (Fukuoka et al., 1987). In addition, active immunization of rats with peptides from the  $\alpha_1$  subunit led to mild weakness and compatible neurophysiological changes (Komai et al., 1999). Finally, mice with mutations in the P/Q type VGCC (CACNA1a) share some of the electrophysiological characteristics of LEMS (Kaja et al., 2007).

## CONCLUSIONS AND FUTURE PROSPECTS

Historically, the classification of MG has been based on AChR Ab status, age of onset, and thymic pathology. MuSK antibodies were first recognized 17 years ago and whilst there was some initial skepticism about their relevance, it is now well established that they are pathogenic, satisfying all the necessary criteria for causation in autoimmune diseases. Defined serologically, this particular form of MG is typically more severe and more refractory to conventional immunosuppressive therapy. From an immunological perspective, the predominance of non-complement fixing IgG4 Abs in a subclass of MG patients contrasts with the predominantly IgG1 AChR Abs in the classical form and raises interesting questions regarding the mechanisms involved in initiation of these two, otherwise similar, forms of autoimmune disease, and the different treatments that might be optimal.

Over recent years further advances in serological assays for MG have been made. Alongside established RIA for detecting AChR and MuSK Abs, cell-based assays have been developed that helped to identify clustered AChR Abs and then more recently LRP4 Abs. Given that LRP4 Abs are predominantly of the IgG1 subclass, it is likely that the role of complement may be more akin to that observed in AChR Ab mediated MG, but LRP4 Abs are usually low titer and most patients have relatively mild disease.

There have been numerous studies on the thymus histology and immunology that is so clearly different from the thymus in healthy individuals. However, it is still unclear to what extent the observed differences are primary to the disease or secondary features associated with the lymphocytic infiltrations and germinal centers that are hall marks of the early-onset disease. Moreover, very few studies have been done on the late-onset MG patients who now represent the greatest and increasing number of patients. The underlying immunological mechanisms may be similar but they don't appear to be present in the thymus.

Conventional treatment for MG relies on symptomatic treatment, oral immunosuppressive agents, and immunomodulatory treatment with intravenous immunoglobulin and plasma exchange. Newer biological agents, such as RTX have shown promise and may benefit those with refractory disease, particularly in patients with MuSK-MG. Thymectomy has been shown to be enhance the beneficial effects of steroids and recent trials inhibiting complement inhibition (Eculizumab) have shown promise for severe cases. In the future, our greater understanding of the immunology of MG may allow the development of other targeted immunotherapies. Potential drugs could include those directed against B lymphocyte proliferation, relevant cytokines and their receptors, lymphocyte adhesion, and migration pathways.

### HISTORICAL BACKGROUND

The concept that the eye harbors autoimmune-inducing or uveitogenic materials has been suggested by many since the beginning of the last century. It was the demonstration by Uhlenhuth (1903) of autoantibody production to the lens that pioneered investigation in this area. Several investigators used homogenates from the eye, which appeared to be capable of inducing an intraocular inflammatory response when injected at locations distant from the animal eyes. Noteworthy of mention are Wacker and Lipton (1968) and Faure (1980).

The presence of uveitogenic antigens in the human eye that are capable of inducing disease is a well-established concept, proposed by Elschnig (1910). Since then several antigens capable of inducing ocular inflammatory disease similar to that seen in humans have been isolated. Retinal S-antigen, or arrestin, one of the most potent uveitogenic antigens defined to date, was isolated and its immunologic properties partially characterized by Wacker et al. (1977). It causes an immune-mediated, bilateral inflammatory response in the eye, named "experimental autoimmune uveitis" (EAU) when injected in microgram quantities at a site far from the globe (Pfister et al., 1986). S-antigen and its clinical relevance in uveitis were widely studied in the 1980s by many investigators (Nussenblatt et al., 1980a,b; Gregerson et al., 1981; Forrester and Borthwick, 1983;

\*Co-first authors.

Gregerson and Abrahams 1983; Nussenblatt et al., 1983). Several other uveitogenic antigens have since been identified, including interphotoreceptor retinoid-binding protein (IRBP) (Gery et al., 1986; Hirose et al., 1986), recoverin (Gery et al., 1994), bovine melanin protein (Chan et al., 1994), rhodopsin (Schalken et al., 1989), phosducin (Lee et al., 1990), RPE65 (Ham et al., 2002), and tyrosinase proteins (Yamaki et al., 2000).

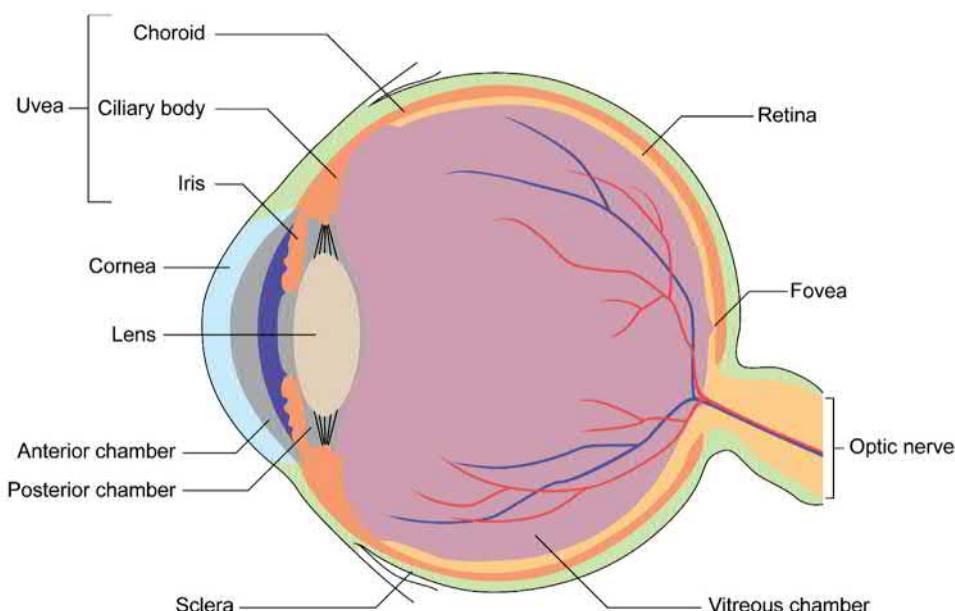

At least some of the mentioned ocular-specific antigens are currently assumed to be the targets for pathogenic processes in patients with autoimmune uveitic conditions. The notion concerning the involvement of autoimmunity in the pathogenesis of certain inflammatory eye diseases received early strong support from data concerning sympathetic ophthalmia. In this rare disease, penetrating injury to one eye is followed by inflammation in the opposite uninjured eye. It is of note that sympathetic ophthalmia had historically provided crucial evidence for the notion concerning pathogenic autoimmunity. This notion was later supported by the findings of cellular and humoral responses to ocular antigens in uveitic patients (Nussenblatt et al., 1980a,b) and by experimental data showing that animals immunized with ocular-specific antigens develop ocular diseases that resemble the human/diseases. These data are discussed in detail below.

## CLINICAL FEATURES

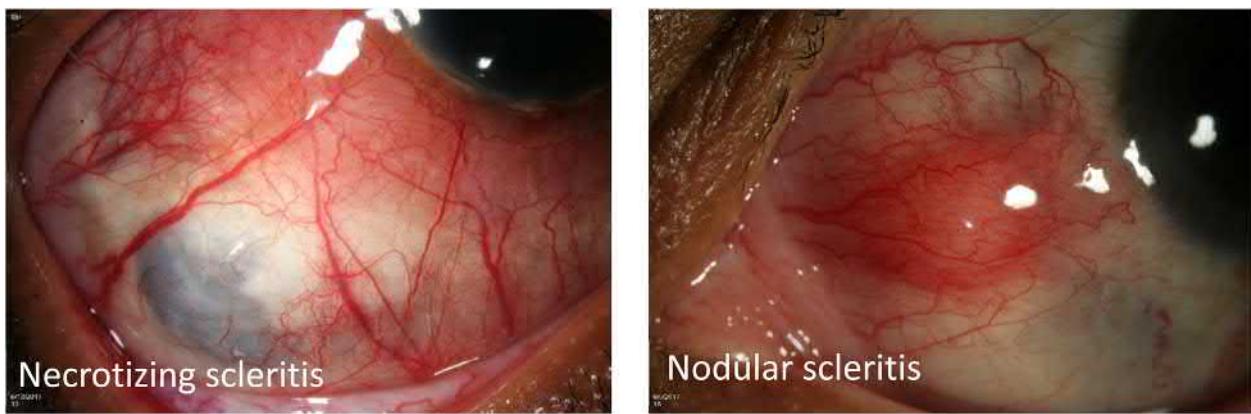

The uveal tract can be divided anatomically into the iris, ciliary body, and choroid (Fig. 54.1). Uveitis is usually defined as any inflammation of the uveal tract. This inflammation may be an antigen-specific, immune-mediated response, or a nonspecific response, which can be elicited by infection, trauma, or surgery. In clinical practice, any intraocular inflammatory reaction involving the structures of the eye (see Fig. 54.1) is collectively referred to as uveitis.

Episcleritis is an inflammatory disease involving the tissue that lies superficial to the sclera. Scleritis is a painful and potentially sight-threatening inflammatory disease involving the sclera. Episcleritis is typically more acute and less severe than scleritis and it is often idiopathic; however, many of the diseases associated with scleritis have also been associated with episcleritis. Clinical examination evaluates for the presence of erythema and edema of the episclera or sclera as well as injection of the deep episcleral vessels (Fig. 54.2). The inflamed sclera is usually characterized by a violaceous hue which can be graded in a standardized fashion (Sen et al., 2011). Many inflammatory systemic disorders are associated with scleritis, the most common being rheumatoid arthritis (RA). Others include juvenile idiopathic arthritis (JIA), reactive arthritis, ankylosing spondylitis, inflammatory bowel disease, polymyositis, polyarteritis nodosa, systemic lupus erythematosus (SLE), granulomatous polyangiitis, sarcoidosis, Lyme disease, and Cogan syndrome. In up to 40% of scleritis, no associated disease can be identified (Sainz de la Maza et al., 2012); however, almost 60% will require oral corticosteroid or immunosuppressive drugs to control the inflammation (Jabs et al., 2000).

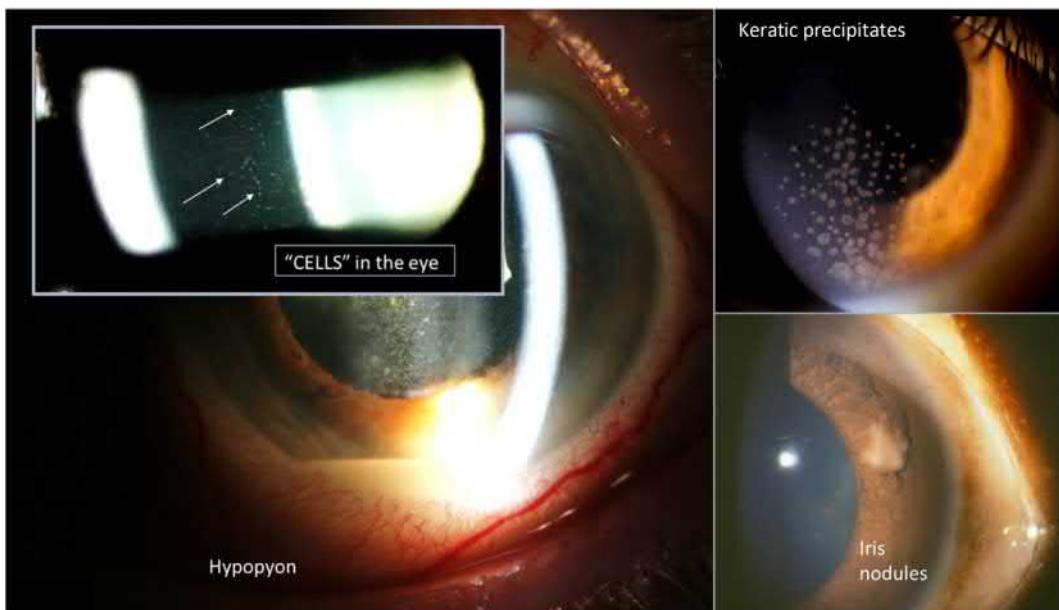

According to the standardization of uveitis nomenclature working group criteria (Jabs et al., 2005), uveitis can be classified based on anatomic location: anterior, intermediate, posterior, and panuveitis. *Anterior uveitis*

**FIGURE 54.1** Key anatomic features of the eye.

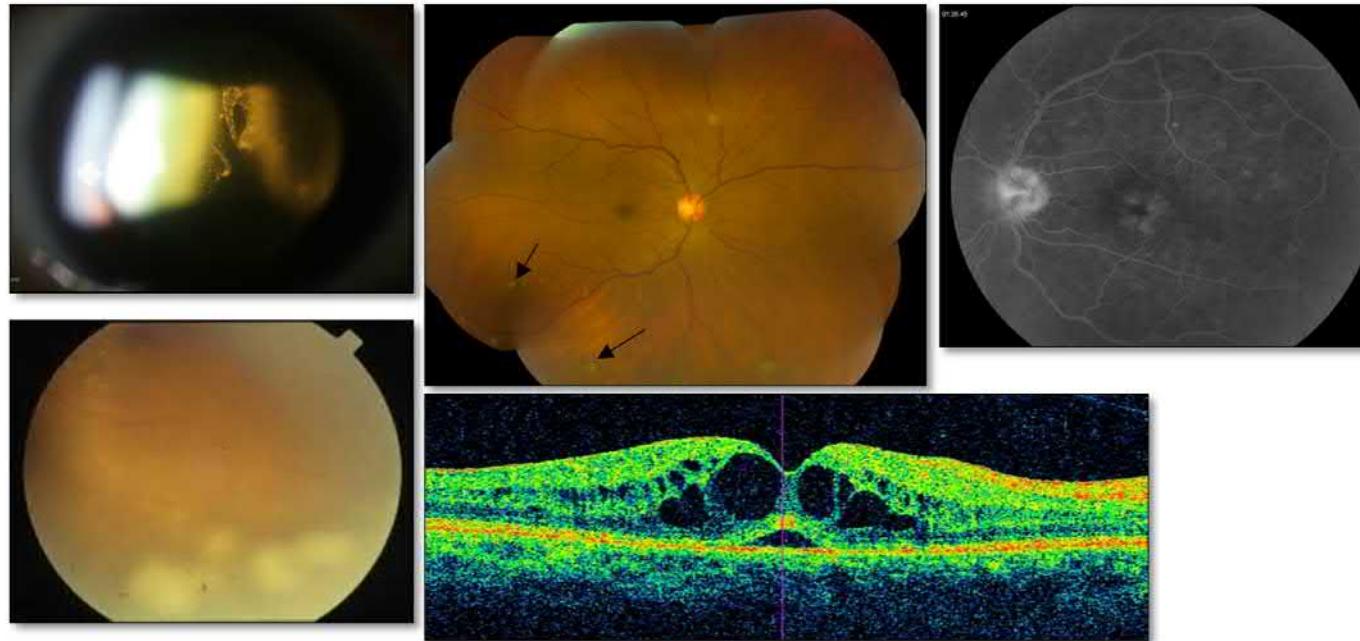

**FIGURE 54.2** Left panel shows necrotizing scleritis with severe thinning of the sclera and visibility of the underlying bluish choroid. Right panel shows a single large nodule on the inner surface of the eye.

**FIGURE 54.3** Various manifestations of inflammation in the anterior chamber of the eye (from top left clockwise)—cells in anterior chamber, “mutton fat” keratic precipitates, iris nodules, and hypopyon.

describes a disease predominantly limited to the anterior segment. There are many inflammatory systemic diseases associated with anterior uveitis, including JIA, human leukocyte antigen (HLA)-B27-associated diseases, Behçet’s disease, and sarcoidosis. The corneal examination may reveal keratic precipitates (Fig. 54.3), small aggregates of inflammatory cells which can be granulomatous or nongranulomatous in nature, which accumulate on the endothelial surface of the cornea. Examination of the anterior chamber via biomicroscopy will reveal the presence of inflammatory cells (Fig. 54.3) and increased protein (flare), resulting from spillover of inflammation from the iris and the ciliary body, graded in a standardized fashion (Nussenblatt and Whitcup, 2004; Jabs et al., 2005). An accumulation of leukocytes associated with fibrin, layered in the lower angle of the anterior chamber, is called a hypopyon (Fig. 54.3) and is commonly associated with Behçet’s disease and the HLA-B27-associated uveitides. Inflammation of the iris may cause synechiae (adhesions) between the iris and the lens capsule or the cornea. It may also develop accumulations of inflammatory cells called nodules on the papillary margin, referred to as Koeppe nodules, or on the iris surface, known as Busacca nodules, commonly seen with sarcoidosis and other granulomatous diseases (Fig. 54.3).

*Intermediate uveitis* refers to uveitis where the vitreous is the major site of inflammation. Inflammation in the vitreous is characterized by increased cells (Fig. 54.4) and protein, vitreous haze (Nussenblatt et al., 1985;

**FIGURE 54.4** Various manifestations of inflammation in the vitreous chamber of the eye (clockwise from top left image)—vitreous cells, collections of cells into “snowballs” in the vitreous cavity, fluorescein angiogram showing dye in a petaloid pattern, cross-sectional optical coherence tomography (OCT) image showing cystic fluid in the fovea “cystoid macular edema,” and hazy view of retina due to large inflammatory snowballs.

**FIGURE 54.5** Various manifestations of inflammation in the retina and choroid (clockwise from top left image)—ocular toxoplasmosis with a new lesion and overlying vitreous inflammation causing “headlight in the fog” sign, Behçet’s disease with inflammation of the retinal blood vessels evidenced by yellow sheathing of blood vessels and hemorrhages; birdshot chorioretinopathy, with yellow choroidal lesions radiating from the optic nerve; viral retinitis, with exudates and hemorrhage and necrosis of the retina due to cytomegalovirus (CMV); serpiginous chorioretinopathy with serpentine lesions spreading outward from the optic disc.

Jabs et al., 2005), or pars plana exudates. Retinal inflammation may cause cystoid macular edema (Fig. 54.4) and retinal vasculitis. There are specific systemic autoimmune diseases associated with this type of uveitis: multiple sclerosis, sarcoidosis, and Lyme disease. A common form of intermediate uveitis is referred to as *pars planitis*, which is by definition idiopathic. Syphilis and tuberculosis are common infectious etiologies of intermediate uveitis.

*Posterior uveitis* refers to inflammation affecting the posterior segment, particularly the retina and the choroid. There are numerous autoimmune diseases that are associated with posterior uveitis: Behçet’s disease (Fig. 54.5), SLE, polyarteritis nodosa, Wegener’s granulomatosis, sarcoidosis, syphilis, and Vogt–Koyanagi–Harada (VKH) syndrome. There are also many infectious etiologies: ocular histoplasmosis, cytomegalovirus retinitis (Fig. 54.5), acute retinal necrosis (varicella zoster virus, herpes simplex virus), toxoplasmosis (Fig. 54.5), and immune-mediated local ocular disorders: sympathetic ophthalmia, birdshot retinochoroidopathy (BCR) (Fig. 54.5), and the “white-dot syndromes,” which can cause posterior uveitis. In addition, primary intraocular lymphoma can masquerade as an intermediate or posterior uveitis.

Finally, *panuveitis* is a term reserved for inflammation involving all segments of the eye in which there is no predominant site of inflammation (Nussenblatt and Whitcup, 2004; Jabs et al., 2005). Typical systemic diseases associated with this form of uveitis are Behçet’s disease, sarcoidosis, VKH syndrome, and syphilis.

## PATHOLOGIC FEATURES

Uveitis can be classified as granulomatous or nongranulomatous. This is a clinical definition, based on the type of inflammatory cells infiltrating the ocular tissues, as seen by biomicroscopy. It is not based on histopathologic analysis. Biomicroscopy will reveal inflammatory precipitates throughout the eye. The most common type of corneal (keratic) precipitates is nongranulomatous, characterized by fine, white-colored lymphocytes, plasma cells, and pigment. Many etiologic factors may be responsible for this type of inflammation. Granulomatous inflammation forms large, greasy-appearing collections of lymphocytes, plasma cells, and giant cells, also called “mutton-fat” keratic precipitates (Fig. 54.3). It can also cause iris nodules, vitreous inflammatory cells, called “snowballs,” (Fig. 54.4) and retinal vascular inflammation, called “candle wax drippings.” This clinical classification is an important diagnostic clue, because the etiologic agents associated with granulomatous uveitis form a fairly short list including sarcoidosis, VKH syndrome, syphilis, tuberculosis, and toxoplasmosis.

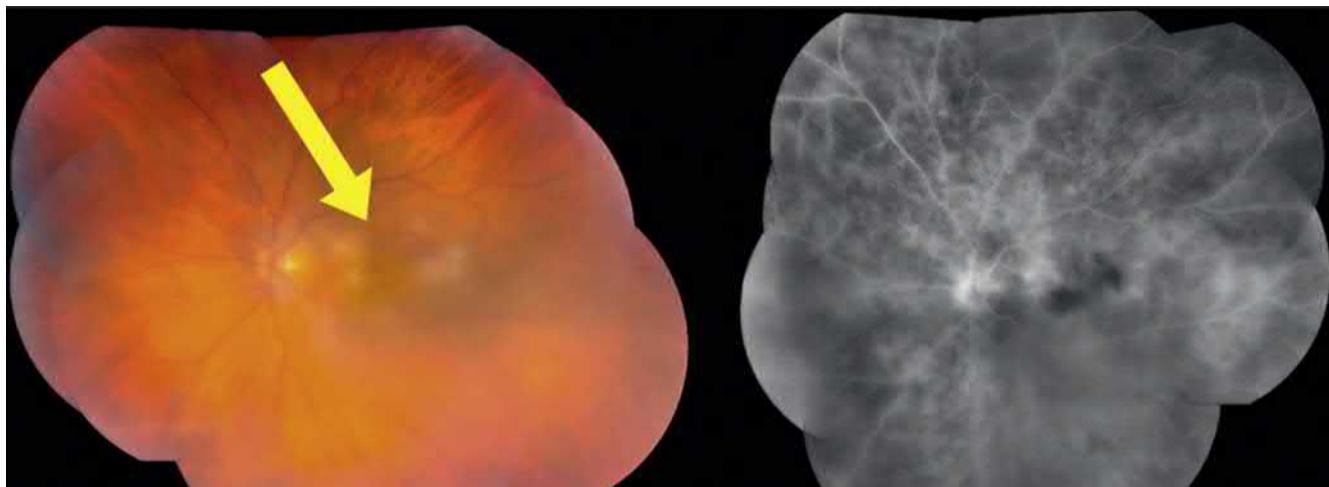

The histopathological changes in eyes of patients with uveitic conditions are described in published reviews (e.g., [Chan and Li, 1998](#); [Boyd et al., 2001](#)). The pathogenic processes responsible for these changes are generally assumed to be similar to those identified in experimental animals, described below.

## EPIDEMIOLOGIC FEATURES

According to a study by [Gritz and Wong \(2004\)](#), the incidence of uveitis was 52/100,000 person-years, and the period prevalence was 115/100,000 persons. It has been found that women have a higher prevalence than men, and the highest incidence and prevalence of disease are in those 65 years and older ([Gritz and Wong 2004](#)), although the age-group with the highest prevalence is still under debate. An insurance claims based dataset estimated that the prevalence of noninfectious uveitis among adults was 121 cases/100,000 persons (95% CI—117.5–124.3), and pediatric uveitis was 29 cases/100,000 among 4 million eligible participants in 2012 ([Thorne et al., 2016](#)). [Rodriguez et al. \(1996\)](#) analyzed their university/referral-based population and found 83% of cases were noninfectious in etiology. There are many demographic features that offer important clues when evaluating a patient with uveitis such as age, sex, race, ethnic heritage, and geographic residence. Specific examples include JIA associated with chronic anterior uveitis seen in children under age of 16. One half of the JIA patients in one study reportedly had chronic uveitis by the age of 6 ([Key and Kimura 1975](#)). It is mostly seen in young females with pauciarticular arthritis and a positive antinuclear antibody test ([Cassidy et al., 1986](#)). The uveitis associated with ankylosing spondylitis is typically a recurrent anterior uveitis seen in young men between the ages of 20 and 30 years ([Brewerton et al., 1973](#)). Sarcoidosis affects young adults aged 20–50 years and has a slightly increased prevalence in women. It can affect all races, but African-Americans are 10 times more likely to be affected compared to white persons, and with chronic sarcoidosis they are more likely to develop ocular manifestations than are white persons ([Jabs and Johns, 1986](#)). VKH syndrome is a multisystem disorder, with ocular, central nervous system, cutaneous, and vestibular-auditory manifestations; the ocular manifestation is usually a severe, bilateral, and granulomatous panuveitis. It is common in Japan and certain parts of Latin America. We have also noted a fairly high Native American ancestry among our patients. Finally, Behcet's disease is a multisystem disorder with ocular involvement; it is especially common in the Far East and the Mediterranean basin ([Ohno and Matsuda, 1986](#)). The ocular disease may be an anterior and/or posterior uveitis, associated with retinal vasculitis ([Fig. 54.6](#)).

## GENETIC FACTORS

Genetic factors play a significant role in the development of endogenous uveitis. Most researchers agree that mechanisms of the autoimmune disease of the eye are multifactorial, so several factors must be present to cause the disease, otherwise disease expression would be far more common. Family studies in patients with uveitis

**FIGURE 54.6** Fundus photograph with corresponding fluorescein angiogram of a patient with Behcet's disease and retinal vasculitis. Arrow points to areas of macular retinitis.

show that the susceptibility to particular types of idiopathic uveitis is possibly due to genetic background (Kimura and Hogan, 1963; Hogan et al., 1965; Giles and Tanton, 1980; Augsburger et al., 1981; Culbertson et al., 1983; DOFT, 1983; Wetzig et al., 1988; Duinkerke-Eerola et al., 1990; Tejada et al., 1994; Lee, 1995). The ability to respond to a specific immune stimulant is genetically determined. Genes for HLA coding for major histocompatibility complex (MHC) proteins are clustered on the short arm of chromosome 6. They have been linked to various uveitic syndromes (Table 54.1). MHC plays an important role in determining disease susceptibility. Genetic predisposition may determine the severity of the disease. A permissive MHC in a nonpermissive background will result in a mild disease or no disease at all (Caspi et al., 1992).

Brewerton et al. (1973) were among the first to observe that a high percentage of white patients with ankylosing spondylitis showed *HLA-B27* positivity. Khan et al. (1977) demonstrated that *HLA-B7* was associated with ankylosing spondylitis in African-Americans to a greater degree than *HLA-B27*. It is clear that HLA associations may be different for various ethnic groups. It is possible that different genes initiate responses that finally lead to a common pathway resulting in a particular disease. The reasons for association between HLA and diseases are unclear.

Among systemic diseases that have associated anterior uveitis, gene association studies show that *HLA-B27*, interleukin (*IL*)-23 receptor, and endoplasmic reticulum aminopeptidase 1 predispose to anterior uveitis and

**TABLE 54.1** HLA Class Association with Autoimmune Diseases That Affect the Eye

HLA	Autoimmune disease
Class I HLA	HLA-A11 Sympathetic ophthalmia
	HLA-A24 Tubulointerstitial nephritis uveitis syndrome
	HLA-A29 Birdshot retinochoroiditis
	HLA-B5 Adamantiades–Behçet’s disease
	HLA-B7 Presumed ocular histoplasmosis Serpiginous chorioretinopathy Acute posterior multifocal placoid epitheliopathy Ankylosing spondylitis
	HLA-B8 Acute anterior uveitis Sarcoidosis
	HLA-B12 Ocular cicatricial pemphigoid
	HLA-B27 Acute anterior uveitis Reiter syndrome
	HLA-B51 Adamantiades–Behçet’s disease
Class II HLA	HLA-DQw3 VKH syndrome

	HLA-DRw53 VKH syndrome

HLA, Human leukocyte antigens; VKH, Vogt–Koyanagi–Harada.

ankylosing spondylitis (Rosenbaum, 2017). Birdshot retinochoroiditis has a very strong HLA association with HLA-A29, seen on over 95% of cases with odds ratio (OR) 157.5 for the disease when the HLA-A29.02 allele is present (Papadia and Herbort, 2015; Herbort et al., 2017). Behcet's disease has shown a strong association with HLA-B51 with 40%–80% of cases having the allele as compared to 10%–30% controls (Horai et al., 2017), Tubulointerstitial nephritis and uveitis is associated with HLA-DQA1\*01, HLA-DQB1\*05, and HLA-DRB1\*01 (Levinson et al., 2003), and HLA-DRB1\*04/HLA-DR4 carriers have an increased risk of VKH with OR 8.42. The risk increases with ethnicity, with highest risk in Eastern Asians. HLA-DRB1\*0401 has been shown to be protective for VKH (Shi et al., 2014).

## THE UNIQUE IMMUNE SYSTEM OF THE EYE

To defend tissues and cell populations of the eye that are highly susceptible to the pathogenic effects of inflammatory processes, the eye is equipped with multiple layers of defense against these processes. The defense layers provide the eye with a status of "immune privileged organ" and include (1) an efficient blood–retina barrier, as well as relatively poor lymphatic drainage of the intraocular tissues; (2) an immunoinhibitory environment composed of several soluble molecules [e.g., transforming growth factor (TGF)- $\beta$ ,  $\alpha$ -melanocyte stimulating hormone, and thrombospondin], as well as cell-attached molecules (e.g., Fas ligand, PD-1), that inhibit immune cells and processes; (3) an active process named anterior chamber associated immune deviation in which foreign antigens reaching the anterior chamber of the eye initiate a complex immunosuppressive process [for details, see review by Taylor (2016)].

Despite these inhibitory mechanisms, pathogenic autoimmune processes do develop in the eye when T lymphocytes specific to ocular antigens are activated and acquire pathogenic capacity. These processes have been mostly investigated in rodents. T cells are generated in the thymus and cells specific against self-antigens are eliminated in this organ when exposed to their target molecules that are expressed in this organ (Derbinski and Kyewski, 2010). Ocular-specific antigens were found to be expressed in the thymus (Zhang et al., 2003; Takase et al., 2005) and are assumed to eliminate the vast majority of T cell specific to these antigens. Small numbers of these cells do escape the elimination process, however, and enter the lymphocyte pool, in their naïve nonpathogenic state. When stimulated, these cells acquire the capacity to cross the blood–retina barrier and initiate inflammatory processes in the eye (Shi et al., 2013).

## ANIMAL MODELS

Animal models for ocular autoimmune diseases have been critical to collect information on the pathogenic processes involved in uveitic diseases, as well as approaches for suppression of these processes. The major animal model, EAU, induced by immunization with uveitogenic antigens, has been established in several species of mammals including guinea pigs (Collins, 1949; Kalsow and Wacker, 1973), rabbits (Wacker and Lipton, 1968), rats (Faure, 1980; de Kozak et al., 1981; Gery et al., 1986), mice (Caspi et al., 1988), and primates (Nussenblatt et al., 1981). Currently, mice and rats are the two most commonly used animals for EAU studies. Lewis rats provide high susceptibility to EAU induction, whereas mice offer the availability of inbred and other genetically modified strains, such as gene knockout or transgenic animals. Typically, uveitogenic antigens are emulsified with complete Freund's adjuvant and injected subcutaneously into the animals ("active immunization"). Coinjection of pertussis toxin is essential for the EAU induction in most strains of mice. EAU can also be induced by adoptively transferring T cells from animals with active EAU (Mochizuki et al., 1985), or uveitogenic cell lines (Cox et al., 2008; Luger et al., 2008), to syngeneic normal recipients.

## AUTOIMMUNE FEATURES

The two known mechanisms that activate naïve T cells specific to autoantigens are initiated by (1) necrotic tissue and by (2) microbial components. Necrotic tissue triggers immune responses (Kono et al., 2014), and such a process is assumed to play a major role in the pathogenesis of sympathetic ophthalmia, mentioned above. It is assumed that the necrotic tissue activates antigen-presenting cells that present the now exposed ocular-specific antigens to naïve T cells specific to these antigens. The activated T cells are capable of invading the opposite eye and initiating pathogenic process typical to this condition. The notion concerning pathogenic autoimmunity as

the mechanism for sympathetic ophthalmia was further supported by the finding that pathological changes similar to those of the human condition are induced in animals immunized with retinal-specific antigens (Gery et al., 1986; Caspi, 2010). The animal disease, EAU, is dealt with below.

The other mechanism assumed to be responsible for activation of naïve T cells specific to ocular antigens is provided by microbial components that include amino acid sequences which “mimic” the uveitogenic epitopes of ocular-specific antigens. This hypothesis is supported by studies in animals: immunization with such mimicking peptides induces EAU in rats (Singh et al., 1990). A recent study by Horai et al. (2015) has provided new data showing the involvement of gut microbiota in initiation of autoimmune ocular disease. In this study, elimination of the gut microbiota prevented the development of spontaneous EAU in mice with T cells transgenically expressing a T-cell receptor (TCR) against a component of IRBP. Further, naïve CD4<sup>+</sup> T cells specific to the IRBP peptide were stimulated by fecal extracts of these mice (Horai et al., 2015). In addition to providing mimicking peptides, the microbial components and products play an important role in initiation of the autoimmune pathogenic process by their capacity to interact with Toll-like receptors expressed on immune cells that stimulate these cells to initiate disease. Thus naïve T CD4<sup>+</sup> cells, with specificity to an ocular antigen, induce uveitic changes in recipient mice when microbial components, such as lipopolysaccharides, are injected as well (Fujimoto et al., 2006; Shi et al., 2013).

Finally, the notion of microbial involvement in ocular autoimmunity in humans has been supported by anecdotal observations of relationship between uveitic conditions and certain microbial infections (Kijlstra et al., 1986; Kaneko et al., 2008).

## PATHOGENIC MECHANISMS

The use of the EAU mouse model has greatly facilitated the understanding of the pathogenic mechanisms of uveitis. The cellular events were dissected mainly in systems in which the disease is induced by adoptively transferred purified populations of T<sub>H</sub> cells, transgenically expressing TCR specific to the uveitogenic antigen, IRBP (Luger et al., 2008), or to a neo-self-antigen (Cox et al., 2008). Two cell subsets are playing major roles in initiating the pathogenic process of EAU, namely, T<sub>H</sub>1 and T<sub>H</sub>17 cells that express interferon (IFN)- $\gamma$  or IL-17A, respectively. Purified T<sub>H</sub>1 or T<sub>H</sub>17 cells induce EAU when adoptively transferred to naïve recipients (Cox et al., 2008; Luger et al., 2008). Furthermore, both cell subsets are present among the inflammatory cells in eyes with actively induced EAU (Shi et al., 2013). Importantly, similar to experimental autoimmune encephalitis, a model for multiple sclerosis (Panitch and Ciccone, 1981; Ben-Nun et al., 1981), the adoptively transferred T<sub>H</sub> cells induce EAU only following activation in vitro (Vistica, Gery et al., unpublished data). Recent studies showed that in addition to the activation in vitro, the T<sub>H</sub> cells acquire the capacity to initiate EAU only after undergoing a second activation phase (“licensing”) in lymphoid organs of the recipient animals (Tan et al., 2017). These authors also identified cellular molecules apparently involved in changes in the mobility of the pathogenic T<sub>H</sub> cells (Tan et al., 2017). T<sub>H</sub> cells, that initiate EAU, secrete cytokines that recruit into the affected eye other inflammatory cells, including macrophages and polymorphonuclear (PMN) cells (Shi et al., 2013). A study by Foxman et al. (2002) identified a large number of transcripts of cytokines, chemokines, and chemokine receptors whose expression was increased in eyes that developed EAU. The major proinflammatory cytokines identified in EAU are IFN- $\gamma$ , IL-1 $\beta$ , IL-6, IL-12, IL-17, IL-23, and tumor necrosis factor (TNF)- $\alpha$ , as well as the chemokine ligands (CCL) CCL2 (MCP-1), CCL3 (MIP-1 $\alpha$ ), CCL4 (MIP-1 $\beta$ ), CCL5 (RANTES), and CCL20 (MIP-3 $\alpha$ ). It is noteworthy that certain cytokines show dual effect. Thus in addition to their pathogenic activity, IFN- $\gamma$  and IL-27 have immunosuppressive capacity (Tarrant et al., 1999; Aparicio-Siegmund and Garbers, 2015).

In addition to the inflammation-inducing cells, the lymphoid cell populations in the inflamed eye with EAU include T regulatory cells (Tregs) that are capable of inhibiting the pathogenic process of this experimental disease (Lee and Taylor, 2015; Silver et al., 2015). There are several subpopulations of Tregs, with their majority expressing the transcription factor FoxP3, a molecule that is immunoinhibitory and serves as a marker for these cells (Morikawa and Sakaguchi, 2014; Tao et al., 2017). The inhibitory activity of Tregs is multifaceted and includes cell–cell contact with the target cells and secretion of immunosuppressive agents, including IL-10, IL-27, IL-35, and TGF- $\beta$  (Sakaguchi et al., 2008; Noval Rivas and Chatila, 2016). The attractive notion of using Tregs to suppress uveitis in humans has not been materialized yet, mainly because the target antigens in individual patients are not known.

Besides T cells, other immune cells have also been investigated for their roles in the pathogenesis of EAU. Recently, studies unraveled new roles for immunosuppressive B lymphocytes, namely, B regulatory cells (Bregs) in

EAU (Wang et al., 2014; Egwuagu and Yu, 2015). Bregs exert their activity similarly to Tregs (Rincon-Arevalo et al., 2016). In addition, natural killer (NK) cells and NKT cells have also been implied in the pathogenesis of EAU. One report suggested that NK cells might play a detrimental role in EAU (Kitaichi et al., 2002), while another study showed increased NK and NKT cells in association with IFN- $\beta$  amelioration of EAU (Suzuki et al., 2002).

Dendritic cells and macrophages are also important in EAU induction and tissue destruction (Jiang et al., 1999). Damage to the ocular tissues of eyes affected by uveitis is mainly induced by macrophages (type "M1") and PMNs recruited to the affected eye by the T<sub>H</sub> cells that initiate the inflammatory process (see above). The damage to the inflamed eye is mainly the result of phagocytic activity and products of the inflammatory cells, including enzymes, such as proteinases, and oxidizing molecules such as nitric oxide (Hoey et al., 1997).

The sera of patients with uveitis often contain antibodies specific to retinal antigens (Heckenlively and Ferreyra, 2008; Adamus, 2009). It is generally assumed that the antibodies are produced against ocular-specific antigens, released as a result of the tissue destruction, but it is conceivable they exert pathogenic effect that may further aggravate the primary damage.

## IMMUNOLOGICAL MARKERS

Recent advances have demonstrated that cytokines are important in the pathogenesis of noninfectious uveitis. T<sub>H</sub>1 cytokines, such as IFN- $\gamma$ , IL-2, TNF- $\alpha$ , and IL-12, are an essential factor in the pathogenesis of uveitis. IFN- $\gamma$  and IL-2 were found to be elevated in ocular tissues with concomitant infiltrating T cells in uveitic patients (Hooks et al., 1988). IL-6 has been shown to be elevated in the aqueous humor of patients with noninfectious uveitis (Murray et al., 1990; Franks et al., 1992). Several studies showed correlation between elevated cytokines levels and disease activity in various uveitic diseases, however, a consensus is still missing. For example, in acute anterior uveitis (AAU), one study found elevated serum levels of IL-1 $\beta$  in patients compared to healthy controls (Zhao et al., 2015), whereas another study found IL-6 elevated but not IL-1 $\beta$  (Chen et al., 2015). In Behcet's disease, patients with active disease show elevated serum level of IL-8 compared to healthy controls or inactive patients (Akkurt et al., 2015). Higher levels of TNF- $\alpha$  and IL-1 have also been demonstrated in both peripheral sera and aqueous humor samples (Palexas et al., 1992; Sakaguchi et al., 1998). Cytokine profile analysis of peripheral T cells from uveitic patients suggested that the intracellular level of IFN- $\gamma$  was increased (Frassanito et al., 2003), but similar analysis of T cells derived from aqueous humor samples showed decreased IFN- $\gamma$  compared to those from peripheral blood (Hill et al., 2005).

Recent interest has surrounded the role of T<sub>H</sub>17/IL-17, which is believed to play a role in chronic inflammation, whereas T<sub>H</sub>1 drives the early pathogenic response (Hoyer et al., 2009). The elevated levels of T<sub>H</sub>17-associated cytokines (IL-22, IL-23, and IL-17A) have been correlated with disease or disease activity in several uveitic diseases, such as BCR, AAU, VKH, sarcoidosis, and idiopathic uveitis (Jawad et al., 2013; Molins et al., 2016). Moreover, IL-17A levels were even higher in active compared to inactive disease (Jawad et al., 2013).

Data derived from animal EAU studies, however, have provided more consistent insights into the molecular mechanisms of autoimmune uveitis. In EAU, TNF- $\alpha$  is associated with the recruitment of CD11b macrophages and CD4 $^{+}$  T cells into the eye (Nakamura et al., 1994; Dick et al., 1996; Robertson et al., 2003), while IL-10 and IL-12 were suggested to be protective to the development of disease (Rizzo et al., 1998; Tarrant et al., 1999). Consistent with findings in humans, IFN- $\gamma$  was also found in the ocular tissues of EAU animals and correlated with the disease course (Charteris and Lightman, 1992). However, the treatment with anti-IFN- $\gamma$  antibody exacerbated EAU, while the treatment with recombinant IFN- $\gamma$  ameliorated the diseases in a murine EAU model (Caspi et al., 1994), leading investigators to conclude that endogenous IFN- $\gamma$  was protective for EAU. The same investigators also showed that IFN- $\gamma$  gene deficient mice developed EAU similar to their wild-type littermates, suggesting that IFN- $\gamma$  is not necessary for the development of EAU (Jones et al., 1997). To further complicate the issue, an independent study using IFN- $\gamma$  transgenic rats showed that overexpression of IFN- $\gamma$  resulted in more severe EAU (Egwuagu et al., 1999). These studies underscore the complexity of cytokine networks in the pathogenesis of EAU.

## TREATMENT AND OUTCOMES

Corticosteroids have been the mainstay of therapy for ocular inflammatory disease since the early 1950s. Both systemic (oral, intravenous) and local (topical, periocular, and intravitreal) formulations are available. In addition, steroid implants [fluocinolone acetonide (Retisert, Iluvien) and dexamethasone (Ozurdex)] have recently become

popular choices as both adjuvant and monotherapy. They offer the benefit of sustained corticosteroid delivery to the eye while avoiding systemic complications (Larson et al., 2011; Multicenter Uveitis Steroid Treatment Trial Research et al., 2015; Writing Committee for the Multicenter Uveitis Steroid Treatment, Follow-up Study Research et al., 2017).

Some diseases are steroid resistant and for others, long-term steroid therapy carries the risk of developing unacceptable systemic side effects. For these patients, other immunomodulatory agents need to be added as a steroid-sparing agent. Steroid-sparing agents include alkylating agents (cyclophosphamide, chlorambucil), anti-metabolites (azathioprine, methotrexate, mycophenolate mofetil, cyclosporine, tacrolimus, rapamycin), antibodies, and monoclonal antibodies (daclizumab, etanercept, infliximab, adalimumab, rituximab).

Antibodies and monoclonal antibodies directed against various parts of the immune cascade represent the new era of immunomodulation through their ability to interfere with specific molecules or pathways based on our understanding of the inflammatory process (Heiligenhaus et al., 2010). Daclizumab is a humanized anti-CD25 (Tac) monoclonal recombinant antibody. CD25 is a subunit of the IL-2R high-affinity complex. Caspi et al. (1986) demonstrated the presence of high-affinity IL-2R in animal models of uveitis. It was used safely and effectively in the treatment of intermediate and posterior uveitis in adults and children, as well as active JIA-associated anterior uveitis (Yeh et al., 2008; Sen et al., 2009). However, it was pulled from the market in 2009 due to insufficient market demand (Smith et al., 2012).

TNF- $\alpha$  is found during the acute phase of experimental autoimmune uveoretinitis (Kim et al., 2001). Etanercept is a TNF fusion protein that binds to and inactivates TNF, while infliximab is a chimeric monoclonal antibody directed against TNF- $\alpha$ , and adalimumab is fully humanized monoclonal IgG1 antibody against TNF- $\alpha$ . Etanercept was found to be effective in some systemic diseases; however, a review of multiple case series showed new onset of uveitis in previously unaffected rheumatologic patients (Smith et al., 2012). As a result, etanercept is not used in uveitis. Infliximab, demonstrated to be effective in several clinical studies in reducing ocular inflammation, reported successful control of inflammation within 10 weeks of initiating treatment in approximately 75% of patients with refractory uveitides including idiopathic, sarcoidosis, Behcet's disease-associated uveitis, and BCR (Suhler et al., 2009). Adalimumab has also been effective for the treatment of several autoimmune diseases including RA, ankylosing spondylitis, psoriatic arthritis, JIA, and Crohn's disease and is now FDA approved for chronic uveitis in adults and pediatric age-groups (Smith et al., 2012; Jaffe et al., 2016; Nguyen et al., 2016; Ramanan et al., 2017). Rituximab is a chimeric anti-CD20 monoclonal antibody which targets CD20, a surface antigen expressed on pre-B and mature B cells. It has demonstrated success in RA, SLE, and Wegener's-associated scleritis (Smith et al., 2012).

In our treatment approach, cytotoxic agents are often used last, after corticosteroids, cyclosporine, and monoclonal antibodies, for sight-threatening intraocular inflammation. Most uveitis practices follow a stepladder approach, customized to the patient's response to treatment with the goal of maintaining quiescence of inflammation (Foster et al., 2016). Other less commonly used therapeutic modalities include intravenous immunoglobulin therapy, oral tolerance, plasmapheresis, and IFN- $\alpha$ . In addition, nonsteroidal antiinflammatory agents have been used for specific diseases; however, they have not been shown to be effective as a sole agent in the treatment of noninfectious uveitis.

In general, the following therapeutic guidelines can be used:

- Topical corticosteroids for anterior segment disease.
- Periorcular corticosteroids for unilateral disease, the presence of intermediate or posterior complications, and in select uveitic entities to avoid systemic complications of corticosteroids.
- Systemic immunosuppressive agents for bilateral, sight-threatening intermediate uveitis, posterior uveitis, or panuveitis. Biological immunomodulatory therapy for those who fail (or are intolerant of) standard immunosuppressive therapy. Some patients may need more than one immunosuppressive agent at a time.
- Consideration of corticosteroid implants for unilateral disease, contraindication or intolerance to standard agents, or multiple systemic comorbidities which limit the use of systemic immunosuppressive therapy.
- Reserving cytotoxic agents for therapeutic failures.
- For uveitis associated with infectious etiologies, specific agents are indicated, including antivirals and antibacterial or antiparasitic therapy.

## Concluding Remarks and Future Projects

We have learned a great deal since the advent of steroids for uveitis in the early 1950s. Most therapies during the 20th century tended to be monotherapy, and combination therapy only began to be used more frequently

during the 1990s. Concerns about the side effects of steroids, that is, osteoporosis, came to the attention of treating physicians relatively early, as did the goals for therapy, including long-term approaches that reduced secondary effects. Because of this, the use of local therapy, including intraocular therapy, whether by injection or a time-released device, has become more popular. So where will we be going in the 21st century? Some of the possibilities include pharmacogenetics study of variability in drug responses attributed to hereditary factors in different populations; pharmacogenomics determination and analysis of the genome and its products (RNA and proteins) as they relate to drug response; evaluation of patient genomes to identify which patients are the best candidates for a specific therapy; and finally, using cytokines or other biomarkers as a marker for inflammation, as potential therapeutic targets, and to determine the true level of immunological quiescence in chronic uveitis.

### INTRODUCTION

The inner ear has been considered for a long time an immune-privileged site, spared from organ-specific autoimmunity and rarely involved in systemic autoimmune diseases thanks to the blood–labyrinthine barrier (Matsuoka and Harris, 2013).

The hypothesis that sudden or rapidly progressive sensorineural hearing loss (SNHL) often accompanied by vestibular symptoms might result in an autoimmune process was first hypothesized by Lehnhardt (1958) and then proposed by McCabe (1979), who based his findings on the clinical features, presence of abnormal immunological tests, and a positive response to immunosuppressive therapy. Since then, a number of syndromes characterized by SNHL with overlapping clinical features have been described and termed in different ways: autoimmune SNHL, immune-mediated inner ear disease (IMIED), idiopathic progressive bilateral SNHL, sudden SNHL, idiopathic SNHL, bilateral immune-mediated Menière disease, autoimmune vestibulo-cochlear disorders (Rahman et al., 2001a), generating a great confusion in the identification of patients and in the evaluation of different studies. SNHL in adult patients remains idiopathic in the vast majority of the cases (71%); known causes are viral infections (12.8%), inner ear abnormality (4.7%), trauma (4.2%), vascular or hematologic (2.8%), neoplastic (2.3%), central nervous system (CNS) abnormality (Chau et al., 2010), and genetics (Koide et al., 2018). Recently, a case of temporary or permanent SNHL after vaccination with tetanus–diphtheria, meningococcal vaccine, and with influenza vaccine has been reported (De Marco et al., 2018; Kolarov et al., 2019).

In a series of children with idiopathic SNHL, Berti et al. (2013) confirmed an autoimmune origin in the majority of the cases included in the study. It is still debated whether we can define autoimmune in the majority of the cases of SNHL without any apparent cause (Greco et al., 2011a). Although most of the authors in the field refer

to these cases with the term “autoimmune inner ear disease” or “autoimmune SNHL” (Solares et al., 2003; Mathews and Kumar, 2003; Ciorba et al., 2018), we and others (Stone and Francis, 2000; García-Berrocal et al., 2003; Peneda et al., 2018) still prefer the definition of IMIED, since an autoimmune process cannot always be identified. IMIED may be a process confined to the inner ear (primary ear disease) and antibodies against a vast array of different molecular weights inner ear antigens may be found in a percentage of these patients, that is, the inner ear is the direct target of the immune response. Moreover, the inner ear can be damaged by a deposition of circulating immune complexes; in these cases the process can be identified as an organ-specific autoimmune disease. In other cases, IMIED is a feature of a systemic disorder, such as primary vasculitides or of systemic autoimmune diseases (secondary ear disease) (Ciorba et al., 2018; Ralli et al., 2018). Indeed, a systemic autoimmune disorder can be present in one-third of the patients with IMIED (Rossini et al., 2017).

Several studies have focused on the humoral and cellular response of the adaptive immune system. Little was known on the innate immune system of the inner ear. Recently, O’Malley et al. (2016) have identified cells with staining characteristics and the morphology of macrophages/microglia in the human cochlea. The authors suggested that these cells may have an important role in inner ear pathology due to the increased level of proinflammatory cytokines and reactive oxygen species induced by microglia.

## CLINICAL FEATURES

IMIED is characterized by the presence of rapidly progressive (usually between 1 and 90 days), often bilateral SNHL, and in about 50% of the patients by vertigo, tinnitus, and a sense of aural fullness, sometimes indistinguishable from Menière’s disease at the beginning. IMIED usually leads to irreversible damage within hours or days from the onset and involves both ears often asynchronously. Sometimes, the disease shows an initial fluctuating course of remissions and relapses typical of an autoimmune disease. Since the devastating sequelae of IMIED may be avoided with the early institution of aggressive immunosuppression, a prompt diagnosis represents a major goal for the clinician. Indeed, the clinical manifestations are shared with the entities of different etiologies, such as vascular, toxic, metabolic, neoplastic, genetic, traumatic, and infective (Massimo et al., 2012; Abdelfatah et al., 2013; Yariz et al., 2012; Gao et al., 2013; Beyea et al., 2012; Lin et al., 2013; Koide et al., 2018). Therefore all the possible nonimmune-mediated causes of SNHL need to be excluded. Overall, the incidence of SNHL has been estimated to range from 5 to 20 per 100,000 subjects per year (Chau et al., 2010), whereas the estimated yearly incidence of an autoimmune origin is <5 cases per 100,000, and the estimated prevalence is about 15/100,000 (Ciorba et al., 2018).

Menière’s syndrome, characterized by hearing loss and episodes of vertigo, tinnitus, and aural fullness, may accompany several causes of inner ear inflammation, including IMIED. In the absence of an identifiable cause, usually viral, this syndrome is termed Menière’s disease, considered of an autoimmune origin at least in 30%–40% of the cases although the immunological mechanisms involved are not clear (Riente et al., 2004; Greco et al., 2012, 2013; Kim et al., 2014; Kangasniemi and Hietikko, 2018). Recently, some researchers have identified alterations in the TWEAK/Fn14 pathway, which is involved in the modulation of inflammation by increasing the translation of NF- $\kappa$ B, in genetically susceptible individuals (Frejo et al., 2017). Time course is the most important criterion to differentiate IMIED from Menière’s disease where hearing loss occurs over a long period of time, sometimes for several years. Moreover, Menière’s disease is usually limited to one ear in the majority of the cases.

Due to the many different etiologies that can lead to SNHL and to the absence of specific diagnostic markers, García-Berrocal and Ramirez-Camacho (2002) proposed the following criteria to correctly assess IMIED as a distinct entity:

1. Major criteria: Bilateral involvement, the presence of a systemic autoimmune disease, positive antinuclear antibodies (ANAs), reduced number of naïve T cells (CD4RA), and recovery of hearing >80%.
2. Minor criteria: Unilateral involvement, young/middle-aged patient, often female, the presence of antibodies against heat shock protein 70 (HSP70), and good response to steroid therapy.

The suspect of IMIED would be supported by the presence of three major criteria or two major and more than two minor criteria. García-Berrocal et al. (2003) used these criteria to characterize and evaluate the response to therapy of 69 patients with a recent onset of SNHL of different origin, such as viral, vascular, immune mediated, and idiopathic. Patients with IMIED had the best and the earliest recovery rate of hearing after therapy, but also a higher rate of recurrence, typical of an autoimmune disorder. However, profound hearing loss (>90 dB)

presents a low percentage of recoveries, regardless of the etiology. The criteria proposed by Garcia-Berrocal et al. still need to be validated by different groups in a greater number of patients. In particular, we think that the presence of not only ANA but also of other autoantibodies, such as anticardiolipin antibodies, antithyroid antibodies, rheumatoid factor, anticitrullinated peptide antibodies, or myeloperoxidase–antineutrophil cytoplasmic antibodies, anti-CD148 and anticochlin, anti- $\beta$ -tubulin, and anti- $\beta$ -actin antibodies (Bachor et al., 2005; Toubi et al., 2004; Takagi et al., 2004; Lunardi et al., 2002; Berti et al., 2013; Ciorba et al., 2018), may suggest the presence of an autoimmune aggression of the inner ear. Moreover, we believe that a positive therapeutic response to corticosteroid administration should be considered a major criteria for the diagnosis of IMIED (Ruckenstein, 2004; Gallo et al., 2013; Yu et al., 2018; Witsell et al., 2018). More recently, Ciorba et al. (2018) have proposed a possible flowchart to use for the diagnosis and therapy of autoimmune inner ear disease.

Due to the lack of a reliable diagnostic tests (Bovo et al., 2009; Ciorba et al., 2018), MRI/3 Tesla-MRI, positron emission tomography (PET) of the inner ear in association with anti-HSP70 antibody determination, had been proposed as a useful technique for assessing IMIED (Mazlumzadeh et al., 2003). More recently, intratympanic gadolinium MRI (Lobo et al., 2018) and F-FDG PET/TC (Muentes Rasilla et al., 2018) have been proposed as a useful tool in the evaluation of IMIED.

The utility of the determination of antibodies anti-HSP70 is still unclear, and they are not more frequent in Menière's disease compared to healthy controls; moreover, the presence of such autoantibodies was not correlated with bilateral disease, activity or stage of the disease (Hornbrook et al., 2011). According to other authors, these antibodies could correlate to specific subgroups of IMIED (Bonauguri et al., 2014).

## Immune-Mediated Inner Ear Disease Associated With Systemic Autoimmune Diseases

Hearing loss, both sensorineural and conductive, has been reported in patients with rheumatoid arthritis (RA) (Raut et al., 2001; Oczan et al., 2002; Salvinelli et al., 2004), psoriatic arthritis (Giani et al., 2006), primary Sjögren's syndrome (Boki et al., 2001; Ralli et al., 2018), and with inflammatory bowel disease (IBD) (Vavricka et al., 2015). Anticardiolipin antibodies have been found associated with the presence of SNHL in patients with Sjögren's syndrome (Tumiati et al., 1997; Tucci et al., 2005) and with systemic lupus erythematosus (SLE) (Naarendorp and Spiera, 1998; Green and Miller, 2001; Kastanioudakis et al., 2002; Batueca-Caletrio et al., 2013). Moreover, SNHL can be present in patients with primary antiphospholipid syndrome (Vyse et al., 1994; Chapman et al., 2003; Galicia-López et al., 2016). The histopathologic features of temporal bone described in subjects affected by SLE showed the involvement of both cochlear and vestibular structures with various degrees of type I vestibular hair cell and inner hair cell loss, atrophy of the organ of Corti, marked cochlear inflammation with a polymorphonuclear infiltration and vasculitis or the formation of fibrous tissue and new bone throughout the cochlea, degeneration of the spiral ligament and hydrops, findings very similar to the known features of IMIED (Sone et al., 1999; Di Stadio and Ralli, 2017).

Similarly, the histopathology in four patients with Sjögren's syndrome showed severe loss of intermediate cells of stria vascularis and immunoglobulin G (IgG) deposition on the basement membrane of stria vascularis blood vessels. These pathologic changes are very similar to the inner ear histology found in a mouse model of Sjögren's syndrome (Calzada et al., 2012a).

SNHL has also been reported in progressive systemic sclerosis with a prevalence between 20% and 27% of the patients (Kastanioudakis et al., 2001; Mancini et al., 2018) and in ulcerative colitis (Kumar et al., 2000). Granulomatous inner ear disease has been described in Crohn's disease (Dettmer et al., 2011).

Finally, Meniere's disease displays an elevated prevalence of systemic autoimmune diseases, such as RA, SLE, and ankylosing spondylitis (Gazquez et al., 2011).

In conclusion the presence of a systemic autoimmune disease needs to be always rule out in SNHL (Mijovic et al., 2013; Mancini et al., 2018).

## Immune-Mediated Inner Ear Disease Associated With Primary Vasculitides

SNHL is often an early symptom of primary vasculitides, which usually affect both the middle and the inner ear (Ralli et al., 2018). The best example is Wegener's granulomatosis characterized by chronic otitis media leading to conductive hearing loss; SNHL is often associated and is related to vasculitis of the inner ear, and otological involvement can be the first sign of the disease (Takagi et al., 2002; Safavi Naini et al., 2017). Similar findings may be present in patients with relapsing polychondritis (Malard et al., 2002) characterized by vasculitis

of the labyrinthine artery and inflammation of the cartilage within the inner ear. SNHL has been described in polyarteritis nodosa (Tsunoda et al., 2001), microscopic polyangiitis (Koseki et al., 1997), Behcet's disease (Adler et al., 2002), and Kawasaki disease (Silva et al., 2002).

### Cogan's Syndrome

It was first described in 1934 by Morgan and Baumgartner as a nonsyphilitic interstitial keratitis but was defined as a clinical entity in 1945 by the ophthalmologist David Cogan. Cogan's syndrome is a rare chronic inflammatory disease characterized by three main clinical features: vestibulo-auditory dysfunction, interstitial keratitis, and vasculitis (St. Clair and McCallum, 1999; Greco et al., 2012, 2013). It occurs primarily in children and young adults and was first described by Cogan in 1945. Systemic manifestations occurs in approximately half of the cases (Van Doornum et al., 2001); fever and weight loss are associated with active vasculitis that can involve the aorta, aortic arch vessels, or medium vessels (Vollersten, 1990; Weissen-Plenz et al., 2010; Branislava et al., 2011). Central and peripheral nervous system abnormalities may be present in up to 50% of the subjects (Bicknell and Holland, 1978; Albayram et al., 2001). Morbidity in Cogan's syndrome results from permanent hearing loss and cardiovascular disease. In 1980 Haynes and other authors proposed a subdivision of Cogan's syndrome into "typical" and "atypical" forms. The "typical" form is characterized by the ocular involvement, such as nonsyphilitic interstitial keratitis, and by audiovestibular involvement similar to Meniere's disease, progressive loss of hearing to the point of deafness within 1–2 months. The interval between the onset of ocular and audiovestibular manifestations is less than 2 years. Cogan's syndrome is considered "atypical" when is present another type of ocular involvement (such as scleritis, episcleritis, retinal artery occlusion, choroiditis, retinal hemorrhages, papilloedema, and exophthalmos) associated with audiovestibular symptoms that do not resemble Meniere's disease or arise more than 2 years before or after ocular symptoms. Systemic manifestations are often found in the "atypical" Cogan's syndrome. It is important to underline that timing and association between symptoms may be extremely variable and not always is possible to make a clear distinction between the two forms (Iliescu et al., 2015; D'Aguanno et al., 2017).

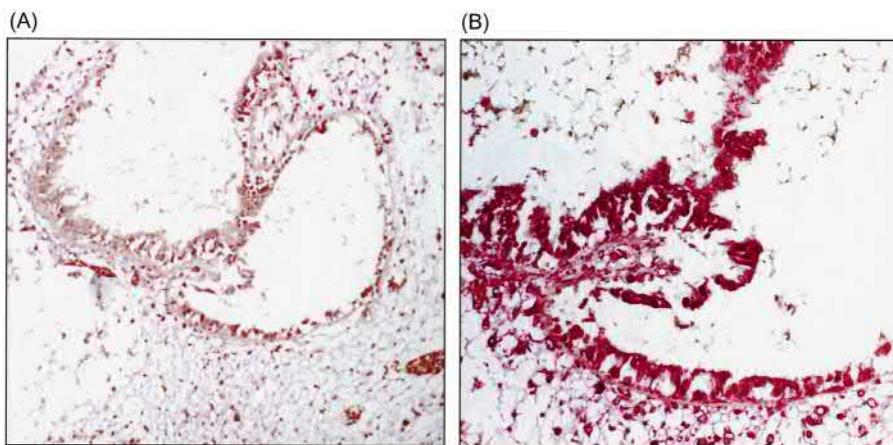

Inner ear pathology reveals endolymphatic hydrops, infiltration of the spiral ligament with lymphocytes and plasma cells, degeneration of the sensory receptors and supporting structures of the cochlea and vestibular apparatus, and demyelination and atrophy of the vestibular and cochlear branches of the eighth cranial nerve. In some cases, extensive new bone formation can be observed (Jung et al., 2016).

The cause of the disease is unknown; upper respiratory tract infections may precede the onset of the disease, suggesting an infectious origin (Vollertsen et al., 1986). Autoimmunity has been implicated because of the presence of serum antibodies to a mixture of corneal antigens and inner ear extracts (Helmchen et al., 1999; Disher et al., 1997). In a few cases, antineutrophil cytoplasmic autoantibodies have been reported.

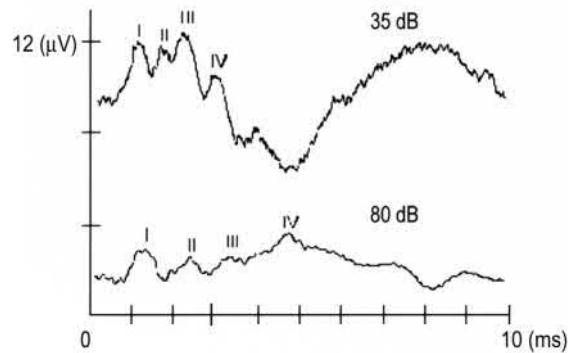

We have demonstrated that Cogan's syndrome is an autoimmune disease and that DEP1/CD148 is the pathogenetically relevant autoantigen (Lunardi et al., 2002). Using the peptide library approach (Puccetti and Lunardi, 2010), already applied to the study of systemic sclerosis (Lunardi et al., 2000), we identified a peptide recognized by the sera of all the patients. The peptide shares homology with autoantigens and with the major core protein lambda 1 (Bartlett and Joklik, 1988) of reovirus type III that causes mild rhinitis and pharyngitis. Peptide-specific IgG antibodies isolated from patients' sera recognized the viral protein, suggesting a viral involvement in the pathogenesis of the disease, possibly through a molecular mimicry mechanism (Zhao et al., 1998).

The peptide showed homology with the high cell density-enhanced protein tyrosine phosphatase-1 (DEP-1/CD148) that is highly expressed on both endothelial cells (Takahashi et al., 1999) and supporting cells of the inner ear (Kruger et al., 1999) and with connexin-26, a gap junction protein expressed in the inner ear (Kikuchi et al., 2000). Affinity-purified antibodies against the peptide obtained from the patients recognized CD148 and connexin-26 in human cochlear extracts. DEP1/CD148 is a widespread cell-surface antigen, and its distribution explains the clinical spectrum of Cogan's syndrome. Connexin-26 represents a major system of intercellular communication, and its loss results in local intoxication of the organ of Corti, leading to hearing loss; moreover, mutations at the connexin-26 gene are responsible for the majority of congenital deafness. Connexin-26 shows homology with connexin-43 and connexin-50, gap junction proteins present in corneal fibroblasts and epithelium, and this homology may explain the eye involvement in the disease. Peptide-specific antibodies bound human cochlea by immunohistochemistry (Fig. 55.1A and B).

To prove that these autoantibodies are pathogenic and that the identified autoantigen is relevant to Cogan's syndrome we induced the clinical features of the disease in animals (Balb/c mice and rabbits New Zealand white (NZW)) following either passive transfer of peptide-specific autoantibodies or active immunization with autoantigen peptides. The animal developed hearing loss as assessed by the auditory brainstem responses evaluation (Fig. 55.2).

**FIGURE 55.1** Antibodies against the Cogan peptide bind human cochlea. Human cochlea immunostained with antibodies purified against an irrelevant peptide (negative control, A) and with antibodies purified against the Cogan peptide (higher magnitude, B). Source: Reprinted with permission from Elsevier, Lunardi, C., Bason, C., Leandri, M., Navone, R., Lestani, M., Millo, E., et al., 2002. Autoantibodies to inner ear and endothelial antigens in Cogan's syndrome. *Lancet* 360, 915–921.

**FIGURE 55.2** Grand average of Auditory Brainstem Responses obtained from the same 6 mice before (upper trace) and one week after (lower trace) the third injection of purified antibodies directed against the Cogan peptide. A higher stimulus intensity (80 vs 35 dB) was needed to obtain much smaller and delayed responses (lower trace), consistent with hearing loss. The traces shown were obtained with above threshold stimuli in order to clearly identify the single components. The delay of waves II, III and IV suggests an impaired transmission along the auditory pathway from the acoustic nerve to the midbrain. Data represent amplitude of the response in microvolt ( $\mu$ V) (vertical axis); time elapsed from stimulus in milliseconds (horizontal axis). The time of stimulus delivery (click) is coincident with the 0 of the horizontal axis; no pre-stimulus baseline is shown. Source: Reprinted with permission from Elsevier, Lunardi, C., Bason, C., Leandri, M., Navone, R., Lestani, M., Millo, E., et al., 2002. Autoantibodies to inner ear and endothelial antigens in Cogan's syndrome. *Lancet* 360, 915–921.

We have so far tested many patients with Cogan's syndrome and with idiopathic SNHL for the presence of antibodies directed against the Cogan peptide, DEP-1/CD148, reovirus, and connexin-26 peptides in order to define the specificity and the sensitivity of the test. We consider positive those patients who have at least two antibodies directed against the four peptides, and one of the two positivity needs to be either anti-Cogan peptide or anti-DEP1/CD148 antibodies. Interestingly, antibodies against Cogan peptide and DEP1/CD148 have been found also in patients diagnosed as affected by an autoimmune SNHL. Interestingly, these autoantibodies can cross-react with an epitope of SSA/Ro60 protein. As well known, anti-SSA/Ro antibodies can cause immune-mediated damage of the cardiac conduction system in fetuses during the pregnancy; we have recently shown that these antiinner ear antibodies can only recognize a part of the whole protein Ro60, so they are not able to cause a congenital heart block in fetus (Bason et al., 2017).

Recently, the role of anti-HSP70 antibodies has been investigated. A group of researchers showed a significant relationship with IMIED and particularly with Cogan's syndrome. According to these authors, anti-HSP70 antibodies has an extremely high sensitivity for the "typical" form of Cogan's syndrome and, in the absence of immunosuppressive therapy, a negative test for these antibodies can rule out the diagnosis of "typical" Cogan's syndrome (Bonauguri et al., 2014). However, the role of these antibodies in the pathogenesis and in the diagnostic evaluation (see next) is debated and further data are needed.

## EVIDENCE OF AUTOIMMUNITY

Autoantibodies and autoreactive T cells have been implicated in the etiopathogenesis of idiopathic SNHL (Yehudai et al., 2006). Different antibodies directed either against inner ear specific or widely distributed autoantigens have been described in patients with SNHL of unknown origin. Antibodies against type II and type IX collagens as well as against other autoantigens in patients with Menière disease and with IMIED have been reported (Yoo et al., 2002). The Kresge Hearing Research Institute-3 (KHRI-3) antibody binds to guinea pig inner ear supporting cell antigen that has been found to be homologous to the human choline transporter-like protein 2 (CTL2), expressed in the inner ear, making this protein a possible target for an autoimmune aggression in IMIED (Nair et al., 2004). Antiendothelial cell autoantibodies have been reported in some patients with SNHL and may represent a marker of vasculitis or vascular damage of the inner ear, which leads to leucocyte infiltration and local immunoglobulin production (Cadoni et al., 2002; Mathews and Kumar, 2003). The detection of antibodies against the myelin protein P0 (30 kDa) has given conflicting results (Passali et al., 2004; Pham et al., 2007). Besides antibodies against the 30 kDa protein, Boulassel et al. (2001a) reported also the presence of antibodies against a 42 kDa protein identified as  $\beta$ -actin and against a 68 kDa protein, identified as HSP70 by some authors (Billings et al., 1998; Bloch et al., 1999) but not by others (Yeom et al., 2003). HSP70 is considered a marker of early cell damage of inner ear, but it is considered by some authors as aspecific and not useful in the diagnosis of IMIED (Lobo et al., 2014). The Western blot test for HSP70 has a very low sensitivity (García-Berrocal et al., 2002); however, its positivity seems to correlate with steroid responsiveness in subjects with IMIED (Hirose et al., 1999). The 58 kDa inner ear protein, recognized by the sera of some patients with SNHL, has been identified as cochlin, a molecule highly expressed in the cochlea (Boulassel et al., 2001b). Mutation at the "coagulation factor C homology gene" (COCH gene) encoding for cochlin causes progressive DFNA9 hearing loss and vestibular disorder (Roberston et al., 2006). Increased expression of cochlin and decreased expression of its associated basement membrane proteins have also been found in Meniere's disease (Calzada et al., 2012b). Evidence has been reported for the role of this protein in the pathogenesis of autoimmune inner ear disease (Baruah, 2014).

Another protein, highly expressed in the inner ear tissues, such as hair cells, supporting cells, spiral ligament of stria vascularis, is  $\beta$ -tubulin. Antibodies against the 55 kDa protein  $\beta$ -tubulin have been identified in 59% of the patients with an autoimmune SNHL and Ménière's disease (Zhou et al., 2011a).

Cochlin,  $\beta$ -tectorin, and  $\beta$ -tubulin have been used to induce SNHL in animal models (see next). A 68–72 kDa inner ear membrane glycoprotein called CTL2 has been identified as a target of autoantibodies in patients with an autoimmune hearing loss. Moreover, the presence of these antibodies seems to be correlated with response to corticosteroids (Kommareddi et al., 2009). Table 55.1 summarizes the putative autoantigens believed or proved to be involved in the pathogenesis of IMIED. The search for immune epitopes of the inner ear has not led to the identification of novel autoantigen targets so far (Platt et al., 2014).

We can conclude that the sera of patients with SNHL recognizes a large array of proteins of variable molecular weight only a few of which have been identified so far. However, there is not direct proof that any of the antibodies directed against such autoantigens may be immunopathogenic and cochleopathic in IMIED. Indeed, the majority of them could not induce SNHL in immunized animals (see next).

The first evidence for an implication of autoreactive T cells was reported by Mc Cabe and McCormick (1984) who observed leukocyte migration inhibition by T cells exposed to inner ear extracts. Lorenz et al. (2002) reported an increased number of inner ear-specific interferon gamma (IFN- $\gamma$ )-producing T cells (Th1 immune response) in the peripheral blood of patients with SNHL believed to be of an autoimmune origin. These findings indicated that proinflammatory T cells specific for as yet unknown inner ear antigens may play a role in the development and progression of inner ear autoimmunity. Moreover, abnormalities in the cytokine milieu in patients with IMIED have been reported (Goodall and Siddiq, 2015).

## GENETIC SUSCEPTIBILITY

Since IMIED and Meniere's disease can be of an autoimmune origin, interactions between genetic factors and environmental factors play a pivotal role in the pathogenesis of the disease.

Variability in acute immune response genes could determine susceptibility and prognosis of SNHL.

**TABLE 55.1** Putative Autoantigen Targets in IMIED (A) and Cogan's Syndrome (B)

IMIED	Molecular weight (kDa)	Reference	Induces hearing loss in animals	Reference

Functional allelic variants of genes encoding for the proinflammatory cytokines, including tumor necrosis factor alpha (TNF-alpha), IFN- $\gamma$ , and macrophage migration inhibitory factor, have not been found associated with disease susceptibility or hearing loss progression in patients with Menière's disease (Gásquez et al., 2012).

Since increased permeability of blood vessels, as shown by MRI, suggests inflammation of the inner ear, different genes involved in inflammatory pathways have been analyzed; polymorphisms of the gene encoding for IL-6 (Hiramatsu et al., 2012) and for IL-1 $\beta$  (Um et al., 2013) have been found associated with the risk of sudden SNHL. Moreover, patients nonresponder to steroid therapy show an overexpression and a dysregulation of IL-1 $\beta$  (Pathak et al., 2011); consensually, they have higher MMP-9 levels than TIMP-1 levels (Eisner et al., 2017). Finally, SNHL has been observed in autoinflammatory syndromes, such as Muckle–Wells syndrome whose hallmark is IL-1 $\beta$  dysregulation (Kuemmerle-Deschmer et al., 2013). Therefore IL-1 $\beta$  blockade may be an alternative method to restore hearing in patients who do not respond to steroid therapy.

Oxidative stress seems to be related to the pathology of inner ear; however, polymorphisms of genes involved in oxidative stress have not been found associated with the risk of SNHL or Menière's disease (Teranishi et al., 2012).

Aquaporins are water channel proteins, which play a pivotal role in the regulation of perilymph and endolymph volume; two of the eight aquaporin subtypes seems to be involved in impaired fluid regulation present in Menière's disease and in Sjögren's syndrome (Eckhard et al., 2012).

Finally, the study of coagulation has identified risk factors, such as hyperhomocysteinemia and polymorphism of the MTHFR gene associated with SNHL (Massimo et al., 2012), whereas decrease in plasminogen activator inhibitor-1 levels due to gene polymorphism may be associated with the reduced risk of sudden SNHL in Italian population (Cho et al., 2012). Recently, a polymorphism of the uncoupling protein 2, a mitochondrial transporter abundant in the inner ear, has been reported to be associated with SNHL (Koide et al., 2018). Finally, polymorphism in transmembrane channel 1 can cause both autosomal dominant and recessive hearing loss (Wang et al., 2018).

## ANIMAL MODELS

A major barrier in understanding the pathophysiology of IMIED derives from the paucity of inner ear tissue available. This problem underlines the importance of animal models of this disorder, which may provide insights into the pathogenesis, diagnosis, and treatment of IMIED.

A recent animal model of an autoimmune inner ear disease has been obtained in Sprague-Dawley rats by combination with the high dose of pertussis toxin; cellular infiltration, missing hair cells, degeneration of the spiral ganglion cells, endolymphatic hydrops, and autoantibodies directed to inner ear-specific antigens were all noted after immunization (Kong et al., 2011).

Immunization with the better characterized putative autoantigens, such as collagen type II, HSP70, myelin P0, have failed to elicit hearing loss (Harris et al., 1986; Billings et al., 1998; Boulassel et al., 2001c). Attempts to develop animal models of IMIED have been made by immunizing guinea pigs with either isologous or bovine inner ear homogenates (Harris, 1987; Gong et al., 2002); this model was hampered by the vast array of immunologically active components involved, making impossible to identify the specific self-antigens involved in disease initiation and progression. The use of fractions of inner ear proteins has partially addressed this problem (Tomiyama, 2002) that will be solved by the availability of recombinant antigens (Billings, 2004). Gloddek et al. (1999) induced SNHL in naïve Lewis rats following a passive transfer of activated T cells specific for bovine inner ear extracts, demonstrating the role of T cells in the initiation and pathogenesis of SNHL. A confirmation of the importance of T cells was recently provided by Solares et al. (2004) who showed that SWXJ mice immunized with peptides derived from two proteins of the inner ear, cochlin and  $\beta$ -tectorin, had significant hearing loss. Two selected peptides elicited a CD4 $+$  T cell response of the Th1-like phenotype. Moreover, the passive transfer of peptide-activated CD4 $+$  T cells into naïve SWXJ recipient induced the leukocytic infiltration of inner ear and hearing loss. However, it is not clear whether cochlin and  $\beta$ -tectorin are implicated in IMIED in humans and how accurately this model reflects events occurring in the spontaneous disease (Billings, 2004). Zhou et al. (2011a) have shown that immunization of Balb/c mice with  $\beta$ -tubulin is able to cause lesions in the cochlear hair cells and cochlear damage of the spiral ganglion, mediated by CD4 $+$  T cells producing IFN- $\gamma$ . Hearing loss was induced by the passive transfer of CD4 $+$  T cells specific for  $\beta$ -tubulin to naïve mice and that this is accompanied by a decreased frequency and impaired suppressive function of regulatory T cells (Tregs). In this murine model of autoimmune hearing loss, systemic infusion of adipose tissue-derived mesenchymal stem cells significantly improved hearing function and protected hair cells by decreasing proliferation of antigen-specific Th1/Th17 cells and by inducing generation of antigen-specific Tregs (Zhou et al., 2011b). Moreover, the severity of  $\beta$ -tubulin-induced experimental autoimmune hearing loss is exacerbated by IL-10 deficiency (Zhou et al., 2012).

Interestingly, oral administration of  $\beta$ -tubulin in female C57BL/6 mice induced decreased hearing loss and inner ear damage through the induction of oral tolerance by increasing Th2 type cytokines (Cai et al., 2009).

The administration of monoclonal antibodies directed either against the guinea pig inner ear supporting cell antigen (KHRI-3 antibody) (Nair et al., 1995) or type II collagen fragment CB11 peptide-induced SNHL with the loss of hair cells, inflammatory cell migration, and endolymphatic hydrops (Matsuoka et al., 2002), suggesting that antibodies also play a critical role in autoimmunity of the inner ear.

IL-1 $\beta$  has been observed as highly expressed in an animal model of autoimmune inner ear disease; in this model, lipopolysaccharide (LPS) was required in addition to Ag reexposure to initiate cochlear IL-1 $\beta$  expression, leukocyte ingress into the cochlea, and hearing loss (Pathak et al., 2011).

## TREATMENT

Since IMIED may result in severe deafness and vestibular dysfunction, patients must be treated aggressively and immediately after the onset of the symptoms. The mainstay of therapy is high dose of corticosteroids (1 mg/kg/day) (Chen et al., 2003) continued for at least 2 weeks and then for other 2 weeks in case of improvement. The steroid is then tapered in a period variable between 2 and 3 months and in some cases maintained at low dosage for a long period (e.g., methylprednisolone 4 mg/day). Different schemes of steroids administration, including intratympanic dexamethasone and 6-methylprednisolone injections, have been used with good results (Garcia-Berrocal et al., 2006; Rauch et al., 2009; Alexander et al., 2009; Gallo et al., 2013; Lim et al., 2012; Witsell et al., 2018; Tang et al., 2018; Yu et al., 2018). In the case of deterioration of symptoms or of a not significant improvement during the first 2 weeks of treatment, other immunosuppressive agents (Buniel et al., 2009) are added, such as cyclophosphamide (CYP), 1–2 mg/kg/die, or methotrexate (MTX), 7,5–20 mg/wk. Because of the well-known side effects of CYP, clinicians prefer the use of MTX; however, despite the preliminary favorable responses (Kilpatrick et al., 2000; Matteson et al., 2001; Rahman et al., 2001a; Matteson et al., 2003), the unique controlled trial published so far does not support the efficacy of long-term MTX in maintaining the improvement achieved with glucocorticoid therapy (Harris et al., 2003). Since MTX is slow acting, its effect may start too late in a disease that rapidly leads to hearing loss. Mc Cabe (1989) reported the promising results obtained with the

CYP–prednisolone combination therapy. We have used oral methylprednisolone and CYP pulse therapy in two particularly rapid and severe cases; this therapy blocked and reverted the hearing loss. Encouraging results derive from the use of azathioprine that would be able to reduce the risk of relapse and to maintain the hearing threshold, modifying the course of the disease (Meta-Castro et al., 2018).

The results obtained with steroids and aggressive immunosuppression are variable (Broughton et al., 2004; Loveman et al., 2004; Ruckenstein, 2004) depending on the characteristics of the patients included, on the severity of the hearing loss at the beginning of the treatment and on how early the therapy is started. Also, proinflammatory cytokines, cytokines receptors polymorphism may affect the steroid responsiveness (Vambutas et al., 2009).

Biological agents can play a role in the management of patients with IMIED (reviewed by Lobo et al., 2012), most studies achieved a hearing improvement or stabilization in more than 70% of the patients treated. The biological agents used include anti-TNF-alpha inhibitors (etanercept, infliximab, and adalimumab), anti-IL-1 antagonist (anakinra) and anti-CD20 surface antigen (rituximab). Infliximab has been also delivered locally through transtympanic administration (Van Wijk et al., 2006) and has been used in the treatment of Cogan's syndrome (Beccastrini et al., 2010). Controversial data are reported on the efficacy of rituximab, and further studies are needed (Orsoni et al., 2010; Bunker and Kerr, 2016).

There are reports on the utility of plasmapheresis (Luetje and Berliner, 1997), therapeutic apheresis of low density lipoprotein (LDL) (Bosch, 2003) and fibrinogen (Suzuki et al., 2003). Suckfull (2002) reported the beneficial effects of a single fibrinogen/LDL apheresis compared to conventional infusion treatment and prednisolone for 10 days. In controlled studies the use of antiviral therapy with valacyclovir (Tucci et al., 2002) and acyclovir (Uri et al., 2003; Westerlaken et al., 2003) in addition to steroids was not more beneficial than steroids alone. There are reports on the utility of low-molecular-weight heparins (Yue et al., 2003; Mora et al., 2004) and antioxidants (Joachims et al., 2003), such as N-acetylcysteine (Pathac et al., 2015) in addition to the usual therapy, and on the efficacy of intravenous infusion of tissue plasminogen activator (Mora et al., 2003) alone.

Emerging therapies appear to target cell death pathways, influence oxidant stressors, and favor the regeneration of hair cells (Crowson et al., 2017).

Hyperbaric oxygen therapy seems to be helpful in increasing the effect of pharmacotherapy (Krajcovicova et al., 2018).

In the case of permanent severe bilateral hearing loss the auditory function may be partially replaced with a cochlear implant, an electrical prosthesis with electrodes inserted into the cochlea through mastoidectomy (Cohen et al., 1993). Cochlear implantation has been successfully used in patients with SNHL (Gaylor et al., 2013), with IMIED and with Cogan's syndrome (Malik et al., 2012; Aftab et al., 2010; Wang et al., 2010). Of the 21 patients with Cogan's syndrome we are following at the moment, 11 (age 7–30) have undergone multichannel cochlear implant, resulting in a great improvement of their quality of life, without any complication. Cochlear implantation has been applied with benefit in children of 12 months of age or younger (Holman et al., 2013). Bilateral cochlear implantation seems to be more beneficial than unilateral implantation (Van Schoonhoven et al., 2013), and the use of implants with thin electronics capsules seems to simplify the simultaneous bilateral cochlear implantation (Perenyi et al., 2018).

Hematopoietic stem cell transplantation led to improvement in sensorineural hearing in patients with mucopolysaccharidosis (Da Costa et al., 2012). The recent emergence of stem cell technology has the potential to open new approaches for the regeneration of hair cells (Okano and Kelley, 2012; Crowson et al., 2017).

## CONCLUDING REMARKS AND FUTURE PERSPECTIVES

It is now evident that the inner ear is not an "immunologically privileged" site and may mount a cross-reactive immune response against both foreign (i.e., viral) and self-antigens, through a mechanism of molecular mimicry. The association of IMIED with systemic autoimmune diseases provides evidence that autoimmunity can damage the inner ear, but it does not address organ-specific disease (Mijovic et al., 2013). Antibodies directed against different inner ear antigens have been identified in some patients; however, they are neither diagnostic nor correlate with disease state. In the future the major goals for research in this field will be (1) the identification of pathogenetically relevant autoantigen(s), (2) the development of highly specific diagnostic test, and (3) a better knowledge of the immunopathological mechanisms in an organ as inaccessible as the inner ear and define the best timing and treatment for the disease. Indeed, despite recent researches, there is nonconsensus on diagnosis and optimal treatment (Peneda et al., 2018).

## INTRODUCTION

Autoimmune central nervous system (CNS) affection comprises an expanding group of potentially treatable disorders that should be included in the differential diagnosis of any type of encephalitis or myelitis.

The extent of CNS involvement in systemic immunopathic disorders such as lupus erythematosus, rheumatoid arthritis (RA), or sarcoidosis has been recognized since long. However, the identification of underlying pathogenic mechanisms has led to the development of revolutionary antibody (Ab)-based therapies improving the prognosis of this group of patients.

Further advances in autoimmune involvement of the nervous system have led to the identification of new clinical syndromes, associated with antineuronal Abs that have transformed the diagnostic and therapeutic approach to these disorders. Starting with auto-Abs to the acetylcholine receptor for myasthenia gravis and against intracellular antineuronal nuclear Ab 1 (ANNA-1) (Hu) antigen, there is still a continuous expansion of the number of cell surface, synaptic, and intracellular molecules, which expose antigenic epitopes for autoimmune neurological disorders. Numerous of these Abs were associated with an extraneuronal malignancy, causing “paraneoplastic neurological syndromes,” while others occur as primary autoimmune diseases. Furthermore, identification of several Abs targeting glial antigens, such as aquaporin-4 (AQP4), has enabled the classification of these disorders as distinct clinical entities.

The particular focus of this chapter is on autoimmune disorders associated with encephalitis or myelitis, subdivided into two groups: (1) systemic diseases with CNS manifestations and (2) Ab-associated disorders of the CNS.

## SYSTEMIC IMMUNOPATHIC DISORDERS WITH ENCEPHALITIS AND MYELITIS

### Systemic Vasculitides

#### **Definition and Classification**

Vasculitides constitute a heterogeneous group of immune-mediated vascular disorders characterized by inflammation and necrosis of the blood vessel wall. Their occurrence can be primary or secondary to a broad variety of systemic infectious, malignant, or connective tissue diseases, whereas they are responsible for marked morbidity and societal burden. Their pathogenic mechanisms have not been fully understood; the initial inflammation can be mediated by circulating auto-Abs, immune complexes, and cell-mediated mechanisms.

An overview of the different vasculitides taking into account the size of affected vessels, histological characteristics, suspected pathogenetic mechanisms with reference to CNS involvement is presented in [Table 56.1](#) (Jennette and Falk, 2007).

#### **Neurological Manifestation**

The spectrum of cerebral vasculitic involvement includes self-limiting benign variants, as well as severe, relapsing, or chronic progressive forms leading to high morbidity and mortality. The involvement of the peripheral nervous system (PNS), often characterized by a painful mononeuritis multiplex, normally precedes the cerebral manifestation. The clinical vasculitic picture differs from atherosclerotic vascular diseases mainly due to the presence of headache in combination with encephalopathic and focal neurological symptoms and a frequently earlier manifestation age.

#### **Central Nervous System Imaging**

In cases of suspected vasculitis as well as for treatment monitoring, a cerebral magnetic resonance (MR) imaging (MRI) with contrast medium including MR-angiography (MRA) should be performed. MRI should include diffusion-weighted images for detection of recent ischemia and T2\*-weighted gradient echo sequences for detection of previous microhemorrhages (Pomper et al., 1999).

Various lesion patterns are associated with cerebral vasculitis: multiple subcortical lesions, cortical lesions, and lesions in the basal ganglia. Individual parenchymal lesions and the meninges may show a contrast enhancement. In the case of a large-vessel involvement, a contrast enhancement of the vessel wall can occasionally be detected as a correlate of the inflammatory vessel wall thickening (Pfefferkorn et al., 2010; Moore and Richardson, 1998).

**TABLE 56.1** Neurological Manifestation of Systemic Vasculitides

Frequency of neurological symptoms	Large vessel		Medium vessel cPAN	Small-vessel (ANCA positive)				Small-vessel (immune complex mediated)				
	GCA	Takayashu arteritis		WG	MPA	EGPA	Cryoglobulinemia	SLE	RA	Sjögren syndrome	Behcet syndrome	
PNS (%)	5–15	0	50–75	15	<1	50–78	10		13	20	20	5
CNS (%)	10	10–36	24–40	23–50	<1	<5	10		10	<5	<5	10–40
Acute encephalopathy	(+)	(+)	+	(+)	0	0	(+)		(+)	(+)	(+)	+
Memory loss	+	(+)	+	+	0	0	0		(+)	(+)	0	(+)
Behavioral disorders	(+)	(+)	(+)	0	0	0	0		(+)	(+)	0	+
Epilepsy	0	+	+	+	0	(+)	(+)		(+)	(+)	(+)	(+)
Other focal signs	(+)	+	+	+	0	(+)	(+)		(+)	(+)	(+)	+
Cranial nerves involvement	+	+	(+)	+	0	(+)	0		(+)	(+)	(+)	+
Spinal symptoms	0	(+)	(+)	(+)	0	0	0		(+)	(+)	(+)	(+)
Meningeal symptoms	0	0	(+)	+	(+)	0	(+)		(+)	(+)	(+)	+
Cerebral hemorrhages	0	(+)	(+)	(+)	0	(+)	(+)		(+)	(+)	0	(+)

ANCA, Antineutrophil antibodies; GCA, giant cell arteritis; cPAN, classical panarteritis nodosa; WG, Wegener's granulomatosis; MPA, microscopic polyangiitis; EGPA, eosinophilic granulomatosis with polyangiitis (formerly Churg–Strauss syndrome); SLE, systemic lupus erythematosus; RA, rheumatoid arthritis; PNS, peripheral nervous system; CNS, central nervous system; +, often, (+), not so often; 0, rare or not reported.

Digital subtraction angiography can detect vessels up to 0.1 mm in diameter and is superior to the MRA in the representation of caliber irregularities (Demaerel et al., 2004). Vascular irregularities, stenoses, vasocompressions, or aneurysmal dilatations are not specific for vasculitis and are also present in noninflammatory vascular processes (e.g., in reversible vasoconstriction syndrome). The specificity of the DSA is, therefore, low (14%–65%, Kadkhodayan et al., 2004). In the absence of extracranial atherosclerotic lesions, intracerebral changes imply a probable vasculitis. The sensitivity of angiography varies between 76% and 94% (Duna and Calabrese, 1995; Chu et al., 1998; Demaerel et al., 2004; Kobayashi et al., 2005).

### **Biopsy**

Due to the severe side-effects of the immunosuppressive treatment of cerebral vasculitis with cyclophosphamide and steroids, the greatest possible diagnostic certainty is required. In patients without bioptic evidence, immunosuppressive treatment does not provide any prognostic advantage (Alreshaid and Powers, 2003).

For systemic vasculitides with CNS involvement, the biopsy should be taken from a clinically affected organ. "Blind biopsies" (e.g., of skin, muscle, sural nerve) do not offer any advantage. Histological confirmation is not necessary if the diagnostic criteria are fulfilled and clinical and radiological involvement of the CNS is present.

An additional advantage of CNS biopsy is the exclusion of other treatable causes such as chronic, indolent inflammation of the basal meninges (tuberculosis, fungi, sarcoidosis), neoplasia, or other noninflammatory angiopathies (e.g., amyloid angiopathy). The brain biopsy has a sensitivity of about 75% and a specificity of 80%. The risk of side effects is estimated to be 1%–5%, so that the indication for biopsy should be restricted to patients with suspected vasculitis after passing through the noninvasive diagnosis. The complication risk is certainly lower than the morbidity risk of long-term cyclophosphamide therapy (Duna and Calabrese, 1995).

## **Large Vessel Vasculitides**

### **Giant Cell Arteritis**

*Definition and epidemiology:* Giant cell arteritis (GCA, temporal arteritis, Horton's disease) is an inflammatory vasculopathy of medium and large arteries and the most common primary systemic vasculitis (Nordborg and Bengtsson, 1989, 1990). Predilection sites are external branches of the carotid artery (Arteria temporalis, rarely occipital artery), the A. ophthalmica and Arteriae ciliates posterior (30%) and the aortic arch and its branches (distal subclavian, axillary arteries) (15%–30%). Only rarely (<1%) the intracranial vessels (mostly posterior circulation) or other organ systems (Salvarani et al., 2012) are afflicted. Approximately 50% of the patients with giant-cell arteritis may also present with polymyalgia rheumatica before, at the time of, or after the diagnosis of vasculitis (Kermani et al., 2013; González-Gay et al., 2017; Dejaco et al., 2017).

*Immune mechanisms:* Histologically, there is a granulomatous panarteritis of medium-sized and large arteries with giant cells, lymphomononuclear infiltration, and narrowing of the lumen by intimal proliferation. Two major immune response networks have been identified: the interleukin-12-type 1 helper T-cell (Th1)–interferon- $\gamma$  axis and the interleukin-6-type 17 helper T-cell (Th17)–interleukin-17 or interleukin-21 axis; only the latter is effectively suppressed with glucocorticoid treatment (Kermani and Warrington, 2013). A genetic predisposition (association with HLA-DR4 or DRB1 \* 04 alleles) has been also reported. Various infectious agents (varicella zoster virus (VZV), *Mycoplasma pneumoniae*, parvoviruses, chlamydiae) have been discussed as putative environmental triggers (Weyand and Goronyz, 2013).

*Neurological manifestations:* The most common neurological symptom (70%–85%) is a new-onset severe headache of throbbing or piercing quality, often unilateral, usually frontotemporal, with a prominent and tender temporal artery (30%–60%). Sometimes jaw muscle claudication is present (30%–40%). Headache often precedes further symptoms such as inappetence, weight loss, and general malaise.

Involvement of the ciliary arteries occurs in 30% of the cases and can lead to sudden unilateral or bilateral vision loss or diplopia (15%–45%). The (often irreversible) blindness caused by anterior ischemic optic neuropathy can follow transient visual disturbances mimicking amaurosis fugax. An involvement of the ocular muscles can lead to pain during eye movement, double vision, and ptosis. Significantly less frequent is the involvement of other brain nerves (Nesher, 2014). Cerebral ischemia, transient ischemic attacks, and other neuropsychiatric manifestations are present in cases of involvement of intracranial arteries mostly of the posterior cerebral circulation (<15%). Vestibulo-auditory manifestations include hearing loss, tinnitus, vertigo, and are present in 5%–25% of the cases. The PNS (14%) can be affected in the form of a mononeuritis multiplex (<10%) (Caselli et al., 1988).

**CNS imaging:** The high-resolution ( $\geq 10$  MHz) color-coded duplex sonography can be used to visualize superficial arteries, with the halo sign (vessel wall edema) distinguishing vasculitis from arteriosclerotic changes (median sensitivity 88% and specificity 97% in 13 studies (Schmidt and Blockmans, 2005). MRA or computed tomographic angiography (CTA) shows wall thickening and increased intramural hematoma, which may not be reversible with treatment and should not be used to assess the inflammatory burden or disease activity. Intramural leaky microvessels give rise to delayed enhancement of the arterial wall, which is consistent with but not specific for inflammatory activity. Traditional angiography is now reserved for planning revascularization procedures, when required. 18F-fluorodeoxyglucose (FDG) PET can detect the increased metabolic activity in the inflamed vessel wall with higher sensitivity than MRI in patients with corresponding symptoms of large vessel vasculitis, but negative temporal biopsy and excludes an occult malignancy (Bley et al., 2005a,b).

**Biopsy:** In cases of suspected giant-cell arteritis, histologic verification of vasculitis should be sought by means of a temporal artery biopsy with assessment of a clinically and sonographically affected vascular segment that is 1.5–2.0 cm in length. A negative biopsy finding does not rule out giant-cell arteritis as it identifies 85%–95% of the cases (Kermani et al., 2013). Treatment prior to biopsy is unlikely to affect the test result, but the biopsy should not be delayed beyond 1–2 weeks of glucocorticoid therapy begin (Achkar et al., 1994; Narváez et al., 2007).

**Treatment:** Prednisone remains the cornerstone of treatment for GCA. No glucocorticoid-sparing agents have been approved for the treatment of giant-cell arteritis; however, a broad spectrum of secondary agents is used in patients with giant-cell arteritis (methotrexate, cyclophosphamide, azathioprine, and antimalarial agents) (Kötter et al., 2012). Randomized controlled trials of anti-TNF- $\alpha$  therapy in GCA have showed disappointing results (Martinez-Taboada et al., 2008; Seror et al., 2014; Roberts and Clifford, 2017). The clinical effectiveness of a treatment with methotrexate can be assessed after approximately 6 months of treatment (Dasgupta et al., 2010; Mukhtyar et al., 2009; Bienvenu et al., 2016).

Elevated levels of IL-6 have been found in both the inflamed arteries and peripheral circulation of patients with GCA (Garcia-Martinez et al., 2010) and data of GiACTA clinical study, showed that subcutaneous tocilizumab (humanized monoclonal Ab against IL-6-receptor, 162 mg weekly or every other week) was superior to prednisolone monotherapy, although serious infections of the respiratory tract and skin/soft tissue have occasionally been described. Other promising options for future consideration include abatacept (CD80, CD86-signal blocker) and ustekinumab (anti-IL-12, anti-IL-23 p40 unit Ab) (Villiger et al., 2016; Stone et al., 2016, 2017; Roberts and Clifford, 2017).

## Medium Vessel Vasculitides

### **Classical Polyarteritis Nodosa**

**Definition and epidemiology:** Classical polyarteritis nodosa (PAN) (cPAN) is a severe, systemic, necrotizing inflammation of the medium-sized arteries without the involvement of smaller vessels. The microscopic form of polyarteritis associated strongly with *p*-antineutrophil Abs (*p*-ANCA)/myeloperoxidase (MPO) should be separated from the classical disease (Jennette et al., 2013). Neurological symptoms occur in both forms, yet more frequently in the classical form. The diagnosis of cPAN should be based on the American College of Rheumatology criteria after exclusion of other small-vessel vasculitides (Watts et al., 2007). More than 50% of the patients have an HBsAg carrier status, so that an infection-associated pathogenesis mediated by immune complexes is suspected. PAN with and without HBV association differ in aspects of clinical course, outcome, and response to treatment; the presence of Hepatitis virus goes along with a high incidence of mononeuritis multiplex and a worse prognosis (Özen et al., 2006).

**Immune mechanisms:** The exact pathogenesis of PAN largely remains unknown (Guillevin et al., 2005). It is probably a type III or immune complex reaction (Trepo et al., 1974; Zuckerman, 1976). The presence of large masses of HBs antigen immune complexes in the recent vascular lesions, lesser amount of these complexes in regressing lesions, and their absence in healed lesions points toward the primary role played by the immune complexes. The interaction of immunocomplexes, Fc $\gamma$  receptors and adhesion molecules probably lead to disturbances in transmigration and activation of polymorphonuclear neutrophils, with consequent vessel damage (Sindrilaru et al., 2007; Scott et al., 1982).

**Neurologic manifestations:** They are among the main clinical characteristics of PAN patients (79%) but since most of them are restricted to the PNS (painful mononeuritis multiplex and distal symmetric sensorimotor polyneuropathy, 50%–75%), 4%–20% of the patients show CNS involvement (Pagnoux et al., 2010; Sharma and Sharma, 2013). This usually occurs only in the later course of the disease and includes a variable

combination of headache (34%), retinopathy (32%), and encephalopathy (23%). Focal symptoms such as hemiparesis due to ischemic lesions or cerebral hemorrhage, epilepsy, and cranial nerve involvement are less frequent (10%). In MRA/DSA multiple-vessel stenoses of medium-sized cerebral and early signs of cerebral ischemia have been described (Provenzale and Allen, 1996). Occasionally there is a spinal cord affliction. The prognosis clearly depends on the organ manifestations (five-factor score, FFS). The 5-year survival probability decreases from 90% with an FFS from 0% to 65% with an FFS of  $\geq 2$  (Guillemin et al., 1995; Gayraud et al., 2001). A combined biopsy of muscle and nerve demonstrates the necrotizing granulomatous inflammation (Khellaf et al., 2007).

*Treatment and prognosis:* In severe cases relapses with neurologic, renal, or cardiac manifestations are frequent. In PAN with negative hepatitis serology induction treatment is started with prednisone and cyclophosphamide. In cases of rapid clinical progression plasmapheresis may be tried. In the case of positive hepatitis serology prednisone is combined with modern virustatics such as lamivudine (in hepatitis B) or interferone alpha and ribavirine (in hepatitis C). Alternatively, rituximab or intravenous immunoglobulins (IVIGs) may be used, the former NOT in the presence of florid hepatitis. The 5-year survival period of the PAN was previously without immuno-suppression around 13%. The combination with cyclophosphamide significantly increased the 5-year survival time to 75%–85% (Gayraud et al., 2001).

## Small Vessel—Antineutrophil Antibodies Positive Vasculitides

ANCA-associated vasculitis is a heterogeneous group of rare diseases potentially involving all organs and systems. During the last years, it has become increasingly evident that it is the specificity of ANCA, rather than clinical diagnosis of granulomatosis with polyangiitis (GPA) or microscopic polyangiitis (MPA) that influences the disease phenotype.

### **Granulomatosis With Polyangiitis (Formerly Wegener's Granulomatosis)**

*Definition and epidemiology:* This small vessel arteritis is characterized by a necrotizing granulomatous inflammation of the blood vessels of the respiratory tract and later in the disease course by glomerulonephritis (Elefante et al., 2017). In Caucasians it is associated with the detection of cytoplasmic ANCA (c-ANCA) against proteinase 3 (c-ANCA-PR3), whereas in Asians dominating Abs against MPO are present. C-ANCA/PR3 are present only in 50% of the patients with limited disease and in >90% of the systemic GPA cases. Interestingly, Rahmattulla et al. (2016) showed specific genetic associations of GPA patients with their ANCA phenotype: c-ANCA-PR3 showed a significant association with HLA-DPB1 and HLA-DPA1, whereas p-ANCA-MPO with HLA-DQA2 and HLA-DQB1 variants. Fibrosing interstitial disease and polyneuropathy are associated with a higher mortality (Miloslavsky et al., 2016).

*Immune mechanisms:* According to the widely recognized pathogenetic model of GPA, ANCA react with PR3 and MPO on the surface of neutrophils and increase their adhesion to the endothelium, which results to the production of reactive oxygen species, proteolytic enzymes, and subsequently to vessel damage (Yang et al., 2016).

A very important aspect relating to the role of neutrophils in GPA pathogenesis is the increased release of neutrophil extracellular traps (NETs) through neutrophil activation. NETs contain various proinflammatory mediators, such as histones, HMGB1, PR3, MPO, and neutrophil elastase that concur to vessel inflammation by damaging endothelial cells and by increasing complement activation. The initial events, which lead to the ANCA production, still need to be elucidated. Lepse et al. (2016) reported that endogenous and exogenous factors including TLR9 agonists, together with BAFF (B-cell activating factor) and IL-21, can promote PR3-ANCA production.

*Neurological symptoms:* Neurologic involvement in GPA has been described in 22%–50% of the GPA patients. When excluding cranial nerve palsies from CNS manifestations, CNS involvement is however rare, representing 7%–11% of the GPA patients (de Groot et al., 2001). Three different pathological CNS-involvement patterns are known:

1. Contiguous granulomatous CNS invasion from extracranial sites: In the limited stage of GPA, necrotizing granulomas of the nose and the paranasal sinuses may lead to compression of neighborhood structures with cranial nerve lesions (II, VI, VII, VIII), cerebral venous sinus thrombosis, diabetes insipidus, or exophthalmus. These patients have often a saddle nose deformity and an episcleritis.
2. Intracerebral, meningeal (pachymeningitis) or cerebral granulomatous lesions (Seror, 2006).

3. A manifestation of generalized GPA, with vasculitis of small-sized cerebral or spinal cord vessels: CNS parenchyma vasculitic involvement presents with ischemic stroke, intracerebral hemorrhages, and encephalopathic symptoms with or without seizures (10%) mostly at late stages of the disease in combination with rapid progressive glomerulonephritis.

The most typical and frequent PNS complication is mononeuritis multiplex (10%–22% or 30%–50%). Symmetrical sensorimotor polyneuropathy with relatively rapid progression, though rare, has also been reported (de Groot et al., 2001).

*CNS imaging:* Aseptic meningitis with enhancement of the basal meninges especially of the tentorium in MRI and the development of an occlusive or communicating hydrocephalus are possible findings. Conventional angiography is inconspicuous for small vessels. In MRI, however, T2-intense parenchyma lesions, hemorrhages, and strongly thickened and contrast agent-containing meninges (pachymeningitis) can be detected (Nishino et al., 1993).

*Biopsy:* The diagnosis is made by the histological examination of a biopsy specimen from the affected area; up to three biopsies may be necessary in the nasal mucosa area as the first biopsy is only diagnostic in 30% of the cases. In addition, biopsies can also be performed from muscle, skin, sural nerve, and especially the kidney.

### **Microscopic Polyangiitis**

MPA is a necrotizing nongranulomatous angiitis of small vessels without immune complex deposits and often associated with necrotizing glomerulonephritis and pulmonary capillaritis (pulmorenal syndrome). Usually pANCA/MPO-ANCA is found in over 90% of the patients. A case of neurological involvement in the form of a hypertrophic pachymeningitis has been reported (Furukawa et al., 2004). The clinical characteristics of small vessels vasculitis in the MPA are similar to those of the GPA.

*Treatment and prognosis for GPA/MPA:* Standard treatment of GPA/MPA in the generalized disease stage with CNS involvement is the combined administration of cyclophosphamide and prednisolone (response rate over 90%, 5-year survival rate 85%, de Groot et al., 2001). However, the side effects include severe infections, the risk of secondary tumors (bladder cancer, lymphoma), and ovarian failure. Based on the results of CYCAZAREM study, treatment deescalation to azathioprine is performed after reaching a remission with cyclophosphamide during the first 12–24 months of treatment (Walsh et al., 2014). Methotrexate and azathioprine were equally effective (Pagnoux et al., 2008). Mycophenolate mofetil is classified as substance of second choice (Hiemstra et al., 2010; Unizony et al., 2016).

Results from two studies published in 2010 (RAVE: Stone et al., 2010; RITUXVAS: Jones et al., 2010) demonstrated a similar efficacy of cyclophosphamide and rituximab (375 mg/m<sup>2</sup> per week for 4 weeks). The secondary malignancy risk was lower in rituximab-treated patients than in those treated with cyclophosphamide and similar to that of the general population (van Daalen et al., 2017; Yates et al., 2016; McGeoch et al., 2016). Further studies have shown a therapeutic potential for ofatumumab, a fully humanized mAb directed against a distinct extracellular epitope of CD20 (McAdoo et al., 2016) and of an orally administered inhibitor of C5a complement receptor (CCX168, CLEAR-Study). IVIG has exerted a beneficial effect as adjunctive therapy (Crickx et al., 2016), whereas a recently published case report of a patient with refractory MPA introduced a potential role for bortezomib, a proteasome inhibitor approved for the treatment of multiple myeloma and that has already showed promising results in systemic lupus erythematosus (SLE) (Novikov et al., 2016a,b).

### **Eosinophilic Granulomatosis With Polyangiitis (Formerly Churg–Strauss Syndrome)**

*Definition and epidemiology:* Eosinophilic GPA (EGPA) is an entity widely considered at a cross-road of ANCA positive vasculitis and hypereosinophilic-associated conditions (Harrold et al., 2005).

EGPA typically develops into three sequential phases: the allergic phase, distinguished by the occurrence of asthma, allergic rhinitis, and sinusitis; the eosinophilic phase, in which the main pathological finding is the eosinophilic organ infiltrations (e.g., lungs, heart, and gastrointestinal system); and the vasculitic phase, characterized by purpura, peripheral neuropathy, and constitutional symptoms. p-ANCA/MPO are present in 40%–60% of the patients (Sablé-Fourtassou et al., 2005). These show an increased frequency of vasculitic renal, lung, and CNS involvement. Patients without ANCA present more frequently with an eosinophilic form of cardiac disease and pulmonary infiltrates (Grau, 2008).

*Immune mechanisms:* The neurological findings in allergic granulomatosis are caused by systemic necrotizing vasculitis, with the eosinophilic infiltrate affecting small vessels. The disease is probably the result of a complex interaction in which genetically and environmental factors lead to an inflammatory response whose principal

players are eosinophils, T, and B lymphocytes. Among the acquired pathogenetic factors, the exposure to different allergens, infections, vaccinations, drugs, and silica exposure have been involved (Gomez-Puerta et al., 2013). An association with HLA-DRB1\*04 and \*07 (Wieczorek et al., 2008a) and with HLA-DRB4 (Vaglio et al., 2007) has been proven. EGPA ANCA-negative subset has been associated with the interleucin-10.2 haplotype of the IL-10 promoter gene, a condition, which leads to an increased production of IL-10 (Wieczorek et al., 2008b). This is apparently in line with EGPA pathogenesis, which is characterized by an increased Th-2 response and IgG4 levels, both of which seem to be mediated by IL-10.

*Neurological manifestations:* CNS events are rare and resemble those of PAN (Puechal et al., 2008; Jennette et al., 2013; Wechsler et al., 2009). CNS involvement may include paralysis of seventh cranial nerve and phrenic nerve palsy, cerebral, or subarachnoid hemorrhage or cerebral infarction, seizures, and coma (Sehgal et al., 1995; Sablé-Fourtassou et al., 2005).

On the other hand, PNS involvement is noted in about 50%–78% of the patients, mainly in the form of painful mononeuritis multiplex and rarely as symmetric mild sensory axonal neuropathy. The neuropathy is caused mainly by nerve ischemia due to occlusion of vasa nervorum; with pANCA probably playing a key pathogenetic role. Symmetrical polyneuropathies possibly caused by eosinophil infiltrates are seen in the ANCA negative group. Nerve biopsy is characteristic and useful to confirm diagnosis (Chao et al., 2007).

*Treatment/prognosis:* Cyclophosphamide (6–12 pulses) in combination with steroids is recommended in case of CNS participation (Cohen et al., 2007). The remission rate is 80%–90%. Patient survival varies between 60% and 97% at 5 years (Mukhtyar et al., 2009; Ribi et al., 2008). Azathioprine, methotrexate, or interferon- $\alpha$  is used after reaching remission. Various case series reported the efficacy of rituximab; in long-term observations studies a decline in serum immunoglobulin levels on long-term rituximab treatment has been reported (Mohammad et al., 2016; Novikov et al., 2016a,b; Thiel et al., 2017). Results of a phase 3 study in patients with treatment refractory EGPA show an efficacy of the monoclonal anti-IL-5 Abs (high-affinity receptor binding site on IgE) mepolizumab (Wechsler et al., 2017).

## Small Vessel—Antineutrophil Antibodies Negative Vasculitides

### Rheumatoid Arthritis

*Definition:* RA is the most common chronic disease of the connective tissue, mainly affecting the joints. Extraarticular features are observed in up to 40% of the patients and are associated with increased morbimortality. Vasculitis is a known complication of RA, often occurring several years after the initial onset of disease (Scott et al., 2010).

*Immune mechanisms:* In RA and SLE there is evidence of a diminished relative percentage of CD4 $^{+}$ CD25 $^{+}$  regulatory T cells and for auto-Abs production such as antiendothelial cell Abs. These as well as circulating immune complexes are thought to activate endothelial cells, leading to upregulation of adhesion molecules and other major histocompatibility class II molecules. Of importance, endothelial cells play a crucial role in inflammation and coagulation, as their activation leads to a procoagulatory/prothrombotic status. Recent theories on the pathogenesis of RA suggest that the synovial cells of these patients chronically express an antigen that triggers the production of rheumatoid factor and polymorphonuclear leukocyte infiltration (Fernández et al., 2004).

## NEUROLOGICAL MANIFESTATIONS

The following mechanisms lead to nervous system involvement:

### 1. Systemic inflammatory processes, resulting to pachymeningitis or vasculopathy/vasculitis.

The exact incidence of cerebral involvement in RA is low compared with spinal and peripheral nerve involvement. The patients may present with stroke-like episodes. Inflammation of the meninges may present with acute or progressive focal deficits, seizures, headache, and cranial nerve affection (Starosta and Brandwein, 2007). Definitive diagnosis requires a meningeal biopsy. Interestingly, these manifestations can occur even in the absence of systemic disease activity (Kurne et al., 2009; Aguilar-Amat et al., 2011).

MRI findings can demonstrate meningeal enhancement after contrast administration (pachymeningitis). White matter lesions with hypointense signal on T1-weighted sequence and hyperintense signal on T2-weighted sequence can suggest diffuse vasculitis. Cerebrospinal fluid (CSF) analysis may present with elevated white blood cells and normal to slightly elevated protein concentration (Joaquim and Appenzeller, 2015).

The main causes of peripheral neuropathy in RA can be divided in two groups: (1) compressive neuropathies (most frequently carpal tunnel syndrome secondary to tendosynovitis of the flexor tendons of the fingers) and (2) noncompressive neuropathies (20%, asymptomatic 85%) mostly painful mononeuritis multiplex but also axonal-length dependent sensorimotor neuropathy probably secondary to vasculopathy/vasculitis (Bayrak et al., 2010; Sim et al., 2014). Finally, an autonomic neuropathy characterized by auto-Abs specific for nicotinic acetylcholine receptors in the autonomic ganglia was described, whereas a decrease of Abs levels correlates with clinical improvement (Vernino et al., 2000).

2. Joint and bone destruction leading to neural compression (e.g., cervical myelopathy symptoms caused by destruction of the atlanto-axial joints) (Richioud et al., 2012; Blom et al., 2013).
3. Potential side effects of the medication used for RA treatment, such as corticosteroids, disease-modifying drugs, and biological agents.

Treatment with anti-TNF drugs can lead to cerebral or spinal demyelinating events (including optic neuritis) mostly from 1 week to 12 months after starting the agents, but delayed presentations are also described (Faillace et al., 2013; Kaltsonoudis et al., 2014). Demyelinating polyradiculoneuropathy has also been observed in RA patients on anti-TNF- $\alpha$  (Alshekhlee et al., 2010).

4. Accelerated atherosclerosis associated with systemic inflammation and auto-Abs.

Observational studies have shown that compared with healthy normal individuals, patients with RA are at double the risk for developing coronary artery disease and the assessment and treatment of risk factors, such as hypertension, diabetes, and obesity is mandatory (Solomon et al., 2003; Maradit-Kremers et al., 2005).

**Treatment—Prognosis:** Currently, corticosteroids and immunosuppressants such as cyclophosphamide are the mainstay of treatment for vasculitis (Krishnan et al., 2004; Hurlmann et al., 2002). The availability of biological immunomodulatory therapies, such as rituximab, tocilizumab, anti-TNF- $\alpha$  inhibitors (infliximab, certolizumab, etanercept) IL-1 blockers such as anakinra and T-cell costimulatory blocking agent (CTLA-4) abatacept, has potentially increased therapeutic options in systemic vasculitis. It has been reported that the combination of rituximab with methotrexate or anti-TNF- $\alpha$  inhibitors and methotrexate are more effective in improving symptoms compared to methotrexate alone, with etanercept appearing to be the safest TNF- $\alpha$  blocker (Aaltonen et al., 2012).

### **Systemic Lupus Erythematosus**

**Definition and epidemiology:** SLE is characterized by multisystem organ involvement, heterogeneity of clinical features, and varied severity levels, and similarities with other autoimmune diseases (Yu et al., 2014).

**Immune mechanisms:** The etiology of the loss of immunological tolerance for nuclear autoantigens in SLE is multifactorial, and includes environmental factors and genetic susceptibility.

Auto-Abs play the main role since most of lupus patients (approximately 95%) present high titers of autoreactive Abs mainly raised against nuclear antigens [such as double-stranded DNA (dsDNA) and ribonucleoproteins (RNPs)], which form circulating immune complexes. Immune complex deposition in target organs initiates and maintains the auto-inflammatory response (Tsokos et al., 2016).

**Autoantibodies:** Disease activity is known to correlate with auto-Ab titers, especially antidouble-stranded dsDNA IgG (Liu and Davidson, 2012). A secondary antiphospholipid syndrome (APS) is present in approximately 25% of all SLE cases. Most antiphospholipid Abs, in particular, anticardiolipin (aCL) and lupus anticoagulant (LAC), have been widely investigated in SLE with neuropsychiatric manifestations but were also brought in association with neurovascular manifestations, migraine headaches, and diffuse neurological manifestations including cognitive impairment (Sanna et al., 2003; Mikdashi and Handwerger, 2004; Govoni et al., 2012). In adult SLE patients, aCL has been found to be associated with neuropsychiatric involvement, whereas LAC was most strongly associated with stroke and in some studies with seizures (Zirkzee et al., 2012). Data from the SLICC study provide evidence that anti-RNP, which are present in 46% of the subjects is significantly associated with psychosis attributed to SLE (Eber et al., 2005; Isenberg and Ramsey-Goldman, 2006; Hanly et al., 2011).

The N-methyl-D-aspartate (NMDA) receptors (NMDAR), NR2a and NR2b, that bind the neurotransmitter glutamate are present on neuronal cells throughout the brain and play a role in many neurological functions including memory and learning (Zandman-Goddard et al., 2007). Studies in animal models of SLE have shown that a subset of anti-ds-DNA Abs cross-react with the extracellular, ligand-binding domain of NR2 receptors, thereby suggesting a plausible biological role for these auto-Abs in the pathogenesis of neuropsychiatric syndromes. Further studies revealed that anti-NR2 Abs can occur in up to 30% of the patients with SLE. Nevertheless, they are infrequent in the absence of detectable anti-dsDNA Abs and their presence in the circulation is not associated with any of the neuropsychiatric syndromes associated with SLE (Gono et al., 2011).

**Neurological manifestations:** The American College of Rheumatology proposed criteria for 19 distinct neuropsychiatric symptoms associated with SLE with 12 of them involving the CNS.

Approximately 13% of the patients with SLE present with the following CNS disorders: headache (39%–61%), mood and anxiety disorders (69%–74%), cognitive disorders (delirium, dementia, mild cognitive impairment, 75%–80%), cerebrovascular disease (stroke, transient ischemic attacks, and cerebral venous sinus thrombosis, 2%–8%), seizures (8%–18%), psychosis (3%–5%), cranial neuropathy (1.5%–2.1%), movement disorders (chorea or ataxia, 1%), aseptic meningitis, demyelinating syndromes; their mortality rate was 18.8% ([Chiewthanakul et al., 2012](#)). In patients with neuropsychiatric features attributed to SLE, these were the presenting signs in some 40% ([Padovan et al., 2012](#)).

Although risk factors for atherosclerosis in SLE patients are similar to those in patients with RA, there are additional SLE-related risk factors due to auto-Abs to endothelium, immunocomplexes, high-density lipoprotein, and phospholipids, as well as dyslipidemia, which contribute to the greatly increased cardiovascular risk.

Transverse myelitis with typical sensory, motor, and urinary dysfunction is described in 1%–2% of the SLE patients ([Schulz et al., 2012](#)). Birnbaum et al. distinguished two subgroups with myelitis: those with primarily long-tract signs (spasticity, hyperreflexia) and those with flaccid paralysis (indicating gray matter damage). The former group was more likely to meet criteria for neuromyelitis optica, and the second group had a worse outcome ([Birnbaum et al., 2009](#)). Episodes of transverse myelitis are accompanied by other signs of active SLE in only half of the cases, and in 25% of the patients with SLE-associated myelitis, there were no prior systemic signs of SLE ([Espinosa et al., 2010](#)).

The complications of the PNS in SLE are rare, and arise in approximately 10% of the patients, due to vasculitis. They include trigeminal neuropathy or distal symmetric sensory or sensorimotor polyneuropathy. The involvement of the neuromuscular synapse in coexisting myasthenia is rare (10%).

**MRI manifestation:** MRI shows T2 hyperintense lesions of the cervical or mid-lower thoracic spinal cord in some patients with less extensive disease and some of them with lesions involving more than four cord segments ([Kovacs et al., 2000](#); [Espinosa et al., 2010](#)). The inflammatory vasopathy is not detectable by MRA—a cerebral DSA is not helpful for diagnosis of a neuro-SLE. Although in individual studies a higher accuracy of PET and SPECT regarding the detection of inflammatory activity in SLE, MRI in combination with CSF diagnostics is usually sufficient for the clarification of a patients with neuropsychiatric manifestation ([Govoni et al., 2004](#)). Recent MR techniques such as MR spectroscopy, diffusion, and perfusion measurements may be used for the early detection of vascular lesions.

**Treatment and prognosis:** Cyclophosphamide is the most effective substance for the treatment of neuropsychiatric manifestations ([Ortmann and Klippel, 2000](#)). Mostly azathioprine or alternative mycophenolate mofetil are used after induction of remission ([Mok et al., 2002](#)). Antiplatelet/anticoagulation therapy is indicated when manifestations related to antiphospholipid Abs and particularly thrombotic cerebrovascular disease are present ([Ruiz-Irastorza et al., 2001](#)). Furthermore, medication side effects have to be considered in the differential diagnosis as high-dose corticosteroids can lead to psychopathological abnormalities.

The initial promising results from the last decade for the use of rituximab in SLE are in clear contrast with the poor results of the completed EXPLORER and LUNAR randomized controlled trials. In contrast to EXPLORER and LUNAR results controlled trials for belimumab (a humanized IgG1 monoclonal Ab that antagonizes BLyS, a B lymphocyte stimulator) showed positive results and subsequently, belimumab was the first drug approved for the treatment of SLE patients ([Hahn, 2013](#)). Further studies with anti-CD22 Abs (epratuzumab), anti-BLyS Abs (blisibimod, tabalumab), anti-IL-6 receptors (tocilizumab), anti-IL-1 receptor antagonists (anankira), antiinterferon-alpha (sifalimumab) showed positive preliminary results ([Cuadrado et al., 2013](#); [Bakshi et al., 2017](#)).

### Sjögren's Syndrome

**Definition:** Sjögren's syndrome (SS) is characterized by CD4<sup>+</sup> T-cell infiltration and destruction of salivary and lacrimal glands leading to loss of tears (keratoconjunctivitis sicca) and saliva (xerostomia). Primary SS is associated with enhanced risk for B-cell lymphoma, in which the presence of purpura or vasculitis is clinical risk indicators for future non-Hodgkin's lymphoma development ([Soliotis et al., 2004](#)).

**Immune mechanisms:** The vascular injury may be related to the presence of antineuronal Abs. SS-A/Ro Abs against extractable nuclear antigens occurs in patients with SS (up to 90% of the cases), however also in SLE (40%–60% of the cases) and RA. SS-B/La Abs are found primarily in patients with SS or SLE (60% or 15%, respectively). SS-B/La Abs occur only infrequently in the absence of SS-A/Ro Abs. A direct role of these Abs in damaging tissues is postulated ([Both et al., 2017](#)).

**Neurological manifestations:** Approximately 25% of the patients have features of PNS or CNS involvement and may precede the sicca symptoms in 40%–93% of the cases, most typically a sensory neuropathy or mononeuritis multiplex (Sène et al., 2011). Very characteristic is the ataxic sensory neuronopathy (ganglionitis) with pseudoathetosis, gait ataxia, and dysesthesia and is associated with antiganglionic acetylcholine receptor Ab (Soliotis and Moutsopoulos, 2004). It was recently observed that Abs against the type-3 muscarinic receptor may eventually explain part of the broader autonomic dysfunction found in patients with SS. There is often the involvement of the cerebral nerves, in particular of the trigeminal, facial, and vestibulocochlear nerve.

The true percentage of CNS affected patients is controversial, in part due to the wide diversity of manifestations such as encephalitis, cerebellitis, optic neuritis, aseptic meningitis, brainstem syndromes, spinal cord involvement, migraine, seizures and psychiatric symptoms (Soliotis et al., 2004). Alexander et al. (Alexander, 1993; Alexander et al., 1986) demonstrated intrathecal Ab synthesis in patients with encephalopathic SS, suggested vasculopathy as a pathogenic mechanism, and reported an association between the presence in serum of anti-Ro (SS-A) and more severe CNS disease. Estiasari et al. (2012) found that one-third of patients with SS, particularly those with spinal cord lesions or optic neuritis, had Abs to AQP4. The pathophysiology of anti-AQP4-negative patients with SS and CNS symptoms is unclear (Carvalho et al., 2014). The MRI changes of the SS may resemble those of multiple sclerosis. Since also mild lymphomonocytic pleocytosis, protein elevation, and positive oligoclonal bands can be detectable in the cerebrospinal fluid, the differential diagnosis is difficult in individual cases. However, in contrast to multiple sclerosis, oligoclonal bands are not only present in the IgG region, but also in the IgA and above all IgM band (Reske et al., 2005).

**Treatment and prognosis:** In general, intravenous corticosteroids are first-line therapy for patients with primary SS associated neuropathy. Methotrexate is also used in the treatment of arthritis in SS patients. Further options are mycophenolate mofetil, cyclosporine, azathioprine. Cyclophosphamide or IVIGs can be considered in patients who do not improve with corticosteroids (Skopouli et al., 1996).

Several studies have demonstrated a favorable effect of rituximab in approximately 60% of the patients after 6 months. As a consequence of rituximab treatment, serum BAFF levels are increasing in order to stimulate B-cell maturation, which can be countered by anti-BAFF treatment (belimumab) to achieve a longer B-cell depletion and associated longer treatment effect (Ramos-Casals et al., 2010; Pollard et al., 2013; Quartuccio et al., 2016). Currently, new potential anti-B-cell therapies are being evaluated in preclinical trials including anti-CD40 (decreases antigen presentation by B cells), anti-BAFF receptor (inhibits the effects of BAFF), antiinducible costimulatory ligand (ICOSL, decreases activation of T cells), and phosphoinositide 3-kinase delta inhibitor (PI3Kδ, inhibition of B-cell development and activation) (Sharma et al., 2016; Belkhir et al., 2014; Nakamura et al., 2013; Le et al., 2016).

## Behçet's Disease

**Definition and epidemiology:** Behçet's disease is a multisystem disease of vasculitic genesis which affects skin/mucous membranes (oral ulcers), eyes (relapsing uveitis), the joints (mono- or oligoarthritis), the gastrointestinal tract (mucous ulcers in the ileum or cecum), the pulmonary artery (pulmonary arteritis), and the aortic extremity vessels (thrombophlebitis, arteritis with the development of pseudoaneurysms) (Akman-Demir et al., 1999).

**Immune mechanisms:** Although the cause and pathogenesis are still unclear, possible factors contributing to the disease are infectious triggers, autoimmune-mediated processes, prothrombotic anomalies of the coagulation system, and a genetic predisposition. There is an association with circulating immune complexes and the tissue antigen HLA-B5 (Siva and Saip, 2009). There is evidence that natural killer T cells and distinct  $\gamma\delta$  T cells may also play a role. Pathological studies have revealed perivascular lymphocytic or neutrophilic infiltrates, especially in the basal ganglia, midbrain, and thalamus.

**Neurological manifestations:** Nervous system involvement occurs in about 30% of the patients after an average of 5 years, almost always involving the CNS (Borhani Haghghi et al., 2005). Of these, 80% present parenchymal disease (Mirsattari et al., 2004). Only 3% of the patients develop neurologic symptoms without mucocutaneous lesions or ocular symptoms (Akman-Demir et al., 1999).

The following parenchymal syndromes have been described:

- Brainstem (most frequently): Ophthalmoparesis, cranial nerves affection, symptoms of cerebellar, or pyramidal dysfunction.
- Multifocal (diffuse): Variable combination of brainstem signs and symptoms, cerebral or spinal cord involvement

- Myelopathy
- Cerebral: Sensory and motor symptoms and signs suggestive of cerebral hemispheric involvement as well as encephalopathic symptoms, optic neuropathy, seizures, cognitive impairment, and psychosis

The following nonparenchymal syndromes are described:

- Cerebral venous thrombosis ([Seyahi et al., 2012](#))
- Intracranial hypertension syndrome (pseudotumor cerebri, 20%)
- Acute meningeal syndromes

In the cerebrospinal fluid, 50% of the patients show pleocytosis and protein increase. Usually there is a lymphocytic, more rarely a mixed cell or predominantly granulocytic pleocytosis (0–485, median 30/ $\mu$ L) or isolated protein elevation. Whilst in 70% of the cases there is a pathological IgG index, oligoclonal bands are often only temporarily positive, whereas an increase of IL-6 in CSF has been reported ([Hatemi et al., 2008](#)).

*Cerebral imaging:* Interestingly, brain perfusion MRI showed decreased relative cerebral blood flow in patients with Behcet's disease with and without neurological symptoms ([Alkan et al., 2012](#)), suggesting that subclinical CNS involvement may be common. MRI typically shows contrast-absorbing extensive T2 lesions, preferably in the basal ganglia or in the brain stem. These lesions are not restricted in one vessel territory; no clear predisposition for periventricular regions can be seen; in 10%–20% of the cases the spinal cord is also affected ([Banna and el-Ramah, 1991](#)).

The vascular neuro-Behcet (20% of the total group) shows intracranial hypertension as a guiding symptom. Sinus vein thromboses are presented in MRA ([Akman-Demir et al., 1999](#)). A vasculitic inflammatory affection of the arteries is rare. In the vascular Behcet syndrome, cerebrospinal fluid is usually normal except for an increased opening pressure.

*Treatment and prognosis:* There is no evidence-based standard therapy for Behcet's syndrome with neurological manifestations. Combinations of high doses of corticosteroids and immunosuppressive drugs are recommended. Cyclophosphamide, methotrexate, interferon-alpha, or azathioprine (up to 3 mg/kg) may be used as immunosuppressive agents in parenchymal Behcet. Because of its potential neurotoxicity, cyclosporine A should not be used in the treatment of NB patients. Chlorambucil should be avoided because of its myelotoxicity and increased risk of malignancies ([Hatemi et al., 2008, 2009](#)). In treatment of refractory patients infliximab or etanercept may be tried ([Sfikakis et al., 2004](#)). Interferon-alpha was found to induce long-lasting remissions. Small observational studies with non-TNF biologics such as ustekinumab, anakinra, and canakinumab report beneficial results, which await confirmation ([Hatemi et al., 2017](#)).

## Sarcoidosis

*Definition:* Sarcoidosis is not formally characterized as an autoimmune disease, although this possibility has been raised from time to time. Sarcoidosis is defined as a multisystemic granulomatosis of unknown etiology affecting mainly young adults. The characteristic histology exhibits nonacidifying epithelioid-cell granulomas. Main manifestations are located in the lymph nodes of the lung hilus, the lung parenchyma, the skin, and the eyes.

*Neurological manifestations:* Neural tissues are clinically affected in 5%–13% of the patients, including peripheral nerves, cranial nerves, meninges, brain (including hypothalamus), and/or spinal cord ([Lacomis, 2011](#)) and in autopsy in up to 27% of the cases. This is the case in the early course of a systemic sarcoidosis and rather in younger patients (30–40 years) as in about half of the cases, the neurological symptoms are included in the initial presentation ([Joseph and Scolding, 2009](#)).

Ischemia of the nervous system is the first manifestation of sarcoidosis in about 50% and in the case of cerebral infarction even 85%. In over 90% of the patients with neurosarcoidosis, there are also other system manifestations mostly hilus lymphomas (80%) and eye disease (uveitis, keratoconjunctivitis) (50%).

Cranial nerve involvement of the optic, facial, or multiple cranial nerves is common (50%–70%) ([Joseph and Scolding, 2009; Pawate et al., 2009](#)).

The second most common manifestation is an aseptic meningitis (18%–26%), especially of the basal meninges with typical meningeal signs ([Gullapalli and Phillips, 2002](#)). The third most frequent manifestation is a hydrocephalus (9%–17%), either obstructive with granulomas in the region of the III. or IV. ventricle or communicating with an inflammatory occlusion of pachyionic granulations. Hypothalamus and pituitary gland (15%–26%) are particularly frequently infected presenting with diabetes insipidus, bulimic behavior, and hypersomnia. Cerebral, subdural, and meningeal (en plaque) mass lesions can also lead to epileptic seizures (about 20%). A myelopathy

due to compressive extramedullary or intramedullary granulomas is observed in 6%–10%, peripheral neuropathy (mainly type mononeuritis multiplex) in 4%–14%, and myopathy in 7%–12% (Stern, 2004). The clinical course is unpredictable in individual cases; in two-thirds of cases it is monophasic, recurring in one-third (Zajicek et al., 1999).

**Cerebral imaging:** The typical MRI finding is a knotted or also flat thickening of the meninges, especially on the cranial base with strong contrast enhancement (Smith et al., 2004). T2 lesions can also be found without a typical distribution, therefore depending on the MRI findings; the differential diagnosis is very broad (lymphoma, glioma, meningioma, tuberculosis, multiple sclerosis in predominantly periventricular lesions, leukemic or carcinomatous infiltrations, etc.). Therefore CSF analysis including bacteriology and cytology (to rule out infectious or neoplastic differential diagnoses) is necessary. In the case of isolated CNS affliction meningeal and/or cerebral biopsies depending on the MRI findings are necessary.

**Treatment and prognosis:** Patients refractory to initial therapy with corticosteroids should receive other immunosuppressive medications, including azathioprine, cyclophosphamide, and methotrexate (Lower et al., 1997; Scott et al., 2007; Joseph and Scolding, 2009; Lacomis, 2011), or even cranial irradiation (Chapelon et al., 1990; Agbogu et al., 1995). The actual immunological nature of the sarcoid process remains obscure. In view of the recognized morbidity and mortality of the neurosarcoidosis, most authors recommend early and aggressive therapy. However, there are currently no controlled studies for therapeutic guidelines (Hoitsma et al., 2004) Single cases were also successfully treated with mycophenolate mofetil, hydroxychloroquine, TNF- $\alpha$  blockers (infliximab), and monoclonal anti-CD20 Abs (rituximab) (Scott et al., 2007).

## ANTIBODY-ASSOCIATED DISEASES OF THE CENTRAL NERVOUS SYSTEM

### General Considerations

#### **Antibodies Targeting Intracellular and Cell Surface Antigens**

Neurological diseases associated with antineuronal Abs are mostly caused by a primary autoimmune- or tumor-induced (paraneoplastic) disturbance of immune tolerance to neuronal antigens. The intracellular or surface location of the target antigen is probably the most important factor, determining pathophysiological mechanisms as well as clinical course, treatment response, and prognosis of these diseases (Table 56.2).

The Abs directed against intracellular proteins are mostly associated with tumors (so-called obligatory paraneoplastic or onconeural) with an exception of glutamic acid decarboxylase (GAD)-Abs, which are paraneoplastic in the minority of cases only. Effective antitumor immune response can partly suppress tumor growth, however results in a breakthrough of the immunological tolerance to self-antigens. Accordingly, those tumors, expressing neuronal proteins, are of the highest relevance. Tumor size often remains relatively small, so that paraneoplastic syndromes (PNS) develop in two-thirds of the cases prior to cancer diagnosis (Giometto et al., 2010). The Abs against intracellular proteins have probably no direct pathogenetic role and serve, first of all, as an important diagnostic marker. Cell-mediated immune response has a leading pathogenetic role, resulting in progressive and often irreversible neurological deficits within a few weeks or months. Neuropathological studies reveal infiltration with CD8+ cytotoxic lymphocytes, inducing neuronal apoptosis by releasing perforin and granzyme B (Bauer and Bien, 2016). Compartmentalization of cellular immune response in the nervous system and irreversibility of neuronal cell loss limit therapy efficacy and determine generally unfavorable prognosis in these syndromes. Being nonpathogenic, Abs directed against the same intracellular antigen can be associated with a number of clinically distinct neurological syndromes as well as with different tumors (Pittock et al., 2004).

Detection of onconeural Abs confirms paraneoplastic nature of the disease; however, approximately 18% of the cases remain seronegative (Giometto et al., 2010). Some common clinical features support the suspicion of PNS in these cases:

- Subacute initial manifestation, followed by progression of symptoms over weeks or months;
- Multilocular clinical presentation (several structures of the central and PNS can be affected simultaneously);
- Age >45 years (few exceptions, e.g., anti-NMDAR encephalitis associated with teratoma);
- Symmetrical lesions on the cranial MRI, for example, in the cerebellum or temporal lobe, with initial contrast enhancement and atrophy in later stages (however, often MRI is unremarkable, especially in the early stage);
- Inflammatory changes in the CSF: isolated intrathecal immunoglobulin synthesis or identical oligoclonal bands in CSF and serum, moderate lymphocytic pleocytosis (<100/ $\mu$ L), blood–brain barrier disruption.

**TABLE 56.2** Antineuronal and Antiglial Antibodies: Associated Neurological Syndromes and Tumors

Target antigen	Clinical presentation <sup>a</sup>	Association with tumor
<b>OBLIGATE PARANEOPLASTIC ABS (DIRECTED AGAINST INTRACELLULAR ANTIGENS; TUMOR ASSOCIATION &gt;95%)</b>		
Hu (ANNA-1)	Polyneuropathy (mostly sensory), encephalomyelitis, limbic encephalitis, opsoclonus–myoclonus syndrome	SCLC, rarely thymoma, prostate cancer, neuroblastoma in children
Ri (ANNA-2)	Cerebellar degeneration, opsoclonus-myoclonus syndrome	Breast cancer or ovarian cancer, SCLC, NSCLC
ANNA-3	Polyneuropathy, cerebellar degeneration, limbic encephalitis	SCLC
Yo (PCA-1)	Cerebellar degeneration	Ovarian cancer or breast cancer
MAP1B (PCA-2)	Encephalitis, LEMS, polyneuropathy	SCLC > NSCLC
CRMP5 (CV2)	Encephalomyelitis, sensory neuropathy, optic neuritis	SCLC, thymoma
PNMA1/2	Limbic encephalitis, brainstem encephalitis, potentially with hypothalamic involvement	Men <45 years: mostly germ-cell tumor; women, men >45 years: NSCLC, breast cancer
Amphiphysin	Stiff-person syndrome, encephalopathy, myopathy, cerebellar degeneration, opsoclonus–myoclonus syndrome	Breast cancer, SCLC
DNER (Tr) <sup>b</sup>	Cerebellar degeneration	Lymphoma
<b>FACULTATIVE PARANEOPLASTIC ABS (TUMOR ASSOCIATION, %)</b>		
1. Abs to synaptic receptors		
NMDAR (20%–50%)	Anti-NMDAR encephalitis	Ovarian teratoma (age: 12–45 years), carcinomas (rare, mostly >45 years)
AMPA <sub>R</sub> (65%)	Limbic encephalitis	SCLC, thymoma, breast cancer
GABA <sub>A</sub> R (50%)	Limbic encephalitis	SCLC
GABA <sub>A</sub> R (5%)	Encephalitis	Thymoma
mGluR5 (70%)	Encephalitis	Hodgkin's lymphoma
mGluR1 (10%)	Cerebellar degeneration	Hodgkin's lymphoma
α-GlyR (20%)	PERM, stiff-person syndrome	Thymoma, lymphoma, breast cancer
2. Abs to ion channels and other surface proteins		
LGI1 (5%–10%)	Limbic encephalitis	Thymoma
Caspr2 (20%)	Limbic encephalitis, Morvan's syndrome	Thymoma
DPPX (<10%)	Encephalitis	Lymphoma
VGCC (50%–70%)	LEMS, cerebellar ataxia	SCLC >> prostate cancer, thymoma, lymphoma
AQP4 (rare)	NMOSD	Breast and lung cancer, lymphoma, cervical carcinoma, and others
MOG (n.a.)	ADEM, recurrent optic neuritis and myelitis, NMOSD	n.d.
IgLON5 (rare)	Brainstem encephalitis, sleep disturbances	Breast cancer, prostate cancer, non-Hodgkin lymphoma
3. Abs to intracellular antigens		
GAD (<10%)	Stiff-person syndrome, limbic encephalitis, cerebellar degeneration	NET, breast cancer, thymoma
GFAP (22%)	Meningoencephalomyelitis	Ovarian teratoma, adenocarcinomas, others

<sup>a</sup>Rare or not fully characterized associations between Abs and clinical syndromes are not listed.<sup>b</sup>Transmembrane protein.

*Abs*, Antibodies; *ADEM*, acute disseminated encephalomyelitis; *AMPA<sub>R</sub>*, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; *ANNA*, antineuronal nuclear antibody; *AQP4*, aquaporin-4; *Caspr2*, contactin-associated protein-related 2; *CRMP5*, collapsin-response mediator protein 5; *DNER*, Delta/Notch-like epidermal growth factor-related receptor; *DPPX*, dipeptidyl-peptidase-like protein-6; *GABA<sub>A</sub>R*, gamma-aminobutyric acid receptor; *GAD65*, glutamate decarboxylase (65 kDa); *α-GlyR*, glycine receptor alpha 1; *GFAP*, glial fibrillary acidic protein; *LGI1*, leucine-rich glioma inactivated 1; *MAP1B*, microtubule-associated protein 1B; *mGluR*, metabotropic glutamate receptor; *NET*, neuroendocrine tumors; *NMDA*, N-methyl-D-aspartate receptor; *NMOSD*, neuromyelitis optica spectrum disorder; (*N*)*SCLC*, (non)small cell lung cancer; *PCA*, Purkinje cell cytoplasmic antibody; *PNMA*, paraneoplastic Ma antigen; *VGCC*, voltage-gated calcium channel; *NMDAR*, N-methyl-D-aspartate receptors.

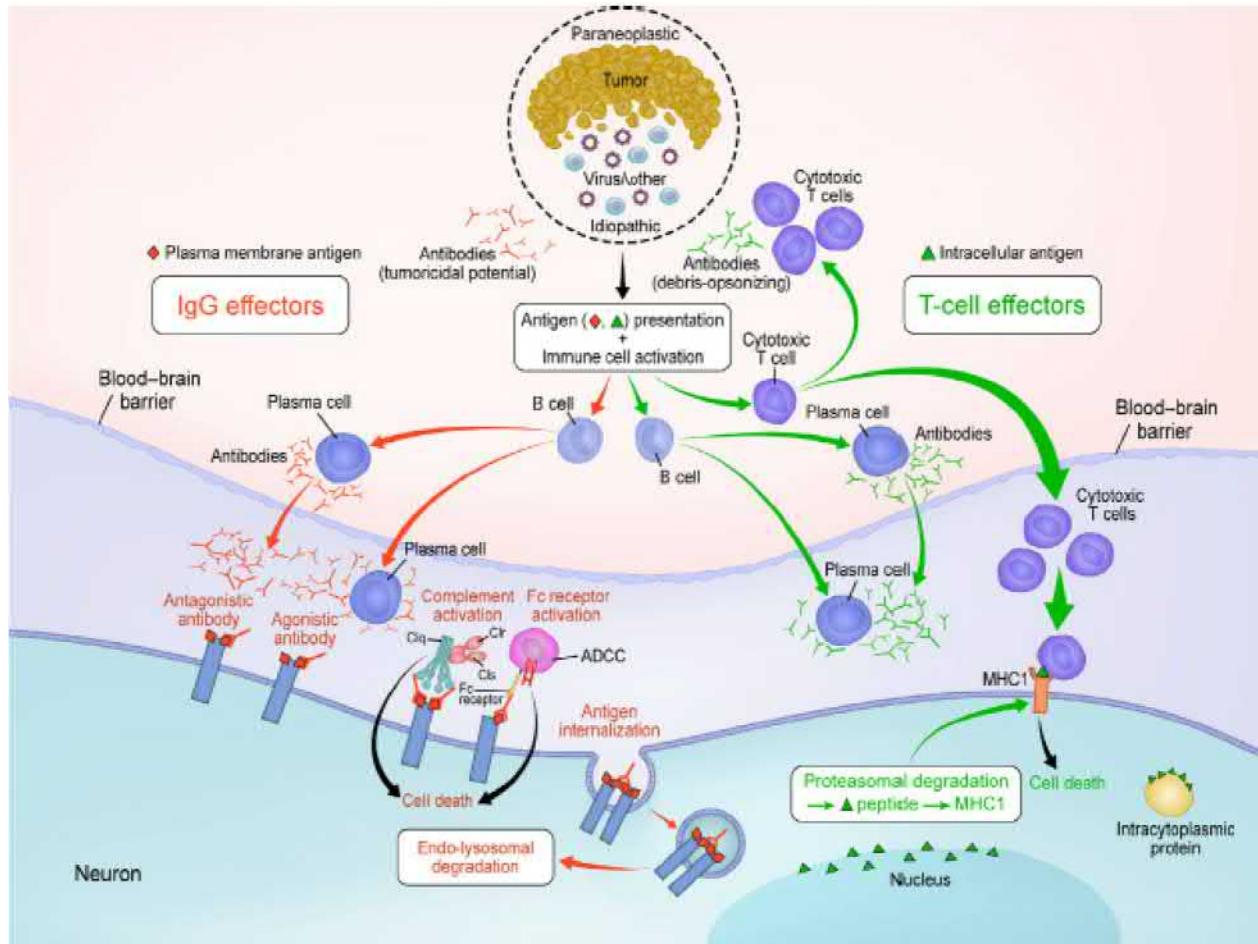

Adapted from Ayzenberg, I., Gold, R., Kleiter, I., 2017. Management of immune-mediated paraneoplastic neurological disorders. *Neuro. Inter. Open* 01 (04), E264–E274. doi: 10.1055/s-0043-112730.

In contrast, *Abs directed against surface antigens* are usually only facultative paraneoplastic and occur, especially in young patients, often as a primary autoimmune disorder. Targeting functionally important surface molecules, for example, synaptic receptors, ion channels, or associated membrane proteins, these Abs are of a direct pathogenetic significance.

Following pathogenetic mechanisms have been supposed (see Fig. 56.1) (Pittock and Vincent, 2016):

- Receptor cross-linking and internalization, leading to a decreased receptor density on the cell membrane;
- Receptor agonistic or antagonistic effects;
- Activation of the complement cascade or Ab-dependent cell-mediated cytotoxicity.

Despite, being usually of IgG1 subclass, several Abs surprisingly demonstrate *predominantly IgG4 reactivity* [leucine-rich glioma inactivated-1 (LGI1)-, contactin-associated protein-like-2 (CASPR2)-, IgLON5-Abs, etc.]. IgG4 are known to be functionally bispecific and monovalent. They are not able to induce cross-linking, complement activation, or cell-mediated cytotoxicity and have been traditionally considered as noninflammatory.

**FIGURE 56.1** Pathogenetic mechanisms of the antibodies, targeting intracellular, and cell surface antigens. Loss of immune tolerability to neural antigens can be initiated as a part of tumor- or infectious-induced immune response or be primary autoimmune (idiopathic). Intracellular antigens (green diamond) are not accessible for antibodies. Accordingly, these antibodies have no pathogenetic role and are diagnostically relevant only. However, peptides derived from these proteins can be displayed on upregulated MHC class I molecules, being accessible to specific cytotoxic T cells. In line with this, denatured proteins can be used for the testing of Abs, targeting nuclear, or cytoplasmic proteins (e.g., Line Blot).

In contrast, Abs-targeting membrane proteins (e.g., receptors, ion channels, or associated molecules, red diamond) are pathogenetic and can cause cellular dysfunction directly. Several injury mechanisms, including agonist or antagonist effects, receptor cross-linking and internalization or its dislocation from the synapse, activation of the complement, or antibody-dependent cell-mediated cytotoxicity have been proposed. Diagnostic tests, using preserved three-dimensional structure of target proteins (e.g., cell-based assays), should be used for their identification. MHC, Major histocompatibility complex. Adapted from Pittock, S.J., Vincent, A. Autoimmune Neurology. Elsevier, Chapter 1, permission requested.

Abs-induced mechanical interference of the ligand-receptor interaction has been supposed as a common pathogenetic mechanism in IgG4-related neurologic diseases (Huijbers et al., 2015).

Dysfunction of the target protein determines characteristic clinical presentation of the syndromes associated with surface antigens [e.g., short faciobrachial dystonic seizures (FBDS) in patients with LGI1-Abs]. Abs-mediated dysfunction of the targeted cell surface proteins is potentially reversible and neuronal or synaptic loss are less severe compared to classical PNS with Abs against intracellular antigens. Accordingly, Abs-depleting immunotherapies, for example, plasma exchange or immunoabsorption in the acute stage, often result in a significant clinical improvement. Patients with Abs to surface targets have a considerably better prognosis compared to those with Abs to intracellular antigens.

### **Antibodies Nomenclature**

Nomenclature of auto-Abs has varied over time and so can be confusing due to a dual terminology. Initially Abs were named after the first two letters of the last name of the index patient (e.g., Hu, Ri) or investigator (e.g., Tr-Abs described by Trotter et al., 1976), later after the antigen localization (ANNA-1) or after clinical syndrome [paraneoplastic cerebellar ataxia 1, Purkinje cell antigen (PCA)-1]. Once target protein identified, the name changed to that of the antigen (e.g., Delta/Notch-like epidermal growth factor-related receptor, DNER).

### **Diagnostical Considerations: Detection of Antibodies**

Antibodies testing can be conducted not only in serum, but also in CSF (Ig level is approx. 300–500 times lower, if no intrathecal production occurs), saliva (100 times lower), or tears (200 times lower) (Burns et al., 1982; Waters et al., 2016). Most of the studies have been performed in serum and CSF. Sensitivity of the Abs-testing may either be better in serum for one disease [e.g., AQP4-Abs bei neuromyelitis optica spectrum disease (NMOSD)] or in CSF for another (e.g., NMDAR-encephalitis). Accordingly, by justified suspicion, both serum and CSF should be tested.

There are several methods for the identification of antineuronal and antiglia Abs.

Indirect immunohistochemistry (IHC) on animal brain tissue is an excellent screening method, detecting Abs against both intracellular and cell surface proteins. Abs binding to intracellular (cytosolic or nuclear) antigens recognize linear, denatured epitopes and so can be further identified with a Western Blot. In practice, commercially available line blots (LBs), allowing testing of multiple targets with high antigen specificity in an individual strip, are the method of choice. In contrast, Abs targeting membrane antigens recognize three-dimensional structure of proteins. Several methods, including cell-based assays (CBAs), primary neuron cultures (in research laboratories), radioactive or fluorescence-based immunoprecipitation assays, or enzyme-linked immunosorbent assay (ELISA), can be used for their identification. Due to several technical issue, ELISA and radioactive or fluorescence-based methods seem to be less specific in some cases (Pitcock et al., 2014; Waters et al., 2012). CBA with (transfected) target antigen expressed in mammalian cells is increasingly being used in the clinical practice.

Combination of IHC, as a screening tool, with an antigen-specific detection assay (LB for intracellular or CBA for surface antigens) in both serum and CSF is diagnostically most useful (Probst et al., 2014). Inconsistent results of several tests and identification of the low titer Abs may occur. Positive reactivity in the brain tissue as well as in CBAs has higher clinical relevance compared to sera positive in CBAs only. Presence of the intrathecal Abs production is of a high significance for some diseases and can even correlate with its course, at least intra-individually (e.g., NMDAR encephalitis) (Dalmau et al., 2017). Presence of low titer Abs in serum without appropriate clinical syndrome have usually no direct significance and can be seen in healthy people as well as in patients with other neurologic disorders as a secondary immune phenomenon. However, in case of positive onconeural Abs, a tumor screening should be performed at diagnosis and up to 4 years later even if there is no corresponding neurological manifestation. Generally, it is unclear if healthy people with positive antineuronal Abs in serum are of an increased risk to become ill in the future. Concerning the Ig-class, the Abs of IgG class (mostly IgG1 or IgG4) are clinically relevant, while those of IgA and IgM class seems to have no pathogenetic role in the Abs-associated CNS diseases (Dahm et al., 2014; Dalmau et al., 2017). Abs testing under treatment with an IVIG or natalizumab (due to  $\alpha$ 4 chain integrin expression on HEK (human embryonic kidney) cells) must be interpreted with caution, as false positive (and probably also false negative under IVIG) findings may occur (Sánchez Gomar et al., 2014).

### **Principles of Treatment**

Given that the majority of the Abs-associated disorders are rare, treatment recommendations are usually based on case series and expert opinions. Considering potentially irreversible damage (especially in case of

intracellular target antigen), treatment should be started as early as possible. There are three main principles of management:

1. Immunotherapy should be started in both primary autoimmune and paraneoplastic cases as early as possible, preferably within few weeks after disease onset (Keime-Guibert et al., 2000; Vernino et al., 2004; Widdess-Walsh et al., 2003). If the suspicion of PNS is clearly supported by clinical evidence, immunotherapy may be started even before definite tumor diagnosis clarified (exception: steroid in case of suspected lymphoma!). Adequate immunosuppression seems not to affect the tumor outcome (Keime-Guibert et al., 1999).
2. In paraneoplastic cases prompt and aggressive tumor therapy must be initiated to remove the source of peripheral antigen stimulation. Adequate tumor treatment alone can result in the stabilization or even improvement of the neurological deficits (Candler et al., 2004; Graus et al., 2001; Shams'ili et al., 2003).
3. Symptomatic treatment can provide effective control in several syndromes.

#### TUMOR DETECTION AND MANAGEMENT

In about two-thirds of the paraneoplastic cases, the tumor remains unknown at the time of onset of neurological symptoms (Giometto et al., 2010). Since the autoimmune response slows down malignant growth, the tumors may be initially relatively small and difficult to diagnose. Following tumors are most frequently associated with PNS: lung cancer (small cell >> non-small cell lung cancer), carcinoma and teratoma of the ovaries, breast cancer, Hodgkin's disease and non-Hodgkin lymphoma, thymoma, and prostate cancer (Darnell and Posner, 2006; Giometto et al., 2010). Testicular tumors in young men and neuroblastoma in small children should be also considered. Multiple anti-neuronal Abs are not rare and help to focus the diagnostic workup on specific tumors (Horta et al., 2014; Pittock et al., 2004). Based on suspected tumor, a targeted stepwise diagnostic approach is recommended (Table 56.3, Titulaer et al., 2011). If standard workup is negative, a whole-body FDG PET/CT should be performed (Hadjivassiliou et al., 2009). Potentially false-negative findings of the FDG PET/CT in tumors with low proliferation rates (e.g., differentiated teratomas) or nonmetastatic skin cancers should be considered. If no tumor is detected, the diagnostic workup should be repeated in 3 months and then every 6 months for a period of at least 4 years (Titulaer et al., 2011).

#### PRINCIPLES OF IMMUNOTHERAPY

Immunosuppression at the acute stage usually includes either corticosteroid pulse therapy (e.g., 5 × 1000 mg methylprednisolone IV, if needed followed by oral tapering) or IVIG G (IVIG, e.g., 0.4 g/kg bodyweight for 5 days). Should the patient not improve, treatment escalation to an apheresis therapy (plasma exchange or immunoabsorption) can be undertaken. IVIG treatment and apheresis therapies are more effective in patients with Abs directed against surface antigens compared to intracellular antigens (Graus et al., 1992; Leyboldt and Wandinger, 2014; Uchuya et al., 1996; Vernino et al., 2004). If no improvement occurs, an early (up to 2 weeks after the primary treatment) escalation to cyclophosphamide (as a short-term high-dose treatment with 750–1000 mg/m<sup>2</sup> IV) or rituximab (e.g., 500 mg IV on days 1 and 15) can be undertaken (Shams'ili et al., 2006; Stark et al., 1995; Vernino et al., 2004).

**TABLE 56.3** Recommendations for Stepwise Cancer Screening in Patients With Paraneoplastic Syndromes (Giometto et al., 2010; Titulaer et al., 2011)

Tumor, prevalence <sup>a</sup>	Stepwise diagnosis (sensitivity of test method)
Lung cancer SCLC 38.4%, NSCLC 7.9%	Chest CT scan (80%–85%) → FDG PET(CT) → bronchoscopy/EB-US with biopsy
Ovarian cancer 10.5%	Transvaginal US (69%–90%), CA125 (62%) → pelvic/abdominal CT scan → FDG PET (CT)
Ovarian teratoma <sup>a</sup>	Transvaginal US (58%–94%) → pelvic/abdominal CT/MRI (93%–96%) → → chest CT scan, if required (extrapelvic teratomas)
Breast cancer 9.7%	Mammography, US → breast MRI (71%–100%), FDG PET (CT), if required
Hodgkin's disease 3.0%, non-Hodgkin's lymphoma 3.4%	Chest/abdomen CT scan, US → FDG PET (CT)
Thymoma 2.7%	Chest CT/MRI (75%–90%) → FDG PET (CT)
Testicular tumors 1.7%	US (72%), AFP + β-HCG → pelvic CT/MRI*, biopsy in the case of microcalcifications

<sup>a</sup>Prevalence among all PNSs, based on Euronetwork Database; no data on ovarian teratoma available.

AFP, alpha fetoprotein; β-HCG, beta human chorionic gonadotropin; CA125, cancer antigen 125; EB-US, endobronchial ultrasound; (N)SCLC, (non)small cell lung cancer; US, ultrasound; PNS, peripheral nervous system.

Adapted from Ayzenberg, I., 2017. *Neurol. Int. Open*, Thieme permission requested.

Long-term treatment usually includes oral immunosuppressants (e.g., azathioprine 2–3 mg/kg/d, mycophenolate mofetil 250–1000 mg b.i.d., cyclophosphamide 1–2 mg/kg/d) as a monotherapy or in combination with oral steroids or rituximab (e.g., every 6 months). IVIG at regular intervals (usually every 4–8 weeks) are effective in some conditions (e.g., stiff-person syndrome).

## Antibody-Associated Clinical Syndromes

Immune response can be directed against proteins expressed in central or PNS, neuromuscular synapses, or muscles. In many cases patients develop a combination of several syndromes (multilocular manifestation) and may have several auto-Abs simultaneously. Clinically, following group of diseases can be differentiated ([Gozzard and Maddison, 2010](#); [Leypoldt and Wandinger, 2014](#)):

- In the central nervous system:
  - Encephalomyelitis
  - Limbic encephalitis (LE)
  - Subacute cerebellar degeneration (SCD)
  - Brainstem encephalitis
  - Opsoclonus–myoclonus syndrome (OMS)
  - Stiff person syndrome
  - Isolated optic neuritis and/or retinopathy
  - Isolated myopathy/myelitis
  - Neuromyelitis optica and further disorders associated with antigliial Abs
- In the PNS, neuromuscular junction and the muscle:
  - Paraneoplastic polyneuropathies (include subacute sensory neuronopathy, distal symmetric sensorimotor neuropathy, polyradiculoneuropathy)
  - Pandysautonomia (include chronic intestinal pseudo-obstruction)
  - Neuromyotonia
  - Myasthenia gravis
  - Lambert–Eaton syndrome
  - Myositis

In this chapter we will focus on the clinical and pathophysiological features of the Abs-associated CNS disorders. With regard to myasthenia gravis, Lambert–Eaton syndrome, polyneuropathies, and myositis reader should refer to appropriate chapters.

Disorders associated with surface antigens often have a characteristic clinical presentation (e.g., NMDA receptor encephalitis) and are described for every well-characterized antigen separately. If no clear association between a distinct syndrome and a specific auto-Ab exists (e.g., SCD), typical clinical features and most common serological findings are discussed. Finally, a short characterization of both intracellular and surface antigens is given.

### **Autoimmune Encephalomyelitis and Limbic Encephalitis**

Clinical spectrum of the Ab-associated encephalomyelitis can be quite heterogeneous, depending on the target antigen and disease severity. The full-blown autoimmune encephalomyelitis (AE) has multilocular manifestation, often involving limbic systems, brainstem, spinal cord as well as PNS ([Giometto et al., 2010](#)). Combination of a psychiatric symptom (from depression and irritability to hallucinations and bizarre behavior), cognitive changes (e.g., short-time memory loss), and seizures is characteristic and classified as LE. This term is diagnostically helpful, as LE is usually autoimmune, however anatomically inaccurate as other areas beside the limbic systems are often involved. Historically, so-called classical variants of AE and LE have been thought to be obligatory paraneoplastic and mostly associated with Abs against intracellular antigens [e.g., Hu, Ma, GAD, CV2/collapsing response mediator protein 5 (CRMP5)]. Over the last decade, this disease spectrum has been substantially expanded, due to the identification of Abs to functionally active surface molecules [NMDAR, voltage-gated potassium channels (VGKC), dipeptidyl-peptidase-like protein 6 (DPPX),  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor (AMPAR),  $\gamma$ -aminobutyric acid (GABA) type-b receptors (GABAbRs), GABA type-a receptors (GABAaR), IgLON5, metabotropic glutamate receptor (mGluR) 5, dopamine receptor 2, glycine receptor (GlyR)].

By "classical" forms the prognosis is usually poor with the exception of Ma2-Ab-associated encephalomyelitis, in which approx. 30% of the patients experience improvement after adequate tumor treatment and immunotherapy (Dalmau et al., 2004). In contrast, patients with Abs to surface antigens have a much better outcome, except for cases with additional onconeural Abs (Höftberger et al., 2013, 2015).

#### ANTI-N-METHYL-D-ASPARTATE RECEPTOR ENCEPHALITIS

**EPIDEMIOLOGY AND CLINICAL CHARACTERISTICS** NMDAR encephalitis is the most common type of Ab-mediated encephalitis and accounts for approx. 4% of all encephalitis (Granerod et al., 2010). About 80% patients are female (with peak incidence between 13 and 30 years), the majority of whom have ovarian teratomas (Dalmau et al., 2008). The occurrence of teratomas increases among adolescents and is at 15% in female patients <14 years, at 30% <18 years and at 60% >18 years (Dalmau et al., 2011). In patients >45 years NMDAR encephalitis can be also associated with carcinomas (Titulaer et al., 2013b). In children <12 years and in men paraneoplastic etiology is rare. Prompt and targeted tumor screening, including abdominal MRI and a thorough gynecological examination, is crucial in NMDAR encephalitis. FDG PET-CT is not sensitive enough to detect well-differentiated teratomas.

Autoimmune encephalitis may also occur as a secondary autoimmune phenomenon after herpes simplex encephalitis (Armangue et al., 2014a). About 20% of these patients develop NMDAR-Abs, resulting in behavioral changes and choreoathetosis in children and cognitive and psychiatric abnormalities in adults (Armangue et al., 2015). Other cases seem to be primary autoimmune or of unknown etiology.

Clinically, NMDAR-encephalitis can manifest with a prodromal phase, resembling a viral infection, and further rapid deterioration. Patients develop behavioral and psychiatric changes (including an acute psychosis, hallucinations, delusions, and agitation), memory loss, and seizures. Afterwards a catatonic or comatose state with autonomic instability develops and patients frequently undergo intensive care unit treatment. The acute stage of the disease can last for several months and mortality, mostly due to secondary complications, is about 7% (Titulaer et al., 2013a). In case of adequate treatment patients slowly recover (up to 1–2 years), often exhibiting previous disease stages in a reverse order. In some patients mild cognitive deficits may persist (Finke et al., 2012).

Positive NMDAR-Abs testing is crucial for the diagnosis. Testing in CSF is more sensitive than in serum and is obligatory if anti-NMDAR-encephalitis is suspected (Gresa-Arribas et al., 2014). NMDAR-Abs of IgM and IgA class have probably no clinical relevance (Dahm et al., 2014; Dalmau et al., 2017). Isolated positive NMDAR-IgG of a low titer in serum only can be also seen in healthy controls. Brain MRI is abnormal in less than a half of patients and usually demonstrates nonspecific transient T2/FLAIR signal abnormalities in medial temporal lobe and hippocampus as well as other cortex areas, basal ganglia, cerebellum, and white matter (Titulaer et al., 2013a). CSF lymphocytosis is common during first weeks and oligoclonal bands appear later (Irani et al., 2010b). Electroencephalographic abnormalities can be seen in the majority of patients, including epileptiform activity, generalized slowing and characteristic "extreme delta brush" pattern in ca. 30% (Schmitt et al., 2012).

**PATHOPHYSIOLOGY** Expression of NMDAR in the neuronal component of teratomas or other tumors (or release by viral encephalitis) triggers an initial peripheral autoimmune response. Further restimulation of memory B-lymphocytes in CNS results in antigen-driven affinity maturation, clonal expansion and differentiation into long-lived plasma cells, producing NMDAR-Abs intrathecally (Dalmau, 2016). Antibodies target NR1 subunit of NMDAR and are directly pathogenic (Hughes et al., 2010; Planagumà et al., 2015). Despite being predominantly of IgG1 subclass, NMDAR-Abs do not cause relevant neuronal loss yet impair their function. Binding of Abs results in cross-linking and internalization of NMDA receptors from the cell surface (Hughes et al., 2010; Moscato et al., 2014). This mechanism explains the good outcome, with good or even complete recovery in about 75% after adequate therapy (Dalmau et al., 2011).

**TREATMENT** Treatment efficacy data of four larger retrospective studies are available (Dalmau et al., 2008; Irani et al., 2010b; Titulaer et al., 2013a; Viaccoz et al., 2014). Any tumor detected should be immediately removed. Up to 80% of the patients improve with tumor resection in combination with a first-line immunotherapy: steroid pulse therapy, IVIG, or apheresis therapy (Dalmau et al., 2011). Early immunotherapy (<40 days after initial manifestation) is associated with a significantly better prognosis (Irani et al., 2010b). Early plasma exchange therapy or immunoabsorption are probably preferable (Dogan Onugoren et al., 2016; Heine et al., 2016; Pham et al., 2011). In nonparaneoplastic cases, first-line immunotherapy is effective in approximately half of the patients only (Dalmau et al., 2011; Titulaer et al., 2013a). If no improvement occurs, second-line therapy with rituximab or cyclophosphamide should be considered (Gastaldi et al., 2016). Cyclophosphamide crosses the

blood–brain barrier but is associated with toxic effects and has a negative impact on fertility which is highly relevant in young women. For this reason, rituximab continues to be increasingly used in clinical practice. In approx. 75% of the cases, second-line therapy results in further significant improvement of the symptoms (Dalmau et al., 2008, 2011; Pham et al., 2011; Titulaer et al., 2013a). Successful administration of other immunosuppressants, including azathioprine, methotrexate, and mycophenolate mofetil, has also been reported (Gastaldi et al., 2016). Of a special interest is an escalation therapy with the proteasome inhibitor bortezomib. Bortezomib results in a targeted reduction of plasma cells and consequently Abs production. In two case series significant clinical improvement and a rapid decrease in serum NMDAR-Ab-titers have been reported (Behrendt et al., 2016; Scheibe et al., 2017).

**RELAPSES** Relapses can occur several months to years after the first episode. The relapse rate lies in the range of 12%–25%; it is higher in patients with nonparaneoplastic disease compared with patients after teratoma resection (Dalmau et al., 2008; Titulaer et al., 2013a). In these cases, second-line immunotherapy for a limited period of time (e.g., 2 years) is recommended. The reason why some patients relapse remains unclear; however, an intraindividual correlation between Ab-titer changes (especially in the CSF) and development of a recurrence has been reported (Gresa-Arribas et al., 2014). In contrast rapid decline in anti-NMDAR-Ab-titers in serum and CSF is characteristic for the monophasic course (Gresa-Arribas et al., 2014; Irani et al., 2010b).

#### ANTIVOLTAGE-GATED POTASSIUM CHANNELS ANTIBODY ENCEPHALITIS (VOLTAGE-GATED POTASSIUM CHANNELS ENCEPHALITIS)

VGKC are expressed both in the CNS and juxtaparanodally on peripheral motor nerves. Depending on the precise target antigen patients may develop both central and PNS disorders. Historically, VGKC-Abs were first described in Isaacs–Mertens syndrome, an autoimmune peripheral nerve hyperexcitability, that manifests with spontaneous muscle contractions and stiffness (Hart et al., 1997). Interestingly, clinical features of this condition resemble symptoms of poisoning with the VGKC (Kv1) toxin alpha-dendrotoxin. However primary antigens in this disease are not the Kv channel subunits, but three VGKC-associated proteins: LGI1, CASPR2, and contactin-2 (Irani et al., 2010a; Lai et al., 2010; Lancaster et al., 2011). While LGI1- and CASPR2-Abs are associated with well-defined clinical syndromes, the pathogenetic role of contactin-2 Abs remains unclear as it never occurs isolated. The significance of other anti-VGKC-Abs (positive in screening test against VGKC, but negative in specific CBA for LGI1-, CASPR2-, and contactin-2-Abs) also remains questionable (van Sonderen et al., 2017). About 38% of these Abs target an intracellular epitope of the Kv1 subunit and are presumably of no clinical significance (Lang et al., 2017).

**LEUCINE-RICH GLIOMA INACTIVATED-1 ENCEPHALITIS** LGI1-Abs are the most prevalent type of VGKC-Abs. In contrast to NMDAR encephalitis, the majority of patients with LGI1-encephalitis (60%–80%) are men, mainly in the second half of life. Anti-LGI1 encephalitis mostly develops as a primary autoimmune disorder. Paraneoplastic cases are rare (5%–10%) and usually associated with thymoma or lung cancer (Irani et al., 2010a; Lai et al., 2010).

Typical clinical manifestation includes LE with a subacute disturbance of memory, behavior changes and loss of spatial orientation, hyponatremia (in approx. 60%), and characteristic FBDS (in approx. 50%). FBDS last only few seconds (<3 seconds), involve unilateral arm and face (or leg) and occur up to 100 times a day (Irani et al., 2011). They usually develop prior to cognitive impairment and prompt start of immunotherapy may probably prevent disease progression (Irani et al., 2013). However, due to atypical presentation FBDS often remain unrecognized by physicians. At a later stage of the disease, patients develop generalized seizures. MRI reveals T2 hyperintensities of the medial temporal lobe in two-thirds of cases (Irani et al., 2010a). Approximately 75% of the patients respond to immunotherapy and have favorable prognosis (van Sonderen et al., 2016a,b). Yet recovery is often incomplete and cognitive deficits including memory impairment may persist (Malter et al., 2014). In line with this, neuropathological findings show immunoglobulin deposits, partially with complement activation and moderate lymphocytic infiltration, as well as neuronal loss in the hippocampus and amygdala (Bauer and Bien, 2016). This finding is unexpected, as LGI1-Abs predominantly belong to IgG4 subclass and do not activate complement (Irani et al., 2012). Correlation of the LGI1-Abs titer and clinical syndrome confirms the pathogenetic role of these Abs. LGI1-Abs have been shown to inhibit interaction between LGI1 and ADAM22/23 proteins, reducing synaptic AMPA receptor clusters and provoking epileptogenic activity (Ohkawa et al., 2013).

**CONTACTIN-ASSOCIATED PROTEIN-LIKE-2 ENCEPHALITIS** Caspr2 encephalitis is a rare variant of LE. It occurs almost exclusively in men (80%–90%) with a manifestation age around 60 years. The reason for the male predominance remains unclear as most of autoimmune diseases occur more frequently in women. Being a transmembrane protein with a large extracellular domain, Caspr2 is expressed in both central and PNS and serves as a good accessible antigen target. Accordingly Caspr2-Abs are associated with a wide range of central and peripheral neurologic syndromes, including autoimmune encephalitis, cerebellar symptoms, neuromyotonia (Isaac–Mertens' syndrome), neuropathic pain, dysautonomia, and weight loss (Joubert et al., 2016). Combination of at least three of these core symptoms can be found in 77% of the patients (van Sonderen et al., 2016a). Full-blown variant, including encephalitis signs and neuromyotonia accompanied by autonomous involvement and insomnia is known as Morvan's syndrome. Tumor incidence lies by approximately 15%–20% (Joubert et al., 2016; van Sonderen et al., 2016a). Thymomas, being most common tumor type, can be also associated with myasthenia gravis in some patients. Signs of neuromyotonia are almost always present in paraneoplastic cases. In contrast tumors are rare in patients with isolated LE. In nonparaneoplastic cases immunotherapy is usually beneficial and the prognosis favorable. CASPR2-Abs have been identified in several cases of Creutzfeldt–Jakob disease, probably as a secondary immune phenomenon. This finding can be diagnostically misleading due to partly similar clinical manifestation of both conditions (Zuhorn et al., 2014).

Precise pathogenesis of Caspr2-Abs associated disorders remains unclear. Similar to LGI1-Abs, Caspr2-Abs of IgG4 subtype are present in all patients, in 63% in combination with IgG1. As known, IgG4 are able to exchange half-molecule (so-called Fab-arm exchange) and so are functionally monovalent (Aalberse et al., 2009). Accordingly, IgG4 are unable to induce cross-linking and internalization of the target antigen. These Abs have only low affinity for the Fc $\gamma$  receptor and do not induce cellular as well as complement-dependent cytotoxicity. Direct binding and alteration of the Caspr2 function (e.g., downregulation of Caspr2/Kv1.1/1.2 complexes on the peripheral nerve) has been supposed as a possible mechanism; however, further investigations are needed (Irani et al., 2010a; van Sonderen et al., 2016c).

**TREATMENT OF LEUCINE-RICH GLIOMA INACTIVATED-1- AND CONTACTIN-ASSOCIATED PROTEIN-LIKE-2-ENCEPHALITIS** Data are scarce and partly reported before identification of LGI1- and CASPR2-Abs. There are no prospective comparative studies available. In most cases, symptomatic treatment with anticonvulsants alone is insufficient. In paraneoplastic cases, treatment of the underlying tumor is crucial. Regarding initial immunotherapy, either steroids, IVIG, or apheresis therapy may be used. Some findings indicate that combined and earlier (within the first 2 months after manifestation) treatment is associated with a better prognosis (Gastaldi et al., 2016; Thieben et al., 2004). Combination of IVIG with steroids was superior to steroid monotherapy in a small retrospective study (Shin et al., 2013). In an open prospective study all patients ( $n = 9$ ) improved when treated with the combination of plasma exchange, IVIG, and steroid pulse therapy, followed by oral steroid treatment (Wong et al., 2010). In most cases first a reduction in seizure frequency is noted, while cognitive deficits tend to respond much later (Vincent et al., 2004). Data regarding long-term therapy are limited. Azathioprine, tacrolimus, mycophenolate mofetil, rituximab, or tocilizumab may be tried in refractory cases (Gastaldi et al., 2016; Krogias et al., 2013). Patients with both LGI1- and CASPR2-encephalitis may experience relapses (van Sonderen et al., 2016a,b). In LGI1-encephalitis a correlation with an increase in Ab-titers has been observed (Irani et al., 2013).

### **Encephalitis Associated With Antibodies to Other Neuronal Surface Proteins**

#### **DIPEPTIDYL-PEPTIDASE-LIKE PROTEIN 6 ENCEPHALITIS**

DPPX encephalitis is a rare and mostly primary autoimmune condition. Target protein is a regulatory subunit of neuronal Kv4.2 potassium channels, highly expressed in hippocampus, cerebellum, and plexus mesentericus (Nadal et al., 2003). Typical clinical manifestation includes LE with symptoms of central hyperexcitability (agitation, myoclonus, tremor, sleep disturbance, and seizures), brainstem pathology (eye movements abnormalities, ataxia, dysarthria, or dysphagia) often preceded or overlapped with intense diarrhea and weight loss (Boronat et al., 2013; Tobin et al., 2014). Few patients with DPPX-Abs and PERM (progressive encephalomyelitis with rigidity and myoclonus) syndrome were also reported (Balint et al., 2014). CSF analysis usually demonstrates inflammatory changes, including pleocytosis and increased IgG index or positive oligoclonal bands. DPPX encephalitis was rarely associated with lymphoma or chronic lymphocytic leukemia. Being often insidious in onset, encephalitis can be severe on the later stages. In a retrospective case series, early immunotherapy (corticosteroids, IVIG, PLEX (plasma exchange) alone or combined with rituximab or cyclophosphamide) resulted in

improvements in about two-thirds of the patients (Tobin et al., 2014). Long-term immunotherapy is usually needed and its decrease or cessation may cause relapses (Boronat et al., 2013).

#### **α-AMINO-3-HYDROXY-5-METHYL-4-ISOXAZOLEPROPIONIC ACID RECEPTOR ENCEPHALITIS**

AMPAR encephalitis mostly occurs in females with a manifestation age between 30 and 70 years. This form of encephalitis is tumor-associated in about two-thirds of cases (mostly thymoma, lung, or breast cancer) and accordingly often characterized by an aggressive course (Lai et al., 2009). Almost all patients develop symptoms of LE such as short-term memory loss, confusion, and abnormal behavior (Höftberger et al., 2015). Additionally, seizures, prominent psychiatric symptoms, ataxia, or abnormal movements may occur. In some cases disease manifests as a pure psychosis (Graus et al., 2010). MRI is usually pathologic and demonstrates abnormalities predominantly located in the temporal lobe. Involvement of other regions, corresponding diffuse encephalitis, is also not rare. AMPAR-Abs testing in CSF seems to be more sensitive than in serum (Höftberger et al., 2015). Auto-Abs target GluA1 or GluA2 subunits of the AMPA receptors (Lai et al., 2009). Similar to NMDAR-encephalitis, binding of the Abs cause selective internalization and degradation of AMPAR clusters as well as decrease of AMPAR-mediated excitatory postsynaptic currents (Peng et al., 2015).

Tumor resection in combination with early immunotherapy (steroids or IVIG) can lead to clinical improvement. However, relapses may occur and are unrelated to tumor recurrence. In most cases, relapses can be prevented by treatment with rituximab and cyclophosphamide (Höftberger et al., 2015). Presence of classical onconeural Abs (e.g., CRMP5, amphiphysin, SOX1) is associated with a poor outcome.

#### **GABA-B RECEPTOR ENCEPHALITIS**

GABA<sub>B</sub>R is a metabotropic inhibitory receptor, mainly expressed in hippocampus, amygdala, cerebellum, and thalamus. Dysfunction of these receptors results in excessive neuronal activity and synchronization, leading to seizures and memory deficits (Emson, 2007; Enna and Bowery, 2004). In line with this, patients with GABA<sub>B</sub>R encephalitis usually develop LE, including early and often refractory seizures, memory loss, and variety of neuropsychiatric symptoms (Lancaster et al., 2010). Rare atypical presentations include cerebellar ataxia and OMS (Höftberger et al., 2013). GABA<sub>B</sub>R-encephalitis is usually monophasic and in 50% paraneoplastic [mostly small-cell lung cancer (SCLC) in patients >50–60 years old] (Höftberger et al., 2013; Lancaster et al., 2010). Both genders are almost equally affected. MRI is pathologic in about half of patients and often demonstrates abnormalities of the mesial temporal lobe. Out of the total number of patients, two-thirds have pleocytosis in CSF.

GABA<sub>B</sub>R-Abs are directed against extracellular B1 subunit of the receptor and are mainly of IgG1 class. It is supposed, that these Abs have a direct pathogenetic role (Höftberger et al., 2013; Lancaster et al., 2010). Few available histopathological findings demonstrated infiltration of plasma cells as well as granzyme B-producing CD8+ lymphocytes, assuming that probably both humoral and cellular (especially in paraneoplastic cases) mechanisms can be involved in the pathogenesis of this condition (Golombeck et al., 2016; Höftberger et al., 2013).

Consistent with surface location of the target protein, immunotherapy (if necessary in combination with tumor resection and chemotherapy) is effective in most cases and may even result in complete recovery (Höftberger et al., 2013). Unfavorable tumor prognosis and presence of the classical onconeural Abs (e.g., Ri, amphiphysin, SOX1) are associated with a poor outcome.

#### **γ-AMINOBUTYRIC ACID TYPE-A RECEPTOR ENCEPHALITIS**

This form of encephalitis seems to be very rare and until now three case series have been reported only (Petit-Pedrol et al., 2014; Pettingill et al., 2015; Spatola et al., 2017). It may occur in children as well as in adults. Paraneoplastic cases of the disease are not rare in adults and usually associated with thymoma (Spatola et al., 2017). Few small children developed GABA<sub>A</sub>R encephalitis few weeks after viral encephalitis (both in combination with NMDAR Abs). Refractory status epilepticus is one of the main clinical features of the disease. Further core symptoms include cognitive impairment, behavior changes, decreased levels of consciousness, altered behavior, and movement disorders (more often in children). In contrast to other LE, MRI reveals extensive multi-locular subcortical and cortical abnormalities predominantly in temporal and frontal lobes in 80% (Spatola et al., 2017). MRI lesions may occur asynchronous. Epileptiform activity can be seen in 76% of the patients. Immunotherapy can be effective and patient recover at least partly, if survive the acute phase of the illness. Usually no relapses occur. The GABA<sub>A</sub>R-Abs targeting α1, β3, or γ2 subunits of the receptor have been reported. The last one is probably not pathogenic, as it has been always detected in association with Abs against α1- or β3-subunits. Patient's sera induce specific loss of synaptic (but not dendritic) GABA<sub>A</sub>R in the cell culture (Petit-Pedrol et al., 2014). High titers of GABA<sub>A</sub>R Abs are associated with severe clinical presentations.

### OPHELIA SYNDROME OR METABOTROPIC GLUTAMATE RECEPTOR 5 ENCEPHALITIS

This rare form of autoimmune encephalitis was firstly described 1982 in the setting of Hodgkin lymphoma. Due to some similarity with a character of Shakespeare's play Hamlet, this clinical entity was termed the Ophelia syndrome (Carr, 1982). Typical clinical features include confusion, progressive loss of memory with bizarre behavior, depression, and hallucinations. The course of this disease is milder comparing to NMDAR encephalitis. Usually patients do not have seizures and autonomic instability. Patients improve dramatically with treatment of the lymphoma. Antibodies to mGluR5 have been identified in this condition and are supposed to be pathogenic (Lancaster et al., 2011). Antibodies targeting another receptor of this group—mGluR1 are linked with cerebellar degeneration (Lopez-Chiriboga et al., 2016). Only minority of these patients have tumor. Consistent with expression of the mGluR1 in the limbic system seizures, memory loss, and psychiatric symptoms may be infrequently present; however, ataxia remains the core symptom. Experimental data support pathogenicity of mGluR1 as well and immunotherapy is usually effective. Despite being 85% homologous, the Abs targeting mGluR1 and mGluR5 do not cross-react and the clinical syndromes are distinct.

### IGLON5 ENCEPHALITIS

Encephalitis associated with IgLON5-Abs is probably a most mysterious Abs-associated neurologic disease with features of both autoimmune and neurodegenerative disorder. It occurs in older patients (median age about 60) (Gaig et al., 2017). Clinical manifestations are multilocular, usually insidious at onset and gradually progressive over years. Complex sleep disturbances (with vocalizations during REM (rapid eye movement) and non-REM phase, sleep apnea, insomnia, and excessive daytime sleepiness) are most characteristic. Further typical presentations include gait instability and brainstem signs such as stridor, dysphagia, and central hypoventilation. Movement disorders are sometimes present and may include Parkinsonism, dystonia, or chorea as well as myoclonus. Sudden death due to laryngospasm or respiratory failure has been reported. Paraneoplastic cases are rare.

IgLON5-Abs are predominantly of IgG4 subclass; however, IgG1 Abs are also present in all patients. In vitro IgLON5 Abs (of IgG1 subclass only) recognize the immunoglobulin-like domain 2 and cross-linked receptors, resulting in an irreversible internalization of IgLON5 clusters from the surface of the hippocampal neurons (Sabater et al., 2016). It remains unclear if Abs of IgG4 subclass have a direct pathogenetic effects due to other mechanisms. Strong association with HLA-DRB1\*1001 and HLA-DQB1\*0501 haplotypes was demonstrated in several studies (Gaig et al., 2017; Sabater et al., 2014). All these findings support an underlying immune pathogenesis. In contrast, neuropathological findings demonstrate lack of inflammatory infiltrates. Characteristic are neuronal loss and accumulation of hyperphosphorylated tau protein, involving the midbrain tegmentum and the hypothalamus (Gelpi et al., 2016). The neuropathological changes cannot be classified within known taupathies such as progressive supranuclear palsy or corticobasal degeneration. Accordingly, it remains unclear if the IgLON5 autoimmunity is primary and pathogenetically relevant or just a secondary immunologic phenomenon.

Despite surface localization of the target antigen, data on immunotherapy remain controversial, with moderate improvement in selected reports (Bonello et al., 2017; Gaig et al., 2017; Honorat et al., 2017; Sabater et al., 2014). It may be speculated that neuronal-specific tau accumulation and further neurodegeneration is Ab-mediated and, thus, a secondary feature. In this case an early immunotherapy could be promising.

### DOPAMINE-2 RECEPTOR (BASAL GANGLIA) ENCEPHALITIS

Dopamine-2 receptor (D2R) Abs have been identified in some children with basal ganglia encephalitis, presenting with different movement disorders: Parkinsonism, chorea, or dystonia. Furthermore these Abs were present in a few patients with Sydenham chorea and Tourette syndrome (Dale et al., 2012). Psychiatric disturbances such as emotional lability, attention deficit, or psychosis are typical in these patients. Half of the patients demonstrated MR-signal abnormalities in basal ganglia. Onset is often associated with previous infections and an early immunosuppression is partly effective. D2R-Abs recognize extracellular N-terminal domain of the receptor and are able to decrease its surface expression on the transfected cells (Sinmaz et al., 2016). Further studies are needed to confirm this finding and better characterize an associated clinical syndrome.

### Subacute Cerebellar Degeneration

SCD is one of the most common Ab-associated diseases of the CNS. It often develops in context of tumors, representing about a half of all paraneoplastic syndromes (Giometto et al., 2010). After acute or subacute onset symptoms of ataxia worsen progressively and reach a plateau within the first weeks to months with 50%–70% of the patients becoming wheelchair-bound (Jones et al., 2015). MRI is usually normal at onset or rarely

demonstrates inflammatory lesions with contrast-enhancement, symmetrical in some cases. In the following course, cerebellar atrophy becomes more apparent. CSF examination demonstrates inflammatory changes with a mild pleocytosis (at initial stage) and intrathecal Ig-production or oligoclonal bands. Interestingly, in some cases antineuronal Abs can be produced intrathecally, making CSF screening diagnostically relevant (Bernal et al., 2003; Mitoma et al., 2016).

In the majority of patients with PCD, Abs to intracellular antigens (mostly Yo, Hu, and GAD; less frequently Ri, Ma2, CV2/CRMP5, amphiphysin, Zic4, ANNA-3, PCA-2/MAP-1B and sporadically, Homer3, CARPVIII, PKC $\gamma$ , Ca/ARHGAP26) can be detected (Jarius and Wildemann, 2015). Abs targeting surface antigens Tr/DNER and very rarely mGluR1 (facultative paraneoplastic) can be found in the setting of Hodgkin's lymphoma and those against voltage-gated calcium channel (VGCC) in patients with lung cancer (with or without Lambert–Eaton myasthenic syndrome) (Dalmau et al., 2017).

Irreversible loss of Purkinje cells is the main underlying cause of subacute cerebellar ataxia. Neuropathological findings usually reveal CD8+ T cells infiltrates and no relevant IgG or complement products. Cell-mediated cytotoxic immune response seems to be pathogenetically most relevant in SCD with Abs targeting intracellular antigens; however, several studies demonstrated possible direct role of Abs as well (Mitoma et al., 2015). Auto-Abs can be internalized by Purkinje cells and at least those targeting Yo were demonstrated to increase neuronal death ex vivo (Greenlee et al., 2015).

The prognosis is generally unfavorable, especially if Hu-, Yo-, or CV2/CRMP5-Abs is present (Shams'ili et al., 2003). In some patients, stabilization can be achieved with early tumor resection, followed by chemotherapy (Vernino et al., 2004). While immunotherapies, including corticosteroids, IVIG, plasma exchange, cyclophosphamide, and tacrolimus, are generally disappointing, some improvement in individual cases has been reported (Peterson et al., 1992; Phuphanich and Brock, 2007; Rojas et al., 2000; Vernino et al., 2004). Patients with Tr/DNER-Abs after successful lymphoma treatment and patients with Ri-Abs under immunotherapy have a more favorable prognosis (Briani et al., 2011; Greenlee, 2013). Prompt immunotherapy can be beneficial in GAD-Abs positive SCD; however, overall efficacy remains much lower comparing to stiff-person syndrome (Ariño et al., 2014; Mitoma et al., 2016). In patients with VGCC-Abs, cerebellar symptoms stabilize in up to 40% of the patients after tumor therapy and immunotherapy (Graus et al., 2002). Rare variant of SCD with mGluR1-Abs (initially described in context of lymphoma) is often nonparaneoplastic and respond well to immunotherapy (Lopez-Chiriboga et al., 2016). In all cases additional symptomatic treatment with propranolol, primidone, topiramate, or clonazepam can be attempted (Deuschl et al., 2012).

### **Stiff-Person Spectrum Disorder**

These syndromes are associated with a storage of inhibitory synaptic transmission mediated by GABA and glycine in the brainstem and spinal cord. Antibodies targeting an intracellular enzyme GAD65 (approx. 40%–80% of the cases) and cell surface-associated GlyR  $\alpha$ 1 subunit (GlyR, approx. 10%–20% of the cases) are by far most frequently identified in stiff-person spectrum disorder (SPSD) (Martinez-Hernandez et al., 2016; McKeon et al., 2012). These Abs can infrequently occur in a paraneoplastic context (see Table 56.2); however, most of the cases are idiopathic. More rarely Abs to synaptic vesicle-associated protein amphiphysin can be identified. These Abs are often associated with breast cancer (typically in women around 60 years) and small-cell lung carcinoma (Pittock et al., 2005). Three rarely reported antigens include DPPX, GABAaR, and gephyrin (Martinez-Hernandez et al., 2016).

Typical symptoms of SPSD reflect hyperexcitability of the CNS and include generalized muscle rigidity with painful muscle spasms, an exaggerated startle response and a characteristic gait abnormality with freezing of gait and hyperlordosis. In case of a limited variant, symptoms can affect one limb only (stiff-limb syndrome). Apart from classical manifestation, GlyR-Abs may induce more aggressive and generalized progressive PERM, as a so-called plus variant of the disease (Carvajal-González et al., 2014). These patients can additionally develop myoclonus, seizures, cognitive decline, brainstem signs and autonomic dysregulation.

In contrast to other Abs-associated disorders, patients with SPSD may experience a significant improvement with symptomatic treatment alone. First-line therapy includes GABAa receptor agonists (e.g., diazepam or clonazepam) and GABAb receptor agonist baclofen. In many cases these medications effectively reduce muscle spasm and rigor; however, tolerance may develop later (McKeon et al., 2012). In extremely severe cases, intrathecal baclofen treatment can be used (Stayer et al., 1997). In paraneoplastic SPSD cancer treatment, including chemotherapy, has the highest priority. With regard to immunotherapy, both corticosteroids and immunosuppressants (e.g., cyclophosphamide) can be effective (Faissner et al., 2016; Murinson and Guarnaccia, 2008; Schmierer et al., 1998). Long-term therapy with oral steroids is usually limited due to often comorbid GAD-Abs associated diabetes, necessitating administration of steroid-saving medications, such as mycophenolate

mofetil, azathioprine, or cyclophosphamide. In SPSD patients with GAD65-Abs, IVIG (2 g/kg per cycle every 4 weeks) is recommended as a first-line therapy (Dalakas et al., 2001; McKeon et al., 2012). Treatment escalation to apheresis therapy can be effective, regardless of the type of Ab (Pagano et al., 2014). Rituximab was effective in individual cases; however, failed in a smaller blinded study (Baker et al., 2005; McKeon et al., 2012). As a general rule, treatment should be started as early as possible. Relevant improvement of symptoms can be achieved during the first year after initial manifestation only (McKeon et al., 2012).

In case of a GlyR-Abs-associated SPSD substantial benefit of immunotherapy and better prognosis has been reported (Carvajal-González et al., 2014). Relapses may occur in approx. 10%.

### ***Opsoclonus–Myoclonus Syndrome***

Abs-associated brainstem syndromes are often quite heterogeneous and can be present as a part of AE. In contrast, OMS is a characteristic-distinct clinical entity that frequently occurs isolated. This syndrome is characterized by the combination of opsoclonus (arrhythmic multidirectional conjugate saccades without an intersaccadic interval) with or without myoclonus and ataxia. The onset is usually acute or subacute with vertigo, vomiting, and gait instability, so that initial diagnosis of vestibular vertigo is common (Armangué et al., 2016). Brain MRI is usually normal, while mild pleocytosis and protein elevation can be seen in CSF.

OMS occurs in small children (usually <5 years, also known as Kinsbourne syndrome) and adults. Children are mostly seronegative for auto-Abs (except for a few cases with anti-Hu-Abs) and in a half of the cases have neuroblastoma (Gorman, 2010). Adult cases are in 40% of the paraneoplastic and in 60% of the idiopathic origin (Armangué et al., 2016). In young adults with paraneoplastic OMS (20–30 years), ovarian teratoma and in older (>45 years) lung or breast cancer (last one in association with Ri-Abs) are most frequently detected. Antibodies to other intracellular antigens (Hu, Ma2, amphiphysin, CV2/CRMP5) have been also less frequently reported. Antibodies targeting surface antigens (GABA<sub>B</sub>R, NMDAR, DPPX, and α-GlyR, last one probably unspecific) have been described in a few patients only (Armangué et al., 2016). In many cases OMS remains seronegative; however, CSF flow cytometry demonstrates B-cell expansion as a possible biomarker of disease activity (Pranzatelli et al., 2010). Parainfectious cases of OMS are mostly associated with HIV and rarely several other infections (Klaas et al., 2012).

Standard treatment (tumor therapy, corticosteroids alone or combined with IVIG, PLEX) is often insufficient in children and associated with residual deficits (Vedeler et al., 2006). More aggressive therapies, such as rituximab and cyclophosphamide, can improve long-term prognosis, including cognitive and behavioral deficits (Mitchell et al., 2015; Pranzatelli et al., 2010). In adults some clinical improvement can be achieved in case of adequate tumor management (Bataller et al., 2001). A subgroup of young patients with teratoma and OMS as a part of an NMDAR-Abs negative encephalitis (mostly with brainstem involvement) have often a very good outcome. After tumor resection and immunotherapy (methylprednisolone, in some cases combined with IVIG and plasma exchange), 8 of 10 patients became symptom-free (Armangue et al., 2014b). Likewise, patients with parainfectious OMS respond well to immunotherapy (e.g., IVIG) and have better prognosis (Klaas et al., 2012). Symptomatic treatment with clonazepam, propranolol, or topiramate can be tried.

### ***Isolated Myopathies and Visual Loss, Associated With Antineuronal Antibodies***

Auto-Abs found in patients with isolated myopathy and/or isolated optic neuritis mostly target glial (see the “Neuromyelitis optica and further disorders associated with antiglial antibodies” section) and only rarely neuronal antigens.

In myopathies most commonly onconeural amphiphysin-, CV2/CRMP5- and more rarely Ri-, ANNA-3-, Hu-, Yo-, Ma1/2-, GAD-, and PCA-2-Abs can be detected (Flanagan et al., 2011; Flanagan, 2016). Paraneoplastic myopathies are mostly associated with breast and lung cancer. In contrast to patients with primary immune-mediated myopathies, they are usually older, with a first manifestation of around 60 years. Cytotoxic (CD8+) cell-mediated immune response is involved and accordingly immunotherapies, targeting T cells (e.g., cyclophosphamide) in parallel to tumor treatment can be tried.

Visual loss due to antineuronal Abs is also rare. Most reported cases describe CRMP/CV2-Abs associated optic neuritis or recoverin-Abs associated retinopathy (Cross et al., 2003). A number of further Abs have been identified in so-called cancer-associated retinopathy (usually in lung or gynecological cancer) and melanoma-associated retinopathy; however, further studies are required for their precise characterization (Braithwaite et al., 2014). Treatment is usually ineffective and prognosis depends on the underlying tumor.

### ***Neuromyelitis Optica and Further Disorders Associated With Antiglial Antibodies***

There are four glial autoantigens with definite or probable clinical relevance: membrane proteins AQP4 and myelin-oligodendrocyte glycoprotein (MOG), cytoplasmatic glial fibrillary acidic protein (GFAP), and nuclear sex determining region Y box protein (SOX1, earlier described as an antiglial nuclear Ab). Antibodies to AQP4 are strongly associated to mostly primary autoimmune neuromyelitis optica spectrum disorder. Direct pathogenetic role of AQP4-Abs and MOG-Abd has been demonstrated in animal models (Saadoun et al., 2012, 2014). Concerning recently described GFAP-Abs further studies are needed in order to evaluate its clinical relevance. Despite its intracellular localization, associated disease seems to be responsive to immunotherapies. SOX1-Abs are first of all diagnostically relevant, as a paraneoplastic marker (mostly by small-cell lung cancer) (Sabater et al., 2008). GFAP- and rarely AQP4-Abs (but not MOG-Abs) can be of paraneoplastic origin also.

#### **NEUROMYELITIS OPTICAL SPECTRUM DISEASE**

NMOSD is one of the best characterized Ab-mediated autoimmune disorders and serves as one of the model diseases of this group. Historically it has been long seen as a rare atypical form of multiple sclerosis (also called Devic's disease). Despite clinical similarity of both diseases the pathophysiology, immunology and treatment of neuromyelitis optica clearly differ. A crucial role in the pathogenesis of the disease plays Abs, targeting astrocytic water protein AQP4, classifying neuromyelitis optica as an autoimmune astrocytopathy (Lennon et al., 2004). AQP4-Abs can be found in approximately 80% of the patients. Being almost always a primary autoimmune disorder of unknown origin, NMOSD can rarely occur in a paraneoplastic context in elderly patients (Ontaneda and Fox, 2014).

**EPIDEMIOLOGY AND CLINICAL CHARACTERISTICS** NMOSD is a rare disease with an overall prevalence of 0.3–4.4 per 100,000 (higher in Asian, South American, and African population) and clear female predominance (f:m 9:1) (Pittock and Lucchinetti, 2016). Diagnostic criteria of NMOSD have been recently reviewed (Wingerchuk et al., 2015). Characteristic clinical features include recurring and often severe attacks of uni- or bilateral optic neuritis and myelitis. The last one classically involves equal to or more than 3 myelon segments (longitudinal extensive transfer myelitis, LETM); however, shorter lesions don't exclude the diagnosis (Flanagan et al., 2015). Further typical yet less prevalent manifestations include area postrema syndrome (presenting as a triad of hiccup, nausea, and vomiting), diencephalic (narcolepsy), or brainstem syndrome. Beside usually centrally located LETM, typical MRI changes can be found in the dorsal medulla and at periependymal surfaces, surrounding ventricular system (e.g., along aqueduct and third ventricle) (Kim et al., 2015). In contrast to MS (multiple sclerosis) periependymal lesions are not ovoid and perpendicular to ventricle, but usually follow ependymal lining. Sometimes tumefactive ( $>3$  cm) and even confluent lesions may occur. Being partly due to a vasogenic edema, they can be largely reversible. CSF analysis often reveals pleocytosis ( $50–1000 \times 10^6$ ) with a predominance of granulocytes and eosinophils, especially during attacks (Wingerchuk et al., 2007). Oligoclonal Abs can be detected in 15%–30% only and are transitory in some cases. Intrathecal synthesis of AQP4-Abs is also rare, reported in 1 of 23 patients only (Jarius et al., 2010).

Approximately 20%–25% of the patients remain seronegative. Interestingly, Abs targeting full length MOG have been detected in a part of NMOSD patients without AQP4-Abs (see the "Neurological syndromes associated with myelin-oligodendrocyte glycoprotein-antibodies" section). Despite overall clinical similarity, another pathogenetic mechanism with leading oligodendrocytopathy underlies this disease (Reindl et al., 2013).

**PATOPHYSIOLOGY** The pathology of NMOSD-lesions reflects an Ab-mediated autoimmune astrocytopathy, with an extensive astrocytic degradation, demyelination, and damage of axons and neurons (Pittock and Lucchinetti, 2016). AQP4-Abs are polyclonal and bind to multiple epitopes on both M1 and M23 isoforms of AQP4, which have identical extracellular domain. AQP4 is colocalized and functionally coupled with an excitatory amino acid transporter (EAAT2), responsible for 90% of the glutamate reuptake. Binding of the Abs results in a cross-linking and internalization of M1-isoform together with EAAT2 and following storage of water transport and glutamate uptake (Hinson et al., 2008). Increased glutamate excitotoxicity is able to cause oligodendrocyte damage with subsequent demyelination. The M23-isoform clusters cannot be internalized due to its size. Abs binding results in its further aggregation on the cell membrane and astrocytic degradation due to a complement-mediated cellular cytotoxicity (Hinson et al., 2012). Accordingly, regions with higher expression of M23 are supposed to undergo more destructive damage, while isolated loss of AQP4 and EAAT2 has been demonstrated in nondestructive lesions (Lucchinetti et al., 2014).

In parallel AQP-Abs induce reactive activation of astrocytes and increased production of proinflammatory cytokines, chemokines, and c1q compliment factor, stimulating recruitment of inflammatory cells (including granulocytes and eosinophiles), blood–brain barrier disruption, and compliment activation. Among cytokines, particular IL-6 seems to play an important role. A CD19intCD27highCD38highCD180– population of plasma-blasts was demonstrated to produce AQP4-Abs under IL-6-stimulation (Chihara et al., 2011). Increased levels of IL-6 in CSF have been demonstrated in NMOSD patients and anti-IL-6 receptor therapy seems to be effective even in refractory NMOSD cases (Ayzenberg et al., 2013; Uzawa et al., 2009).

**THERAPY** Similar to MS, acute attacks can be treated with a high-dose steroid pulse or apheresis therapies. Due to often aggressive course and incomplete recovery, it should be started as soon as possible. In severe attacks, plasma exchange or immunoabsorption can be tried also as a first-line therapy (Bonnan et al., 2017; Kleiter et al., 2015).

Many preventive long-term immunotherapies, being effective in MS, have in contrast no influence on NMOSD (e.g., glatiramer acetate) or can even worsen the course of disease: interferon-beta, fingolimod, natalizumab, alemtuzumab (Ayzenberg et al., 2016; Trebst et al., 2014). Rituximab, azathioprine, or mycophenolate mofetil are used as a first-line therapies, whereby rituximab seems to be more effective than both oral medications but is still off-label (Jeong et al., 2016). Methotrexate or combination therapies can be also used as a second-line therapy. Efficacy of an IL-6-receptor antagonist tocilizumab and recently proteasome-inhibitor bortezomib has been demonstrated in refractory cases (Ayzenberg et al., 2013; Zhang et al., 2017). Other potentially high-effective medications, including complement system inhibitor eculizumab, IL-6-receptor inhibitor SA-237 and anti-CD19 monoclonal Ab inebilizumab, are currently under investigations.

#### NEUROLOGICAL SYNDROMES ASSOCIATED WITH MYELIN-OLIGODENDROCYTE GLYCOPROTEIN-ANTIBODIES

MOG-Abs can be found in the number of pediatric and adult inflammatory CNS diseases, including acute disseminated encephalomyelitis (in 36.4%, especially often in children), AQP4-Abs negative NMOSD (in 26.9% of the cases), recurrent optic neuritis and myelitis, multiple sclerosis (especially with spinal and brainstem involvement), and NMDAR-encephalitis (Hyun et al., 2017; Peschl et al., 2017; Reindl et al., 2013). Monophasic course is usually associated with a transient presence of MOG-Abs and better prognosis. Antibody persistence is more characteristic for recurrent diseases. Modern CBA with the full length, conformationally intact, and correct glycosylated MOG have better sensitivity comparing to older tests. Earlier methods, such as peptide-based ELISA or Western blot, demonstrated partly controversial findings and are considered obsolete (Berger and Reindl, 2015).

Although clinical presentation in adults most commonly resembles those of classical NMOSD, there are several points differentiating these two pathogenetically separate entities (Jarius et al., 2016b; Peschl et al., 2017). MOG-Abs occur more often in males (1:2.8 comparing to 1:9 in NMOSD), these patients are usually younger and have more often simultaneous optic neuritis and myelitis. Beside characteristic findings such as optic neuritis and longitudinally myelitis, MRI frequently demonstrates brain involvement: supratentorial lesions in 47% at least once during the course of the disease and brainstem—in 29%. Periventricular and callosal lesions can be also found in 26% and 17% accordingly. Presence of less than four cerebral lesions and their fluffy pattern as well as absence of MS-typical Dawson’s fingers, ovoid periventricular lesions, and hypointense T1-lesions helps to differentiate it from MS (Jurynczyk et al., 2017). Minority of patients only (13%) has oligoclonal bands (Jarius et al., 2016b). MOG-Abs can be detected in CSF in 67%; however, there is usually no specific intrathecal synthesis (Jarius et al., 2016c).

MOG-Abs belong to complement-activating IgG1 subclass. Available histopathological findings demonstrated MS pattern II lesions, with prominent loss of myelin, macrophages, containing myelin degradation products, perivascular and parenchymal T- and fewer B cells as well as deposition of terminal complement complex C9neo (Jarius et al., 2016a; Spadaro et al., 2015). MOG-immunoreactivity was diminished and the remaining oligodendrocytes were MOG-negative, likely representing oligodendrocyte progenitor cells. In contrast to AQP4-Abs positive NMOSD astrocytes remain largely intact, and there were no neutrophilic or eosinophilic infiltrates (Wang et al., 2016). While GFAP levels in CSF are significantly increased in AQP4-Abs positive cases, elevated myelin basic protein has been reported in MOG-Abs positive variant of the disease (Ikeda et al., 2015). Taking altogether primary occurring autoimmune oligodendrocytes injury indicates that it is pathogenetically a distinct disease.

Relapses can be severe; however, remarkable recovery both clinically and paraclinically (even with normalization of evoked potentials and resolution of MRI lesions) can be generally achieved (Kitley et al., 2014). High-dose steroids or apheresis therapies are usually effective. Flare-up of symptoms after temporary improvement under

high-dose steroids is rather common (44%) and oral tapering should be considered (Jarius et al., 2016c). Due to the lack of studies an optimal long-term immunotherapy remains speculative. Some efficacy has been reported for azathioprine, methotrexate, and anti-CD20 monoclonal Abs.

#### NEUROLOGICAL SYNDROMES ASSOCIATED WITH GLIAL FIBRILLARY ACIDIC PROTEIN-ANTIBODIES

A new GFAP-Abs associated meningoencephalomyelitis has been recently reported in two large case series (Fang et al., 2016; Flanagan et al., 2017). Clinical presentation is not always specific and may include encephalopathy (memory loss, confusion, seizures), myelitic, and meningeal symptoms, optic disc edema with blurred vision and tremor. In 22% this disease occurs in a paraneoplastic context (most common ovarian teratoma) and in 21% in association with other autoimmune diseases (diabetes mellitus type 1, RA, myasthenia gravis). Diagnostically the highest sensitivity and specificity of Abs-testing was demonstrated in CSF. The cell count and protein in CSF can be also markedly elevated, and 54% have CSF-exclusive oligoclonal bands. MRI reveals at least in a half of patients characteristic radial linear and sometimes dotted perivascular contrast enhancement, extending from ventricles and frequently resolving under corticosteroid therapy (Flanagan et al., 2017). Spinal lesions are often extensive and longitudinal along the course of the central canal, however are described as more thin and subtle, comparing to those in AQP4-positive NMOSD.

Being directed toward an intracellular antigen GFAP-Abs have probably no direct pathogenetic role and T cell-mediated mechanisms must be supposed. However, this syndrome seems to be responsive to immunotherapy. The presence of GFAP-Abs is probably not always clinically relevant or can be secondary in a number of cases. In two cases GFAP-Abs have been found in patients with gliomas (astrocytoma and choroid plexus glioma) as a primary CNS disease. These Abs have been also found in serum of 0.5%–1.5% of the healthy controls. In 40% of the patients GFAP-Abs coexisted with other auto-Abs, most often directed against two membrane proteins: NMDAR (22%) and AQP4 (10%). Although no animal model has been yet established, a kind of natural model of the disease, necrotizing meningoencephalitis with GFAP-Abs in CSF, has been previously described in dogs (Uchida et al., 2016).

### Target Antigens: Main Functions and Role in the Central Nervous System Autoimmunity

#### *Neuronal Cell Surface Antigens*

##### EXCITATORY RECEPTORS

**N-METHYL-D-ASPARTATE RECEPTOR** The NMDAR is one of the excitatory ionotropic glutamate receptors (similar to AMPA and kainite receptors) (Kalia et al., 2008). NMDARs are tetramers, composed of polypeptide subunits, forming the ion channel, permeable to K<sup>+</sup>, Na<sup>+</sup>, Ca<sup>++</sup>. Three groups of subunits (NR1, 2, 3) have been identified. Opening of the ion-channel requires binding of glutamate (on the NR2 subunit) and glycine (on the NR1 subunit) as well as simultaneous depolarization (Paoletti and Neyton, 2007). NMDAR plays an important role in calcium-dependent synaptic plasticity. However, increased concentrations of glutamate result in neuronal injury due to excessive NMDAR activity and Ca<sup>++</sup> inflow (glutamate excitotoxicity), being relevant in a number of neurological diseases (Waxman and Lynch, 2005). In case of encephalitis, NMDAR-Abs bind the NR1 subunit of the receptor, resulting in its internalization from the cell surface and reduction of NMDAR-mediated currents (Hughes et al., 2010). For clinical features of NMDAR-encephalitis, see the “Anti-N-methyl-D-aspartate receptor encephalitis” section.

**$\alpha$ -AMINO-3-HYDROXY-5-METHYL-4-ISOXAZOLEPROPIONIC ACID RECEPTOR** The AMPAR is an ionotropic transmembrane glutamate receptor that mediates most of the rapid excitatory synaptic transmission in the CNS (Shepherd and Huganir, 2007). Structurally AMPARs are heterotetramers, assembled from the four subunits (GluA1-4), differently expressed depending on the brain region. Amongst them the GluA2 subunit seems to be the most preferred in the assembly process and functionally important, due to control of Ca<sup>2+</sup> permeability. Regulation of the AMPAR (mostly through subunits phosphorylation and receptor trafficking) is a fundamental mechanism of the postsynaptic LTP and LTD. Activity of the AMPAR can be also regulated by its interaction with LGI1 and metalloproteinase (ADAM22) proteins (Yokoi et al., 2012). Being actively involved in the synaptic plasticity AMPAR (along with NMDAR) is essential for learning and memory (Sprengel, 2006). High expression levels of GluA1/2 and GluA2/3 heterodimers have been demonstrated in the structures of limbic system, especially at CA3-CA1 areas of the hippocampus. In case of encephalitis, AMPAR-Abs target GluA1 and/or GluA2 subunits and induce internalization and degradation of receptors, resulting in typical clinical picture of LE, as

described in detail previously (see the “ $\alpha$ -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor encephalitis” section).

**METABOTROPIC GLUTAMATE RECEPTORS 1 AND 5** Both mGluR1 and mGluR5 are located postsynaptically and belong to the first group of mGluRs (Niswender and Conn, 2010). The mGluR1 receptors are strongly expressed in Purkinje cells of cerebellum and mGluR5 in cerebral cortex, hippocampus, striatum, and dorsal horn, consistent with the clinical presentation of corresponding syndromes (see the “Ophelia syndrome or metabotropic glutamate receptor 5 encephalitis” section). These Gq-protein-coupled receptors are able to activate phospholipase C to influence calcium/inositol triphosphate cascade. Functionally, they increase neuronal excitability and are involved in the regulation of synaptic plasticity, including long-term potentiation and depression. The mGluR5 receptors are also involved in the pathogenesis of fragile X syndrome and could be potential therapeutic target in this disease (Scharf et al., 2015).

There are five isoforms of mGluR1 (a–e), having identical extracellular domains and accordingly being a potential target for mGluR1-Abs. A direct pathogenetic role of mGluR1-Abs has been demonstrated experimentally both on the cerebellar slices ex vivo and in vivo (Coesmans et al., 2003). Postmortem analysis showed extensive damage with a loss of two-third of Purkinje cells in a patient with mGluR1-Abs positive cerebellitis. Interestingly, Abs targeting mGluR1 associated protein Homer3 have been also reported in cerebellar ataxia (Jarius and Wildemann, 2015).

## INHIBITORY RECEPTORS

**GLYCINE RECEPTOR** GlyR is a major ionotropic inhibitory receptor actively involved into regulation of motor neuron activity (Carvajal-González et al., 2014). It is a heteromeric ligand-gated Cl-permeable channel, formed by the combination of one of the four a-subunits and a single b-subunit. Activation of the GlyR in mature neurons leads to influx of Cl<sup>-</sup>, fast hyperpolarization, and postsynaptic inhibition. GlyRs are actively expressed in the spinal cord and brainstem as well as in granular cell layer of the cerebellum and hippocampus. Many spinal and brainstem interneurons express both inhibitory receptors: GlyR and GABAaR (Todd and Sullivan, 1990). On the spinal cord level, they coordinate reciprocal inhibition in muscle stretch reflexes, allowing contraction of agonists and relaxation of antagonist muscles and in brainstem keep motor atonia during rapid-eye movement sleep.

Abs-mediated dysfunction of GlyR results in neuronal hyperexcitability, including encephalopathy, seizures, myoclonus, and signs of stiff-person syndrome (so-called PERM syndrome, see the “Stiff-person spectrum disorder” section). Postsynaptic clustering of GlyRs depends on the interactions with gephyrin, another rare autoantigen reported in stiff-person syndrome (Martinez-Hernandez et al., 2016; Tyagarajan and Fritschy, 2014).

**GAMMA-AMINOBUTYRIC ACID TYPE-A RECEPTORS** The GABAaRs are heteropentameric ligand-gated inhibitory chloride channels. Receptor pentamers may contain  $\alpha$ ,  $\beta$ , and either  $\gamma$  or  $\delta$  subunits. Synaptic GABAaR (benzodiazepine-sensitive) usually consist of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits and mediate fast inhibitory signal transmission (Jacob et al., 2008). In contrast  $\delta$  subunits (instead of  $\gamma$  subunits) are characteristic for receptors at extrasynaptic sites, mediating tonic inhibitory neurotransmission. Similar to GlyR, gephyrin is one of the central proteins involved in the regulation and clustering of GABAaRs at inhibitory synapses. Impairment of GABAaR function causes increased neuronal excitability and epileptic activity (Hirose, 2014). Genetic alteration of GABAaR was demonstrated in inherited epileptic disorders resembling the main symptom of GABAaR-encephalitis and indirectly confirming a direct pathogenetic role of GABAaR-Abs.

**GAMMA-AMINOBUTYRIC ACID TYPE B RECEPTORS** The GABAbR is a metabotropic inhibitory receptor, mainly expressed in hippocampus, amygdala, cerebellum, and thalamus. This receptor is composed of two subunits, B1 (necessary for GABA binding and also target antigen in GABAbR encephalitis) and B2 (determines localization of the receptor and G-protein coupling) (Emson, 2007). GABAbR are located both pre- and postsynaptically and are involved in pre- and postsynaptical inhibition. GABAbR suppress excessive synchronization in neuronal network, associated with epileptic activity. Accordingly, dysfunction of GABAbR results in an overactivation and generation of epileptic activity. Both genetic and pharmacologically induced alteration of GABAbR function cause seizures as well learning and memory deficits, resembling features of GABAbR encephalitis (Enna and Bowery, 2004; Lancaster et al., 2010; Schuler et al., 2001). GABAbR polymorphism is also associated with temporal lobe epilepsy (Gambardella et al., 2003).

## OTHER NEURONAL CELL SURFACE ANTIGENS

**LEUCINE-RICH GLIOMA INACTIVATED-1** LGI1 is an extracellularly secreted neuronal protein, actively expressed in temporal cortex and hippocampus. In contrast to CASPR2, LGI1 expression in peripheral nerves is weak (Irani et al., 2010a). Binding to presynaptic ADAM23 (a disintegrin and metalloproteinase 23) and postsynaptic ADAM22, LGI1 organizes a transsynaptic complex essential for inhibitory signal transmission from presynaptic VGKC to postsynaptic AMPA receptors. Mutations of LGI1 cause autosomal dominant lateral temporal lobe epilepsy (Kalachikov et al., 2002). LGI1 knock-out mice develop lethal seizures (Fukata et al., 2010). LGI1-Abs induced loss of the interaction between LGI1 and ADAM22 reduces the AMPA receptor-mediated synaptic transmission, resulting in epileptic seizures (Ohkawa et al., 2013).

**CONTACTIN-ASSOCIATED PROTEIN LIKE 2** CASPR2 is a transmembrane protein with a large extracellular part, expressed in the central and PNS. At the neural juxtaparanodes Caspr2 is colocalizes with Kv1.1 and 1.2, being essential for VGKC clustering (Horresh et al., 2008). In the CNS Caspr2 is more prominently expressed in hippocampus and cerebellum. Mutations in Caspr2 gen cause epilepsy and cognitive impairment—signs resembling those of Caspr2-encephalitis (Friedman et al., 2008). It has been supposed that Caspr2-Abs cause down-regulation of Caspr2/Kv complexes on the membrane of peripheral nerves. Similar, dispersed Kv1 have been demonstrated in Caspr2-knockout mice as well as patients with mutations of the Caspr2 encoding gen (Strauss et al., 2006).

**Dipeptidyl-peptidase-like protein 6** DPPX is a cell surface regulatory subunit of the voltage-gated A-type Kv4.2 potassium channels, responsible for transient inhibitory currents and regulating repetitive firing rates and back-propagation of action potentials. Kv4.2 truncation mutation has been identified in temporal lobe epilepsy (Singh et al., 2006). Enhanced neuronal excitability has been also demonstrated in DPPX knockouts as well as experimentally after application of sera containing DPPX-Abs to guinea pig and human enteric neurons (Piepgras et al., 2015; Sun et al., 2011). Taking altogether, both genetic and immunological alterations of the DPPX-Kv4.2 complex seem to result in neuronal hyperexcitability, confirming direct pathogenetic role of DPPX-Abs.

**DOPAMINE-2 RECEPTOR** D2R is one of the five related G-protein-coupled receptors. There are two splice variants of this receptor, short D2Rs, that are predominantly expressed presynaptically and involved in autoreceptor functions, and long D2R, expressed postsynaptically (Beaulieu and Gainetdinov, 2011). These receptors are highly expressed in nucleus accumbens, striatum, substantia nigra, olfactory tubercle, hippocampus, and cortex. D2R are involved in the regulation of motor control, behavior as well as learning, memory, and prolactin secretion. Dopaminergic dysregulation is involved in the pathogenesis of many neurological and psychiatric diseases, such as schizophrenia, depression, bipolar disorder, Parkinsonism, and number of further extrapyramidal disorders.

**IgLON5 RECEPTORS** IgLON5 is a surface adhesion protein, broadly present in the CNS with highest expression level in thalamus and brainstem (Vanaveski et al., 2017). It is highly glycosylated and contains three extracellular immunoglobulin-like domains. In case of IgLON5 encephalitis (for clinical features, see the “IgLON5 encephalitis” section), auto-Abs target the immunoglobulin-like domain 2, independently on its glucosylation, resulting in internalization of IgLON5. Functions of this protein remain incompletely understood, but it is involved in a regulation of neurite outgrowth, neuronal pathfinding, and synaptogenesis during brain development (Sanz et al., 2015). In line with this, proteins of IgLON family are implicated in the pathogenesis of autism spectrum disorders (Minhas et al., 2013).

**AMPHIPHYSIN** Amphiphysin belongs to N-BAR proteins family, involved in the cell membrane remodeling, and is highly expressed in the CNS. It is important for several steps of clathrin-mediated endocytosis, required for the rapid recycling of presynaptic vesicles (Arkhipov et al., 2009). Dysfunction of endocytosis is especially critical for tonic GABAergic inhibitory neurons, characterized by a high vesicles turnover. Amphiphysin-Abs were demonstrated to bind the target antigen in spinal cord presynapses during endocytosis, resulting in fast replenishment of the presynaptic vesicle pool (Geis et al., 2010; Werner et al., 2016). Reduction of GABAergic neurotransmission explains major symptoms of stiff-person syndrome disorder (SPSD)—most characteristic clinical presentation in patients with Amphiphysin-Abs. In contrast to GAD65-Abs positive SPSD, these patients are older and have more prominent cervical stiffness (Murinson and Guarnaccia, 2008). Most of the patients have

breast or lung cancer and further onconeural Abs (Pittock et al., 2005). Beside SPSD, patients may develop neuropathy (including dysautonomia), myelitis, limbic, and brainstem encephalitis or cerebellar ataxia. Spinal cord lesions are often longitudinal, resembling those by NMOSD. Despite an experimentally demonstrated direct pathogenetic role of the Amphiphysin-Abs, CD8+ T-cell infiltrates have been shown histopathologically. Immunotherapy can be effective, especially in nonparaneoplastic and partly in paraneoplastic cases (Moon et al., 2014; Murinson and Guarnaccia, 2008; Pittock et al., 2005).

**DELTA/NOTCH-LIKE EPIDERMAL GROWTH FACTOR-RELATED RECEPTOR (TR)** A punctate staining of the Purkinje cells cytoplasm in a combination with diffuse staining of molecular layer of the cerebellum is characteristic for Tr-Abs (Graus et al., 1997a, 1998). In line with this pattern these Abs are strongly associated with paraneoplastic cerebellar ataxia, mostly in the setting of Hodgkin or more rarely non-Hodgkin lymphoma (Bernal et al., 2003). A transmembrane DNER has been identified as a target autoantigen (de Graaff et al., 2012). DNER is expressed by Purkinje cells and Bergmann glia and is essential for cerebellar development (Saito and Takeshima, 2006). Mice lacking DNER demonstrate impaired cerebellar function, confirming its possible role in the disease (Tohgo et al., 2006). The Abs react with a surface DNER epitope, so that their direct pathogenetic role can be supposed. Improvement of ataxia in some cases under successful tumor treatment or immunotherapy alone (prior to chemotherapy) indirectly confirms it. However, pathological studies demonstrated permanent neuronal loss in others (Bernal et al., 2003; Greene et al., 2014). High sensitivity and specificity of a diagnostic CBA for Tr-Abs has been recently reported (Probst et al., 2015).

### **Intracellular Neuronal Antigens**

#### **ANTINEURONAL NUCLEAR ANTIBODIES**

**HU (ANTINEURONAL NUCLEAR ANTIBODIES 1)** Hu-Abs react with the nuclear and to a lesser extent cytoplasmic antigen, expressed in the central and peripheral (including dorsal root ganglia and enteric plexus) nervous system. Three highly homologous embryonic lethal abnormal visual (ELAV) such as neuron-specific RNA binding proteins 2, 3, and 4 (other names HuB, HuC, and HuD, respectively) have been identified as target antigens (Pignolet et al., 2013). These proteins are highly conserved across species and homologous to the *Drosophila melanogaster* nuclear protein ELAV. ELAV proteins seem to play an important role in the neuronal development (Okano and Darnell, 1997). High titer of Hu-Abs is most frequently associated with paraneoplastic LE and/or paraneoplastic sensory neuronopathy in patients with SCLC. Recovery of neurological deficits is usually poor. Low titers of Hu-Abs may be frequently seen in patients with SCLC without neurologic manifestation and are associated with a better tumor outcome (Graus et al., 1997b). Being rarely found in children, Hu-Abs are associated with neuroblastoma and OMS or LE in tumor-free patients (Honnarat et al., 2013).

**RI (ANTINEURONAL NUCLEAR ANTIBODIES 2)** Unlike Hu-Abs, Ri-Abs react with the neuronal nuclei in CNS only. These Abs can be found in paraneoplastic OMS or cerebellar (often truncal) ataxia mostly in patients with lung, breast, or ovarian cancer. Ri-Abs also target two RNA-binding proteins Nova-1 and 2 (neurooncological ventral antigen), regulating alternative splicing of transcripts encoding synaptic proteins (Yang et al., 1998). Nova-1 expression is mostly restricted to brainstem and spinal cord, being responsible for motor and oculomotor deficits. Nova-2 is more widely expressed in CNS, including cortex and explaining cognitive deficits, occurring in some patients. Prognosis is better, comparing to Hu-Abs. Some patients can improve under tumor and immune therapy (Pittock et al., 2010).

**ANTINEURONAL NUCLEAR ANTIBODIES 3** Target protein of ANNA-3-Abs remains unknown. It is a 170 kDa protein, predominantly expressed in the nuclei of Purkinje cells, granular neurons, enteric neurons, and surprisingly renal glomerular podocytes. Neurological manifestation is usually multifocal and may include polyneuropathies, cerebellar ataxia, myelitis as well as brainstem and LE (Chan et al., 2001). Lung cancer is the most frequently detected tumor in these patients.

**MA (PARANEOPLASTIC MA ANTIGENS)** The Ma-Abs react predominantly with nuclei and nucleoli of all neurons of the central and PNS as well as testicular germinal cells. Three highly homologous proteins paraneoplastic Ma antigens (PNMA)-1, 2, and 3 are targets of the immune response in these patients (Rosenfeld et al., 2001). The precise functions of the PNMA proteins family remain poorly understood. PNMA-2 (expressed exclusively in the brain and number of tumors) seems to be the major antigen, recognized by the serum of almost all patients.

Antibodies to PNMA-1 or -3 almost always occur in combination with PNMA-2. PNMA-1 and -3 proteins can be found in the brain and germ cells of testis. PNMA-1 is known to have proapoptotic function and to be involved in regulated neuronal death in developing brain (Chen and D'Mello, 2010). PNMA-2 seems to play role by the tumorigenesis and to increase chemoresistance of cancer cells, probably inhibiting proapoptotic effects of PNMA-1 (Lee et al., 2016).

LE, often with additional diencephalic or brainstem symptoms, is a most typical clinical presentation; however, cerebellar ataxia, polyneuropathies, and parkinsonism have been also reported (Dalmau et al., 2004; Rosenfeld et al., 2001). Antibodies, targeting Ma2, are usually associated with a testicular cancer (sometimes microscopic tumors!) in men younger than 50 years. Remarkably, neurologic deficits improve in approx. 40% in this subgroup of patients in case of complete response to tumor treatment (Rosenfeld et al., 2001). In contrast, patients with Ma2-Abs in a combination with Ma1 or Ma3 develop more often cerebellar symptoms, have worse prognosis and in 80% are associated with tumors other than germ cells cancer (often lung cancer).

#### CYTOPLASMATIC ANTIGENS

**YO (PURKINJE CELL ANTIGEN-1)** Seres of patients with Yo-Abs react with the cytoplasm of Purkinje cells and some neurons of the deep cerebellar nuclei. Two target antigens have been identified: major (of 62 kDa) and minor (of 34 kDa). The major target protein CDR2 (cerebellar degeneration related-2) is actively expressed in cerebellar and brainstem neurons as well as testes, normal ovary, and ovarian tumors. CDR2 is involved in the cell-cycle control and required for the proper execution of mitosis (O'Donovan et al., 2010). It was also shown to downregulate c-Myc and prevent apoptosis (Okano et al., 1999). Interestingly, Yo-Abs (those targeting CDR2) can be taken up by the neurons and cause dysregulation of calcium homeostasis and neuronal death in the slice culture (Greenlee et al., 2015; Schubert et al., 2014). The precise function of the minor antigen (CDR1) remains unknown.

Yo-Abs are typically associated with an SCD in women with breast or gynecologic cancer (Peterson et al., 1992). Despite effective tumor therapy, neurological deficits usually do not improve, resulting in a significant disability (Rojas et al., 2000).

**MICROTUBULE-ASSOCIATED PROTEIN 1B (PURKINJE CELL ANTIGEN-2)** Initially described in patients with small-cell lung carcinoma and cerebellar ataxia this Ab has been named PCA-2 in order to differentiate it from PCA-1(Yo), associated with ovarian and breast cancer (Vernino and Lennon, 2000). Recently, microtubule-associated protein 1B (MAP1B) has been identified as a target antigen of PCA-2 Abs (Gadoth et al., 2017). As an important component of neural cytoskeleton, MAP1B binds and stabilizes microtubules and is essential for maintenance of the cell shape and polarity, synapse formation, and axonal transport (Tortosa et al., 2011). Mice with genetically deleted MAP1B demonstrate delayed and abnormal nervous system development with lack of corpus callosum and often perinatal death (Takei et al., 1997).

Clinical signs are often heterogeneous. Patients with PCA-Abs may develop brainstem and LE, cerebellar ataxia, and polyneuropathy. Such a mixed presentation can be partly explained by the frequent presence of further antineuronal Abs, such as CV2/CRMP5 (in 26%) or Hu-Abs (in 13%) (Gadoth et al., 2017). PCA-1 Abs are highly predictive for the lung cancer, detected in two-thirds of the cases. Histopathological findings demonstrate infiltration with a cytotoxic CD8 + T-lymphocytes and treatment outcome is usually poor.

**COLLAPSING RESPONSE MEDIATOR PROTEIN 5 (CV2)** Target antigen of the Ab, initially named CV2, is the CRMP5 (Yu et al., 2001). CRMP5 belongs to a family of five cytosolic proteins that are actively expressed during brain development and control neural stem-cell differentiation, neurite outgrowth, and axonal pathfinding. This protein is predominantly located in the dendrites and has negative regulatory effect on dendrite extension, mediated by tubulin binding (Brot et al., 2010). In postnatal brain CRMP5 is actively expressed in the zones of adult neurogenesis (dentate gyrus, olfactory bulb), being involved in the proliferation and survival of newly generated neuroblasts (Veyrac et al., 2011). This protein also promotes proliferation of glioblastoma cells, being an indicator of poor outcome in these patients (Moutal et al., 2015). Interestingly, oligodendrocytes actively express CRMP5 as well and clinical presentation of CRMP5-autoimmunity can mimic symptoms of classical demyelinating disorders (Bretin et al., 2005). Optic neuritis with or without uveitis, loss of olfaction and taste, myelopathy, movement disorders (chorea, Parkinsonism, hemiballism), cerebellar ataxia, behavioral changes as well as involvement of PNS have been described in patients with CRMP5-Abs (Cross et al., 2003; Vernino et al., 2002; Yu et al., 2001). Most of the cases are paraneoplastic, being associated with lung cancer (small cell > nonsmall cell) and sometimes thymoma or other tumors.

**GLUTAMIC ACID DECARBOXYLASE 65** GAD is an intracellular enzyme, converting L-glutamate to GABA by decarboxylation. Both existing enzyme isoforms (65 and 67 kDa) are expressed in the islet cells of pancreas and CNS. In neurons GAD67 is predominantly localized in the cytoplasm and produce a basal level of GABA. GAD65 is concentrated presynaptically, anchored at the cytoplasm-facing side of synaptic vesicles, and is responsible for supplementary GABA-synthesis during sustained neuronal activity. GAD65 is the main clinically relevant autoantigen, while GAD67-Abs often coexist and are rarely autoantigenic in isolation (Fenalti and Buckle, 2010).

Despite being an intracellular protein, GAD65 autoimmunity is relatively rarely associated with tumors (usually thymoma, neuroendocrinial tumors, or breast cancer). A total of 70% neurological manifestation is associated with other autoimmune diseases (mostly type 1 diabetes mellitus, autoimmune thyroid disease, and pernicious anemia). Levels of GAD65-Abs in patients with isolated diabetes are usually much lower (<20 nmol/L) comparing to those with neurological manifestation (often >100 nmol/L) (Pittock et al., 2006). Low values can be also found in up to 8% of the healthy controls (Walikonis and Lennon, 1998). Neurological presentations can be quite heterogeneous, including cerebellar ataxia, stiff-person syndrome, LE (often with seizures), and rarely myelopathy. Intrathecal production of GAD65-Abs can be often detected (Pittock et al., 2006). Target epitopes of T and B cells differ in diabetes patients and those with stiff-person syndrome (Ali et al., 2011; Lohmann et al., 2003). Further antineuronal Abs targeting surface antigens may coexist with GAD65-Abs (Chang et al., 2013). Despite GAD65-Abs were demonstrated to inhibit GABA synthesis and affect transmission ex vivo, it is unlikely to be a central pathogenic mechanism in vivo (McKeon and Tracy, 2017). Pathological findings confirm a T cell-mediated injury in GAD65-Abs-associated autoimmunity (Holmøy et al., 2009). Efficacy of the immunotherapy varies. In patients with LE and seizures improvement occurred in one-third of cases only (McKeon and Tracy, 2017). In another study half of the patients with ataxia improved under immunotherapy (Jones et al., 2015). As in other T cell-mediated diseases an early start immunotherapy is critical.

### **Glial antigens**

#### **AQUAPORIN-4**

AQP4 is the main water channel of the CNS. Its main functions include regulation of the water balance in CNS and extracellular glutamate concentrations. Deletion of AQP4 impairs removal of excess brain water, resulting in increased vasogenic edema and intracranial pressure in experiment (Papadopoulos et al., 2004). AQP4 is especially highly expressed on perivascular endfeet of astrocytes as well as in subependymal and subpial regions, corresponding to the typical localization of NMOSD lesions (see the “Neuromyelitis optica spectrum disease” section). Beside CNS it is expressed in skeletal muscles, placenta, lacrimal and salivary glands, distal renal collecting duct cells, retinal Muller cells, olfactory epithelial cells, and gastric parietal cells. These tissues are generally spared in NMOSD, probably due to coexpression of AQP4 with membrane complement regulators (CD46, CD55, CD59), that are absent on astrocytic endfeets (Saadoun and Papadopoulos, 2015). There are two predominant isoforms of AQP4: M1 and M23. The M23 isoform is able to build tetramers that further cluster to supramolecular assemblies. It has been proposed that due to its size such an assemble cannot be internalized after Abs binding, resulting in the complement-dependent destruction of astrocytes (Hinson et al., 2012).

### **MYELIN OLIGODENDROCYTE GLYCOPROTEIN**

MOG is a CNS-specific minor myelin component. Being involved in myelination, MOG serves as a differentiation marker for oligodendrocytes maturation (Linington et al., 1988). MOG belongs to the Ig superfamily and have 15 alternatively spliced isoforms; however, its function is still not fully understood (Delarasse et al., 2006). It has been supposed to serve as a ligand for dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin on antigen-presenting cells and to keep them in tolerogenic state and as a receptor for nerve growth factor (García-Vallejo et al., 2014; von Büdingen et al., 2015). However, MOG knockout mice display normal myelin and no clinical abnormalities (Delarasse et al., 2003). MOG is one of the best-studied antigens in experimental AE. It is expressed at an outer surface of myelin sheaths and oligodendrocyte processes in CNS, being accessible extracellular target for the auto-Abs. Secreted form of MOG can also probably trigger an autoimmunity (Delarasse et al., 2006). Interestingly, being homologous to butyrophilin proteins of mammary glands, MOG can potentially cause autoimmunity by molecular mimicry (Gardinier et al., 1992; Guggenmos et al., 2004). Earlier results of MOG-Abs testing demonstrated controversial findings (Berger and Reindl, 2015). Modern diagnostic tests, using the full-length, conformationally intact, and glycosylated MOG, have better sensitivity comparing to older one with denatured MOG.

## GLIAL FIBRILLARY ACIDIC PROTEIN

GFAP is the main intermediate filament protein, expressed by astrocytes, ependymal cells, and neural progenitor cells. It is involved in several important astrocytic functions in CNS, including synaptic plasticity, regeneration, and reactive gliosis (Middeldorp and Hol, 2011). Being a cytoplasmic protein, it belongs to intracellular antigens. Among several isoforms of GFAP, mature a-isoform seems to be most relevant as an antigen in GFAP-Abs positive meningoencephalomyelitis (Flanagan et al., 2017). Mutations of GFAP gene result in mental and physical retardation (Alexander disease).

## GENERAL INTRODUCTION

Autoimmune hepatitis (AIH) is an inflammatory liver disease, affecting mainly females, characterized by elevated transaminase and immunoglobulin G (IgG) levels, interface hepatitis on histology, and positive autoantibodies, whose profile allows its distinction into two types. The etiology of AIH is said to be unknown but, as for complex diseases in general, it results from interplay of multiple predisposing causes, genetic and environmental. The outcome is immune reactivity against host liver antigens. AIH responds to immunosuppressive treatment, which should be instituted as soon as the diagnosis is made, as untreated disease progresses to liver failure.

## HISTORICAL ASPECTS

AIH has gone from obscurity to center stage over a period of 70 years. The disease was unrecognized in the 1940s, though scanty reports described some of its features (Amberg, 1942; Wood et al., 1948). The earliest complete description of the clinical characteristics of AIH was made by the Swedish physician Jan Gösta Waldenström during the first meeting after the war of the German society for Digestive and Metabolic Disorders at Bad Kissingen in September 1950 (Waldenstrom, 1950). Waldenström described six patients, five females, with polyclonal hypergammaglobulinemia, hyperproteinemia, and low serum albumin. He suggested that this

hepatitis "sui generis" could derive from viral persistence after an acute infection and interpreted the hypergammaglobulinemia (mainly due to IgG) to antibody formation against viral antigens. Administration of adrenocorticotropic hormone (ACTH) to investigate the nature of amenorrhea resulted in a striking subjective improvement and a dramatic fall in the erythrocyte sedimentation rate, inducing Waldeström to conclude that these "patients may benefit from ACTH treatment." Waldeström's observations were confirmed soon afterward by Kunkel's group (Kunkel et al., 1951; Bearn et al., 1956), who added to the clinical features fever, arthralgia, and arthritis, suggesting a link with systemic disorders such as rheumatoid arthritis and systemic lupus erythematosus (SLE). Joske and King (1955) described lupus erythematosus (LE) cells in the blood of two patients with hypergammaglobulinemic active chronic hepatitis. In a landmark article, Mackay et al. (1956) reported five additional hypergammaglobulinemic chronic hepatitis patients recruited in the same unit and, in view of the presence of LE cells, proposed the term "lupoid hepatitis" to define this condition.

The first to suggest that this type of chronic hepatitis could be due to autoimmunity was the group of Zimmerman (Zimmerman et al., 1951) who, describing a young man with chronic inflammatory liver disease and hypergammaglobulinemia, suggested that an initial liver injury, possibly due to a virus, could have induced alterations of liver proteins, which might have led to the production of antibodies to self-antigens, perpetuating liver damage. Support to the concept of an autoimmune mechanism in the pathogenesis of liver damage in certain acute and chronic liver diseases came from studies performed in Melbourne by Gajdusek and Mackay in 1958 (Gajdusek, 1958; Mackay and Gajdusek, 1958), who described autoimmune reactions against tissue antigens using a complement fixation test. From these initial findings, the idea of investigating liver-specific targets in chronic inflammatory liver diseases was born, leading to a large wealth of information, starting from the pioneering work in Meyer zum Büschenfelde's laboratory in the 1960s (Meyer zum Büschenfelde and Schrank, 1966; Meyer zum Büschenfelde, 1972; Meyer zum and Miescher, 1972; von Meyer zum Büschenfelde et al., 1974; Hopf et al., 1976) to the present time.

The name "lupoid hepatitis" persisted until it became clear that liver disease is rare in typical SLE and that LE cells reflect the presence of antinuclear antibody (ANA), leading Mackay to suggest the alternative name of "autoimmune hepatitis" (Mackay et al., 1965), though already in the mid-1950s, AIH was a well-recognized nosological entity, so much so that at a New York Academy of Sciences meeting on autoimmunity, Mackay proposed the title "Autoimmune Hepatitis" (Mackay, personal communication).

The name "autoimmune hepatitis," however, became universally accepted only in the 1990s, after several different labels (mostly "chronic active hepatitis") had been given to this condition over the years. In addition to seropositivity for ANAs, reports from the early 1960s showed that anti-smooth-muscle antibodies (SMA) are also markers of what is known today as AIH type 1 (zum Büschenfelde, 2003). Thirty years after the first description of "lupoid hepatitis," another milestone in the history of AIH is the discovery that the presence of anti-liver kidney microsomal type 1 and anti-liver cytosol type 1 antibodies (Homberg et al., 1987; Martini et al., 1988) defines a second type of AIH (AIH type 2), typical of children and adolescents.

Awareness over the years that the clinical and pathological picture of chronic hepatitis may be due to causes other than AIH, such as persistent infection with the hepatotropic viruses B and C, alcohol abuse, and nonalcoholic steatohepatitis, prompted the establishment in the 1990s of an expert panel with the brief of defining criteria for the diagnosis of AIH (International Autoimmune Hepatitis Group, IAIHG) (Johnson and McFarlane, 1993), which were later revised (Alvarez et al., 1999) and then simplified for clinical use (Hennes et al., 2008).

## EPIDEMIOLOGY

AIH occurs worldwide. Initial information on prevalence has been obtained for AIH type 1 before the introduction of the IAIHG diagnostic scoring system (Johnson and McFarlane, 1993) (Alvarez et al., 1999), therefore without standard criteria for patient inclusion. Prevalences reported in early papers range from 1.9 cases/100,000 in Norway (Boberg et al., 1998) and 1/200,000 in the US general population (Manns et al., 1998) to 20/100,000 in females over 14 years of age referred to a tertiary center in Spain (Primo et al., 2004). A study from a UK secondary referral center reported an AIH annual incidence of 3.5/100,000 (Whalley et al., 2007). Two studies using standardized criteria for the diagnosis of AIH published in 2002 and 2010 report a point prevalence of 24.5/100,000 in New Zealand (Ngu et al., 2010) and of 34.5/100,000 in Alaskan natives (Hurlburt et al., 2002). In Asia AIH was widely considered less frequent than in Western countries, with a reported incidence in Japan ranging between 0.08 and 0.15 cases/100,000/year (Nishioka and McFarlane, 1998). A better awareness of its clinical characteristics has led to an increased frequency in the diagnosis of AIH in China, where this condition was considered very

rare (Qiu et al., 2011). Also in Japan the incidence and prevalence of AIH may be higher than previously thought (Yoshizawa et al., 2016). AIH prevalence and incidence are, however, reported to be lower in the Asia-Pacific area than in Europe and America (Yang et al., 2015). Studies on large patient cohorts were conducted in Northern Europe. A population-based investigation in Denmark on 1721 patients reports an incidence rate of 1.68/100,000 population/year, which doubled during the 1994–2012 period of observation. Of note, in the first year after diagnosis, patients with AIH had sixfold higher mortality than the general population, while later their mortality remained twofold higher. In a Swedish cohort of 634 AIH patients, AIH point prevalence was reported as 17.3/100,000 inhabitants in 2009, with a yearly incidence of 1.2/100,000 inhabitants between 1990 and 2009 (Danielsson Borsen et al., 2017). In contrast to the Danish study, however, mortality for the first 4 years post diagnosis was similar to that of the normal population, worsening only afterward (Danielsson Borsen et al., 2017). A Dutch study on 1313 patients shows an AIH prevalence of 18.3/100,000, with an annual incidence of 1.1 in adults, the peak incidence being in middle-aged women (van Gerven et al., 2014).

All these epidemiological figures are likely to be underestimates, since AIH may remain undiagnosed for several years and present eventually with decompensated liver disease attributed to “cryptogenic” cirrhosis.

The prevalence of AIH type 2, which affects mainly children and young adults, is unknown, also because the diagnosis is often overlooked. Intriguingly, AIH type 2 has been reported more frequently in Europe than in the United States (Czaja and Freese, 2002), possibly because of the undertesting for anti-LKM1 antibodies in the latter, due to the unsubstantiated belief that AIH type 2 is rare in Northern America and therefore that testing for anti-LKM1 antibodies is not cost-effective (Duchini et al., 2000). In a study in Canada including 159 children/adolescents with AIH, the annual incidence was 0.23/100000 children, type 1 AIH being diagnosed 5.5 times more frequently than type 2 AIH (Jimenez-Rivera et al., 2015).

At the King's College Hospital tertiary pediatric hepatology referral center, there has been a sevenfold increase in incidence of AIH over the last decade, perhaps a result in part of increased awareness of the disease. AIH represents approximately 10% of some 500 new referrals per year, two-third of the cases being AIH type 1 and one-third AIH type 2.

## CLINICAL FEATURES, DIAGNOSTIC PROCEDURES, AND DISEASE ASSOCIATIONS

The diagnosis of AIH is based on a combination of clinical, biochemical, immunological, and histological features and the exclusion of other known causes of liver disease. Liver biopsy is needed to confirm the diagnosis and to evaluate the severity of liver damage (Krawitt, 2006; Manns et al., 2010; European Association for the Study of the Liver, 2015) as transaminase and IgG levels do not reflect the degree of tissue inflammatory changes nor indicate the presence or absence of cirrhosis. Conditions that may share serological and histological features with AIH, such as viral hepatitis B, C, and E, Wilson disease, nonalcoholic steatohepatitis, and drug-induced liver disease, must be excluded by accurate clinical history and appropriate investigations.

Three quarters of patients with AIH are female. AIH type 1 affects all ages with two peaks, one in childhood/adolescence and the other in adulthood around the age of 40 years. Only 20% of the patients are diagnosed after the age of 60 years (Krawitt, 2006; Manns et al., 2010; European Association for the Study of the Liver, 2015). AIH type 2 affects mainly children/adolescents and young adults, being rare, though not absent, in older individuals. In pediatrics, AIH type 2 represents one-third of all cases and has a clinical course similar to AIH type 1, though anti-LKM1-positive children present at a younger age, more often with an acute onset, including fulminant hepatitis, and have associated IgA deficiency (Gregorio et al., 1997; Oettinger et al., 2005).

A percentage of 40–60 of adult patients with AIH type 1 have a chronic disease course with nonspecific symptoms such as fatigue, nausea, abdominal pain, and arthralgia (Al-Chalabi et al., 2008; Czaja et al., 1983). AIH may be diagnosed after the incidental finding of abnormal liver function tests during routine investigations.

About one-third of adult patients present acutely with jaundice, arthralgia, anorexia, and fatigue, symptoms indistinguishable from those of an acute hepatitis due to other causes (Crapper et al., 1986; Amontree et al., 1989). Acute hepatic episodes alternating with spontaneous clinical and biochemical improvement are not uncommon, a relapsing pattern that often leads to a dangerous delay in diagnosis and treatment. The importance of prompt investigation of abnormal liver function is reinforced by a report showing that half of the patients with AIH presenting with a hepatic picture were already cirrhotic and had a high liver-related mortality.

Some of these fatal outcomes could have been prevented by earlier diagnosis, as 49% of the patients had a history of abnormal liver tests, which had not been investigated (Panayi et al., 2014). Occasionally, the first symptoms of AIH are complications of portal hypertension, for example, gastrointestinal bleeding or hypersplenism,

without previous knowledge of liver disease. The acute presentation is more commonly observed in children and young adults than in older patients. At times AIH, particularly AIH type 2, presents as fulminant hepatic failure (Gregorio et al., 1997; Floreani et al., 2013). Because of the variability of its presenting features, AIH should be suspected and excluded in all patients with symptoms and signs of prolonged, relapsing, or severe liver disease so that the appropriate treatment can be instituted promptly.

At least one-third of patients with AIH already have cirrhosis at the time of diagnosis, irrespective of the mode of presentation (Manns et al., 2010; European Association for the Study of the Liver, 2015), indicating that the disease process is longstanding. Also patients presenting acutely have often advanced fibrosis or cirrhosis on liver biopsy (Dohmen et al., 2017). Patients with asymptomatic or symptomatic AIH have been reported to have similar courses of disease progression and responses to immunosuppressive treatment (Muratori et al., 2016; Dohmen et al., 2017).

About 40% of the patients with AIH have a family history of autoimmune disorders, and associated autoimmune features (e.g., thyroiditis, inflammatory bowel disease, type 1 diabetes, arthritis, hemocytopenias, vitiligo) are present at diagnosis or develop during follow-up in some 20% of both adult (Wong et al., 2017; Wong and Heneghan, 2015) and pediatric patients (Gregorio et al., 1997; Mieli-Vergani and Vergani, 2011).

In the absence of a single diagnostic test for AIH, the IAIHG has devised a diagnostic system for comparative and research purposes, which includes several positive and negative scores, the sum of which gives a value indicative of probable or definite AIH (Johnson and McFarlane, 1993). The scoring system was revised in 1999 (Alvarez et al., 1999) (Table 57.1). A simplified IAIHG scoring system published more recently is easier for clinical application (Hennes et al., 2008) (Table 57.2), though the revised scoring system (Alvarez et al., 1999) has been reported to have a superior performance in the diagnosis of patients with AIH compared with the simplified scoring system (43) (Li et al., 2014). In view of ethnic differences in AIH phenotype, modified scoring systems have been proposed for Japanese patients (Ohira et al., 2015; Onji et al., 2014) and specific guidelines have been established for Chinese patients (Chinese Society of Hepatology et al., 2017).

**TABLE 57.1** International Autoimmune Hepatitis Group Revised Diagnostic Scoring System

Parameter	Feature	Score
Sex	Female	+ 2
ALP: AST (or ALT) ratio	> 3	- 2
	1.5–3	0
	< 1.5	+ 2
Serum globulins or IgG (times above normal)	> 2.0	+ 3
	1.5–2.0	+ 2
	1.0–1.5	+ 1
	< 1.0	0
ANA, SMA, or anti-LKM1 titers	> 1:80	+ 3
	1:80	+ 2
	1:40	+ 1
	< 1:40	0
AMA	Positive	- 4
Viral markers of active infection	Positive	- 3
	Negative	+ 3
Hepatotoxic drug history	Yes	- 4
	No	+ 2
Average alcohol	< 25 g/day	+ 2
	> 60 g/day	- 2

**TABLE 57.2** Simplified Criteria for the Diagnosis of Autoimmune Hepatitis

Variable	Cutoff	Points
ANA or SMA	≥ 1:40	1
ANA or SMA	≥ 1:80	2 <sup>a</sup>
or anti-LKM1	≥ 1:40	
or SLA	Positive	
IgG	> Upper limit of normal	1
	> 1.10 times upper limit of normal	2
Liver histology	Compatible with AIH	1
	Typical of AIH	2
Absence of viral hepatitis	Yes	2

<sup>a</sup>Additional points for all autoantibodies cannot exceed a maximum of 2.

Score ≥ 6: probable AIH; ≥ 7: definite AIH. ANA, Antinuclear antibody; SMA, anti-smooth-muscle antibody; anti-LKM1, anti-liver kidney microsomal antibody type 1; SLA, soluble liver antigen; IgG, immunoglobulin G; AIH, autoimmune hepatitis.

Adapted from Hennes, E.M., et al., 2008b. Simplified criteria for the diagnosis of autoimmune hepatitis. *Hepatology* 48, 169–176.

None of the published scoring systems is perfect, particularly for the juvenile form of the disease, in which diagnostically relevant autoantibodies often have titers lower than the cutoff value considered positive in adults, and none of them can distinguish between AIH and AIH/sclerosing cholangitis (SC) overlap syndrome. A scoring system for the diagnosis of juvenile autoimmune liver disease has been recently proposed by the European Society for Paediatric Gastroenterology, Hepatology and Nutrition and awaits validation (Mieli-Vergani et al., 2018). In addition, the scoring systems give negative weight to the presence of hepatitis B or C viral markers, but concomitant AIH and chronic viral hepatitis have been reported (Rigopoulou et al., 2013).

As acute hepatitis E may present with histological and biochemical features of AIH, infection should be ruled out before the diagnosis of AIH is made by testing for specific IgM antibodies and hepatitis E virus RNA (Calisti et al., 2017; Patel et al., 2016). Intriguingly, evidence of exposure to hepatitis E virus has been reported more frequently among AIH patients than in the normal population (van Gerven et al., 2016; Pischke et al., 2014). Even more intriguingly, living in close contact with a pet, especially a cat, has been reported to be a risk factor for autoimmune liver disease, perhaps indicating exposure to an as yet unidentified agent (Tenca et al., 2016).

A careful enquiry about exposure to drugs is also mandatory before the diagnosis of AIH can be made, as drug-induced liver injury (DILI) occasionally mimics AIH (Andrade et al., 2009; Czaja, 2011). While a drug can unmask or induce classical AIH in a predisposed individual, who will usually have already fibrotic changes on liver biopsy and who will need chronic treatment with immunosuppressants, a drug can also cause a clinical picture indistinguishable from AIH but without fibrosis and without long-term steroid dependence. The IAIHG criteria for the diagnosis of definite or probable AIH are fulfilled both in classical AIH and in drug-induced autoimmune-like hepatitis (DILI-AIH), only the successful withdrawal of immunosuppression distinguishing the two conditions. The drugs most commonly associated with DILI-AIH are nitrofurantoin and minocycline, followed by methyldopa and hydralazine (de Boer et al., 2017). Other drugs associated with DILI-AIH are anti-tumor necrosis factor alpha (TNF- $\alpha$ ) monoclonal antibodies (Rodrigues et al., 2015; Bjornsson et al., 2017) and herbal remedies, especially in the Far East (Czaja, 2011). Interestingly, antibiotic treatment has been reported to be an independent risk factor for the development of AIH (Ngu et al., 2013).

AIH has been associated with a variety of liver and extrahepatic autoimmune diseases. Overlap between AIH and other autoimmune disorders affecting the liver is the focus of intense discussion (Vierling, 2015; Czaja, 2013). Some patients with AIH may also have clinical, histological, and serological features of primary biliary cholangitis (PBC) or SC. These overlap syndromes are probably clinical descriptions rather than distinct pathological entities, the dominant component of the disease determining its designation and therapy. In the presence of AIH features, immunosuppression is of benefit also in PBC and SC (Vierling, 2015; Czaja, 2013; Ozaslan et al., 2014; Yoshioka et al., 2014).

In children and young adults, a form of SC, known as autoimmune SC (ASC), and characterized by ANA and SMA positivity, high levels of IgG, and interface hepatitis, is increasingly recognized (Gregorio et al., 2001; Rodrigues et al., 2016; Deneau et al., 2013) (Gregorio et al., 2001). Rarely, anti-LKM1-positive patients with ASC have been reported (Gregorio et al., 2001; Pratico et al., 2013; Gargouri et al., 2013). Alkaline phosphatase and gamma glutamyl transpeptidase levels, which are usually elevated in cholestatic disease, are often normal or only mildly increased in the early disease stages of ASC and a cholangiography is needed to make the diagnosis. In the absence of bile duct imaging, these patients are diagnosed and treated as AIH. The presence of SC may be discovered during follow-up, after the appearance of an overt cholestatic biochemical profile. In childhood, ASC affects equally males and females (Gregorio et al., 2001). If treatment is started early, the parenchymal liver damage in ASC responds well to the same immunosuppressive treatment used for AIH, with good medium-to-long-term survival. However, the bile duct disease progresses in about 50% of the patients despite treatment (Gregorio et al., 2001). Also in an adult series, patients with overlapping features between SC and AIH, treated with immunosuppression, appear to have a better prognosis than those with classical primary SC, suggesting that immunosuppression might have a positive effect on disease progression (Zenouzi and Lohse, 2014).

A subtype of AIH characterized by infiltration of IgG4-expressing plasma cells and particularly responsive to corticosteroids has been described within the IgG4-related disease (Chung et al., 2010; Yada et al., 2013). AIH has been reported in association with celiac disease (CD), some 5% of the patients with AIH also having CD and over 10% of the patients with CD having AIH (Najafi et al., 2014). In a large Dutch study, CD was found in 3.5% of the AIH patients compared with 0.35% in the general Dutch population, reinforcing the notion that CD should be considered in all AIH patients (van Gerven et al., 2014) also in view of the possible benefit that gluten withdrawal may have on the course of AIH in CD patients (Iqbal et al., 2017). Occasional patients fulfill diagnostic criteria of both AIH and SLE, the liver disease responding satisfactorily to standard AIH immunosuppressive treatment (Beisel et al., 2014). AIH has also been rarely described in patients with systemic sclerosis (Assandri et al., 2016) or multiple sclerosis (Sayin et al., 2016).

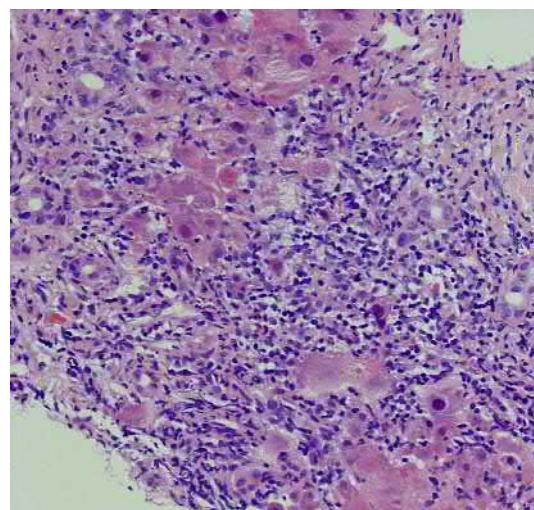

An emerging problem is the association between nonalcoholic fatty liver disease and AIH, resulting from a worldwide increase in metabolic syndrome (Weiler-Normann and Lohse, 2016). Patients with concomitant AIH and nonalcoholic steatohepatitis have been reported to present with cirrhosis and to develop adverse clinical events more frequently than patients with classical AIH, with consequent decreased survival (De Luca-Johnson et al., 2016).

As AIH affects primarily women of childbearing age, most of whom require immunosuppression lifelong, a number of studies have assessed the outcome of pregnancy and postpartum in this condition. Overall, pregnancy and childbirth appear to be safe for both child and mother, even in women with compensated liver cirrhosis, without the need to withdraw azathioprine (Heneghan et al., 2001; Candia et al., 2005; Terrabuio et al., 2009; Braga et al., 2016; Danielsson Borssen et al., 2016). One large series from Sweden reports an increased risk of gestational diabetes, preterm birth, and low-birth-weight infants compared with the general population (Stokkeland et al., 2016). Clinical improvement as well as disease exacerbation have been observed in relation to pregnancy, the latter particularly in the postpartum period (Braga et al., 2016), indicating that high-quality antenatal and postnatal care is essential for women with AIH and their infants.

## PATHOLOGICAL FEATURES

The typical histological feature of AIH is interface hepatitis, which is however not exclusive to this condition (Czaja and Carpenter, 1997). Interface hepatitis is characterized by a dense inflammatory infiltrate composed of lymphocytes and plasma cells, which crosses the limiting plate and invades the surrounding parenchyma (Fig. 57.1). Hepatocytes surrounded by inflammatory cells become swollen and undergo pyknotic changes, representing apoptosis (Searle et al., 1987; Bai and Odin, 2003). We emphasize this feature because not only the liver was the site wherein apoptosis was first recognized nearly a century ago but also, in some other autoimmune diseases, disordered apoptosis can yield potently immunogenic particles—apoptopes (Lleo et al., 2009). Though plasma cells are characteristically abundant at the interface and within the lobule, their presence in low number does not exclude the diagnosis of AIH. When AIH presents acutely, and during episodes of relapse, a common histological finding is panlobular hepatitis with centrilobular and bridging necrosis and, if the disease takes a fulminant course, massive necrosis and multilobular collapse (Tiniakos et al., 2015; Nguyen Canh et al., 2017).

Though sampling variation may occur in needle biopsy specimens, particularly in cirrhotic livers, the severity of the histological appearance is usually of prognostic value (Puustinen et al., 2017). Inflammatory changes surrounding the bile ducts are not uncommon in AIH (Verdonk et al., 2016), but when conspicuous they suggest an overlap with SC or PBC. Other nonspecific features that may point to the diagnosis of AIH are emperipoleisis and hepatocyte rosetting (Miao et al., 2015), which in a recent study have been suggested to be stronger indicators of AIH than interface hepatitis or plasma-cell-rich infiltrate (de Boer et al., 2015). A paper in a pediatric AIH cohort suggests that the finding of hyaline droplets in Kupffer cells is a useful diagnostic marker to distinguish AIH from other forms of chronic hepatitis (Tucker et al., 2015).

Interface hepatitis is the typical histological feature of AIH and is characterized by a dense portal and periportal lymphocyte and plasma cell infiltrate that disrupts the parenchymal limiting plate. Hematoxylin and eosin staining. Original magnification  $\times 40$ . AIH, Autoimmune hepatitis. Source: Courtesy of Dr Alberto Quaglia.

As persisting histological activity despite biochemical remission is frequent in patients with treated AIH and is associated with lower rates of fibrosis regression and reduced long-term survival, repeat biopsy is important in assessing ongoing disease activity, particularly when considering drug withdrawal (Putra et al., 2016; Dhaliwal et al., 2015).

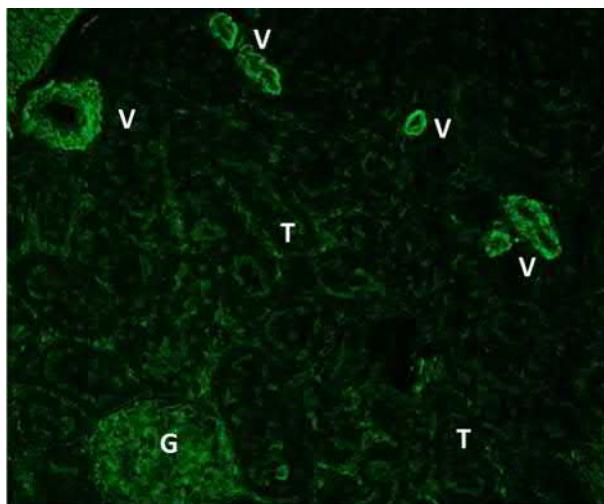

## AUTOIMMUNE FEATURES

AIH has several characteristics of an organ-specific autoimmune disease: it affects mainly females, it is accompanied by serological features of autoimmunity (organ and nonorgan-specific autoantibodies; high levels of IgG), it is associated to human leukocyte antigen (HLA) allotypes predisposing to autoimmunity, it has a strong connectivity with other autoimmune disorders, and it responds satisfactorily to immunosuppressive treatment.

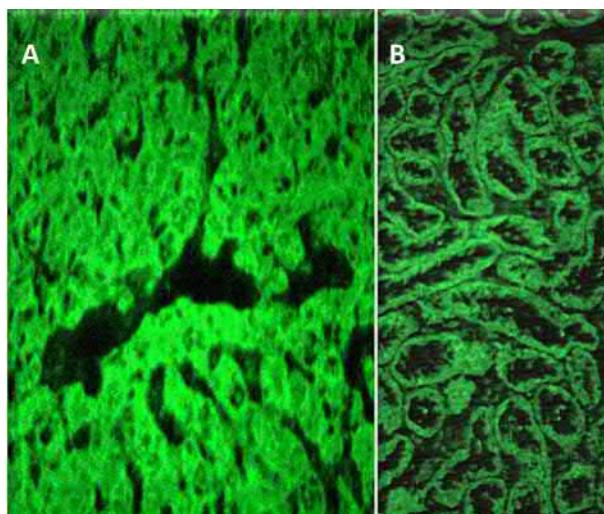

Key to the diagnosis of AIH is positivity for circulating autoantibodies (Johnson and McFarlane, 1993; Alvarez et al., 1999; Hennes et al., 2008; Vergani et al., 2004; Bogdanos et al., 2009; Liberal et al., 2013). Their detection by indirect immunofluorescence (Figs. 57.2–57.5) on a rodent substrate not only assists in the diagnosis but also allows differentiation into two forms of AIH. ANA and SMA characterize AIH type 1, while anti-LKM1 and anti-LC1 define AIH type 2. The two autoantibody profiles may occasionally coexist (Vergani et al., 2004). As

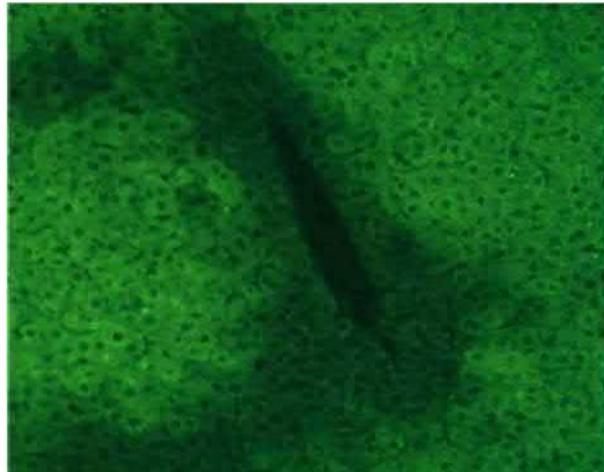

**FIGURE 57.2** Antinuclear antibodies. Immunofluorescence pattern of antinuclear autoantibodies on rodent liver (main image) and HEp2 cells (inset), which, because of their large nuclei, allow pattern recognition. The homogeneous pattern (inset left) is the most common in autoimmune hepatitis; the speckled pattern (inset right) is much rarer. HEp2 cells should not be used for sample screening because of a high frequency of false-positive results.

**FIGURE 57.4** Anti–liver kidney microsomal type 1 antibodies. Immunofluorescence pattern of anti-LKM1 autoantibodies on liver (left) and kidney (right) rodent sections; anti-LKM1 stains the cytoplasm of hepatocytes and proximal renal tubules. *LKM1*, Liver kidney microsomal type 1.

**FIGURE 57.5** Anti–liver cytosol type 1 antibodies. Immunofluorescence pattern of anti-LC1 antibodies on a rodent liver section: they stain the cytoplasm of hepatocytes with a weakening of the staining around the central vein. *Anti-LC1*, Anti–liver cytosol type 1.

interpretation of the immunofluorescence patterns can be difficult, guidelines have been provided by the IAIHG regarding methodology and interpretation of liver autoimmune serology (Vergani et al., 2004). A major advantage of testing for autoantibodies by indirect immunofluorescence on a freshly prepared rodent substrate that includes kidney, liver, and stomach is that it allows the concurrent detection of several autoreactivities relevant to AIH. These include ANA, SMA, anti-LKM1, and anti-LC1, as well as anti–mitochondrial antibody (AMA), the serological hallmark of PBC, the presence of which weighs against the diagnosis of AIH (Johnson and McFarlane, 1993; Alvarez et al., 1999; Hennes et al., 2008; Vergani et al., 2004). Autoantibodies are considered positive when present at a dilution of 1:40 or more in adults, while in children, who are rarely positive for autoantibodies in health, positivity at a dilution  $\geq 1:20$  for ANA and SMA or  $\geq 1:10$  for anti-LKM1 is clinically significant (Mieli-Vergani et al., 2018). Both in adults and children, autoantibodies may be present at a low titer or even be negative at disease onset, particularly with acute presentation (Yilmaz et al., 2016; Fujiwara et al., 2015), to become detectable during follow-up (Gregorio et al., 2001). If AIH is suspected, it is advisable to repeat autoantibody testing and to ask the laboratory to report any level of positivity.

ANA is detectable on all rodent tissues and in AIH usually has a homogeneous pattern (Fig. 57.2). For a clearer and easier definition of the pattern, HEp2 cells that have prominent nuclei are used (Fig. 57.2), though

these cells, derived from a laryngeal carcinoma, should be used with caution for screening purposes, because of a high proportion of low titer positivity within the normal population (Tan et al., 1997). There are no ANA molecular targets specific for AIH. A varied profile of ANA reactivities reminiscent of that found in SLE (e.g., to nuclear chromatin, histones, centromere, double-stranded DNA and single-stranded DNA, and ribonucleoproteins (Peakman et al., 1989; Bogdanos et al., 2009; Czaja et al., 1994; Strassburg et al., 1996; Bogdanos et al., 2008)) has been reported in AIH, but at least a third of AIH patients positive for ANA do not react with known nuclear targets (Bogdanos et al., 2009; Bogdanos et al., 2008). Immunofluorescence remains therefore the gold standard for ANA testing, as surmised by the American College of Rheumatology ANA Task Force (Meroni and Schur, 2010), but is not universally practiced. There is an impression, albeit poorly documented, that higher level of autoantibody and/or multiple autoantibodies are a pointer to a diagnosis of AIH, as pertains in Type 1 diabetes.

The immunofluorescent staining of SMA is detected in the arterial walls of rodent kidney, liver, and stomach. In the kidney, SMA can have three patterns: V (vessels), G (glomeruli), and T (tubules) (Bottazzo et al., 1976) (Fig. 57.3). The V pattern is present also in nonautoimmune inflammatory liver disease, in autoimmune diseases not affecting the liver, and in viral infections, but the VG and VGT patterns are indicative of AIH. Interestingly, the accidental finding of SMA with GT pattern in association with any increase of transaminase levels appears to predict the development of AIH (Healey et al., 2016). The VGT pattern corresponds to the "F actin" or microfilament (MF) pattern observed using cultured fibroblasts as substrate. Neither the VGT nor the anti-MF patterns are, however, entirely specific for the diagnosis of AIH type 1. The molecular target of the MF reactivity observed in AIH type 1 remains to be identified. Though "antiactin" reactivity is strongly associated with AIH type 1, some 20% of the SMA-positive AIH type 1 patients do not have the F-actin/VGT pattern. The absence, therefore, of antiactin SMA does not exclude the diagnosis of AIH (Muratori et al., 2002).

The anti-LKM1 pattern is characterized by bright staining of the hepatocyte cytoplasm and of the P3 portion of the renal tubules (Fig. 57.4). Anti-LKM1 is frequently confused with AMA, as both autoantibodies stain liver and kidney, though AMA, in contrast to anti-LKM1, also stains gastric parietal cells. The identification of the molecular targets of anti-LKM1, cytochrome P4502D6 (CYP2D6), and of AMA, enzymes of the 2-oxo-acid dehydrogenase complexes, has allowed the establishment of immunoassays using recombinant or purified antigens (Vergani et al., 2004; Bogdanos et al., 2009), which can be used to resolve doubtful cases. In the context of AIH, there can be positivity for AMA in a small subset of patients (3%–5%), who respond to immunosuppressive treatment such as classical AIH, some of whom having overlapping features with PBC (O'Brien et al., 2008; Montano-Loza et al., 2008; Muratori et al., 2017). Additional LKM reactivities have been described. Anti-LKM2 antibodies, which target cytochrome P4502C9, are of historical interest only because of their association with ticrynafen-induced hepatitis, a uricosuric diuretic withdrawn from clinical use in 1980 because of its severe hepatotoxicity. Anti-LKM3 antibodies are specific for members of the uridine glucuronosyltransferase family 1 and give an immunofluorescence pattern similar to anti-LKM1. Although anti-LKM3 are most commonly detected in patients with hepatitis delta, they have also been reported in approximately 10% of the patients with AIH type 2 (Strassburg et al., 1996).

Anti-LC1 (Fig. 57.5), which is an additional marker for AIH type 2, can be present on its own but frequently occurs in association with anti-LKM1. In addition to indirect immunofluorescence, it can be detected by line-blot (Villalta et al., 2016). Anti-LC1 targets formimino-transferase cyclodeaminase (FTCD) (Lapierre et al., 1999). Anti-FTCD antibody can be detected by commercial enzyme-linked immunosorbent assay (ELISA) (Vergani et al., 2004).

Other autoantibodies less commonly tested, but of diagnostic importance, include anti-soluble liver antigen (anti-SLA) and anti-perinuclear neutrophil cytoplasm antibodies (pANCA).

Anti-SLA is highly specific for the diagnosis of AIH, usually type 1 (Baeres et al., 2002). Its presence identifies patients with more severe disease and worse outcome (Ma et al., 2002; Czaja et al., 2002; Chen et al., 2015). Anti-SLA was thought to identify a third type of AIH in which tests for conventional autoantibodies were negative (Manns et al., 1987). However, early reports predated the publication of the IAIHG recommendations and used a cutoff point for conventional autoantibody levels higher than that currently used for the diagnosis of AIH. Several patients considered to have AIH type 3 were positive for conventional autoantibodies. At variance with standard diagnostic autoantibodies, anti-SLA is not detectable by immunofluorescence. The molecular target of anti-SLA is Sep (O-phosphoserine) tRNA:Sec (selenocysteine) tRNA synthase (SEPSECS) (Wies et al., 2000; Costa et al., 2000; Paloura et al., 2009). Cloning of this reactant has led to the availability of molecularly based diagnostic assays for anti-SLA, but their full evaluation is still under way.

In AIH type 1, akin to primary SC and inflammatory bowel disease, pANCA are frequently detected, but they are atypical, since they react with peripheral nuclear membrane components (perinuclear antinuclear neutrophil

antibodies, pANNA) (Bogdanos et al., 2009). In curious contrast to AIH type 1, pANNA are virtually absent in AIH type 2 (Vergani et al., 2004).

Anti–asialoglycoprotein receptor (ASGPR) antibodies were identified in 1984 during an attempt to detect putative autoantigenic targets located on the hepatocyte membrane. ASGPR is the main constituent of the crude liver cell extract known as liver-specific protein (LSP) and is the only liver-specific autoantigen discovered so far (Bogdanos et al., 2009). Some 50%–90% of the patients with AIH type 1 or 2 are anti-ASGPR/anti-LSP seropositive (Gregorio et al., 2001); anti-ASGPR is found in combination with ANA, SMA, and anti-LKM1 and its level correlates with disease activity. However, the detection of anti-ASGPR requires either purified or recombinant antigen, and the development of reliable molecular assays has been difficult, therefore their applicability to clinical practice is limited. Moreover, since these autoantibodies have also been detected in patients with viral hepatitis, drug-induced hepatitis, and PBC, they are not disease specific (Bogdanos et al., 2009; Rigopoulou et al., 2012).

A number of antibodies of potential diagnostic relevance for AIH have been described more recently. Anti–programmed cell death-1 (PD-1) antibody has been reported to be a serological marker for AIH type 1 in Japan and its presence may distinguish between AIH and DILI (Miyake et al., 2014; Matsumoto et al., 2014), both findings awaiting confirmation. Anti–ribosomal P protein antibody has been reported to define a group of AIH patients with severe prognosis (Calich et al., 2013), though this has been questioned (Muratori et al., 2014) and requires further analysis. Antibodies to self HLA class II alleles, similar to those detected after transplantation, were detected in nontransplanted patients with AIH more frequently than in patients with PBC and healthy subjects (Yamagiwa et al., 2014).

To detect yet unidentified autoantibodies, protein and peptide libraries are scanned with antibodies generated through the isolation of B cells and plasma cells from the peripheral blood or the liver of patients with AIH. Using this approach, novel specificities have been identified in AIH and PBC, whose relevance remains to be evaluated in large series (Mazzara et al., 2015; Norman et al., 2015; Tanaka et al., 2017).

## GENETICS

AIH is a “complex trait” disease, that is, a condition not inherited in a Mendelian autosomal dominant, autosomal recessive, or sex-linked fashion (Donaldson, 2002, 2004). The mode of inheritance of a complex trait disorder involves one or more genes, operating alone or in concert, to increase or reduce the risk of the trait, and interacting with environmental factors.

Several genes have been reported to confer susceptibility to AIH-1 and influence clinical manifestations, response to treatment and prognosis. Most are located within the HLA region [the human major histocompatibility complex (MHC)], the gene products of which are involved in the presentation of antigenic peptides to T cells and the initiation of adaptive immune responses. The strongest associations lie within the HLA-DRB1 locus. Alleles encoding the HLA-DR3 (*DRB1\*0301*) and DR4 (*DRB1\*0401*) molecules confer susceptibility to AIH type 1 in European and North American populations (Donaldson, 2002, 2004; van Gerven et al., 2015), while DR4 to Oriental populations (Furumoto et al., 2015). These associations are sufficiently strong to score positively for the diagnosis of AIH according to the revised diagnostic IAIHG system (Alvarez et al., 1999). The prominent predisposing role of genes encoded in the HLA region has been confirmed in the largest genome-wide association study performed to date in AIH (de Boer et al., 2014). Links have been reported between possession of these predisposing HLA alleles and clinical manifestations, response to treatment and prognosis. Thus among white Northern Europeans, *DRB1\*0301* is more common in patients who deteriorate despite corticosteroid treatment (Donaldson, 2002, 2004). The residues within the cleft of the HLA class II molecules specifically linked to the pathogenesis of AIH reported from various countries differ, suggesting that the antigenic peptides recognized by T cell-mediated immune responses in AIH may derive from different exogenous triggers and that they are embraced by geographically/ethnically distinct HLA molecules (Donaldson, 2002, 2004). These HLA associations may be the molecular footprints of the prevailing triggers that precipitate AIH in different environments. In this context, it is of interest that in South America possession of the HLA *DRB1\*1301* allele, which predisposes to pediatric AIH type 1 in that population, is also associated with persistent infection with the endemic hepatitis A virus (Fainboim et al., 2001). The combination of HLA *DRB1\*1301* and a specific functional form of the killer cell immunoglobulin-like receptor (KIR2DS4-FL) imparts a strong predisposition to pediatric type 1 AIH in South America (Podhorzer et al., 2016).

Susceptibility to and severity of AIH type 2 has been linked to alleles encoding the DRB1\*0301 and DRB1\*0701 molecules in the United Kingdom and Brazil. Allelic variation within HLA-DRB1 has been linked to differences in the autoantibody seropositivity profiles of AIH type 2 patients (Djilali-Saiah et al., 2006).

There are also reports of susceptibility to AIH linked to polymorphisms in genes located outside the MHC; the cytotoxic T lymphocyte antigen-4 (CTLA-4) (Agarwal et al., 2000), the TNF- $\alpha$  gene promoter (Cookson et al., 1999), and Fas (Agarwal et al., 2007) are notable examples.

A form of AIH serologically resembling AIH type 2 affects some 20% of the patients with autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) (see Chapter 43). APECED is a monogenic autosomal recessive disorder caused by homozygous mutations in the *AIRE1* gene and characterized by a variety of organ-specific autoimmune diseases, the most common of which are hypoparathyroidism and primary adrenocortical failure, accompanied by chronic mucocutaneous candidiasis (Simmonds and Gough, 2004; Liston et al., 2005). Interestingly, there are neutralizing autoantibodies to Type 1 interferons, perhaps accounting for the associated immune deficiencies (see Chapter 76). APECED has a high level of variability in symptoms, especially between populations. Carriers of a single *AIRE1* mutation (heterozygotes) do not develop APECED. However, although the inheritance pattern of APECED indicates a strictly recessive disorder, there are anecdotal data of mutations in a single copy of *AIRE1* being associated with human autoimmunity of a less severe form than classically defined APECED (Simmonds and Gough, 2004; Liston et al., 2005).

The role of the *AIRE1* heterozygote state in the development of type 2 AIH remains to be established, though heterozygous *AIRE1* mutations have been reported in three children with severe AIH type 2 and extrahepatic autoimmune manifestations (Lankisch et al., 2005).

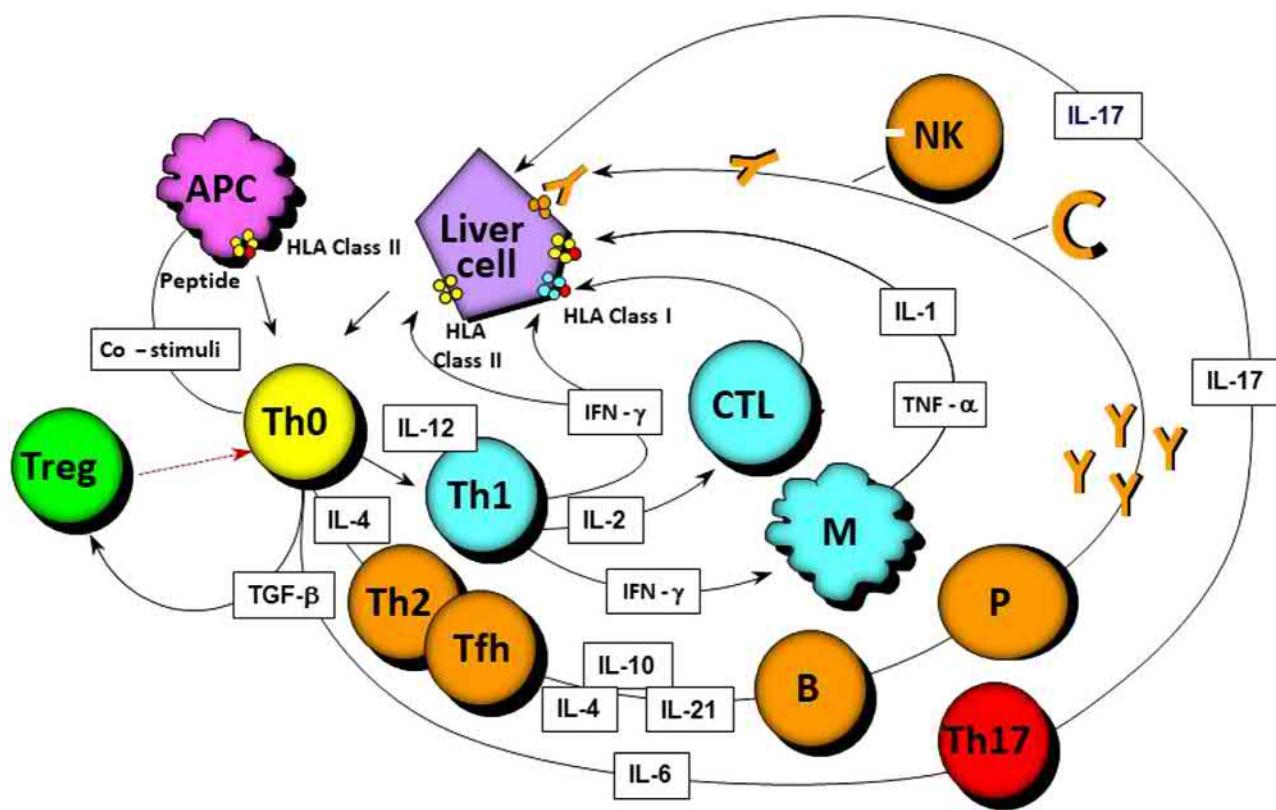

## PATHOGENIC MECHANISMS

In patients with increased genetic susceptibility to AIH, immune responses to liver autoantigens could be triggered by molecular mimicry. Cross-reactivity is an inherent property of the cells of the adaptive immune system (Vergani et al., 2002), derived from the need of T- and B-lymphocytes to recognize a potentially infinite number of non-self-antigens without any prior information as to their structure. This implies that these cells, rather than responding to single antigen specificities, are able to cross-reactively respond to a number of antigens, thus expanding the antigenic specificities of the immune system to a level that reflects the antigenic diversity of the external environment.

This inherent potential for cross-reactivity, whilst allowing efficient responses to a vast array of pathogens, also provides the immune system with the potential to cross-react with self, leading to autoimmunity. This concept has been termed “molecular mimicry,” where immune responses to external pathogens become directed toward structurally similar self components.

The strongest support to this model is in the context of AIH type 2, where T lymphocytes that target a key epitope of CYP2D6 also react with self-mimicking exogenous sequences present on the hepatitis C virus and members of the herpes virus family (cytomegalovirus, Epstein–Barr virus, and herpes simplex virus) (Vergani et al., 2002). It is conceivable that, in genetically predisposed individuals, T cells targeting the self-epitope may be primed and expanded through exposure to the self-mimicking exogenous sequences with consequent initiation and perpetuation of liver autoimmunity. This potential scenario is supported by a case-report describing a 10-year-old girl who acquired hepatitis C virus (HCV) infection following a liver transplant for end-stage liver disease caused by alpha1-antitrypsin deficiency. Two weeks after HCV infection, IgM anti-LKM1 autoantibodies appeared, followed by IgG anti-LKM1 antibodies, suggestive of HCV as the initiator of a primary anti-LKM1/anti-CYP2D6 autoimmune response (Mackie et al., 1994); 10 years later, the patient developed florid AIH type 2, which responded satisfactorily to immunosuppressive treatment, but by this time there was no trace of the previous HCV infection (Bogdanos et al., 2004).

Putative mechanisms of autoimmune liver damage are depicted in Fig. 57.6. The immune response in AIH is believed to be initiated by the presentation of self-antigenic peptides (as yet unknown) to the T-cell receptor of uncommitted naive CD4+ T-helper (Th0) lymphocytes. Self-antigenic peptides are processed and presented by professional antigen-presenting cells (APCs), including dendritic cells (DCs), macrophages, and B lymphocytes. The liver is home to several specialized APC populations, including liver sinusoidal endothelial cells, Kupffer cells, and DCs, so that antigen presentation to both CD4 and CD8 effector T cells can occur in situ, averting the need for trafficking to the regional lymphoid tissues (Crispe, 2011; Ebrahimkhani et al., 2011).

**FIGURE 57.6 Autoimmune attack to the hepatocyte.** An autoantigen is presented to uncommitted T helper (Th0) lymphocytes within the HLA class II molecule of an APC either in the regional lymph nodes or within the liver itself. Activated Th0 cells differentiate into Th1 or Th2 cells in the presence of IL-12 or IL-4, respectively, and according to the nature of the antigen. This triggers a series of immune reactions determined by the cytokines they produce. Th1 cells secrete IL-2 and IFN- $\gamma$ , which are cytokines that stimulate CTL, enhance expression of class I HLA molecules, induce expression of class II HLA molecules on the liver cells, and activate macrophages. Macrophages (M) release IL-1 and TNF. Th2 cells secrete mainly IL-4, IL-10, and IL-13 and stimulate autoantibody production by B lymphocytes. Tregs are derived from Th0 in the presence of TGF- $\beta$ . In the presence of defective Tregs, hepatocyte destruction ensues from the engagement of damaging effector mechanisms, including CTL, cytokines released by Th1 and by activated macrophages, complement activation, or adhesion of NK cells to autoantibody-coated hepatocytes through their Fc receptors. Th17 cells produce the inflammatory cytokine IL-17 and derive from Th0 cells in the presence of TGF- $\beta$  and IL-6. They are the focus of ongoing investigations. Tfh cells, specialized CD4+ T cells that induce activation and differentiation of B cells into immunoglobulin secreting cells through expression of CD40L and production of IL-21, may also have a role in the pathogenesis of AIH, Thf secreted IL-21 being elevated in AIH, its levels correlating with disease activity. APC, Antigen-presenting cell; IL, interleukin; IFN, interferon; CTL, cytotoxic T lymphocytes; HLA, human leukocyte antigen; TNF, tumor necrosis factor; Tregs, regulatory T cells; TGF, transforming growth factor; NK, natural killer; Tfh, T follicular helper.

During antigen presentation, in the presence of appropriate costimulatory signals, CD4+ Th0 cells become activated and undergo differentiation into distinct T-helper cell subsets, depending on the cytokine milieu to which they are exposed. In the presence of IL-12 or IL-4, Th0 lymphocytes differentiate into Th1 or Th2 cells, respectively, while predominance of IL-1beta and IL-6 favors differentiation into Th17 cells. Differentiation into Th1 cells leads to the production of IL-2 and IFN-gamma and the concomitant activation of CD8 T lymphocytes that produce IFN-gamma and TNF- $\alpha$  and exert cytotoxicity upon recognition of an antigen/MHC class I complex (Ichiki et al., 2005). Exposure of hepatocytes to IFN-gamma results in the upregulation of MHC class I and in the aberrant expression of MHC class II molecules, which leads to further T-cell activation and to the perpetuation of liver damage (Lobo-Yeo et al., 1990; Senaldi et al., 1991). IFN-gamma also favors monocyte differentiation, promotes macrophage and immature DC activation (Delneste et al., 2003), and contributes to enhanced natural killer cell killing (Schroder et al., 2004).

Differentiation of Th0 into Th2 cells leads to the secretion of IL-10, IL-4, and IL-13, cytokines essential for B-cell maturation into plasma cells and consequently to the production of autoantibodies, which can participate in mechanisms of damage such as antibody-mediated cellular cytotoxicity and complement activation (Longhi et al., 2010; Liberal et al., 2016). Of note, the titers of several autoantibodies, including anti-liver-specific-protein

and its components, correlate with indices of disease severity (Jensen et al., 1978; McFarlane et al., 1986). Moreover, in AIH type 2, the target of the disease-defining antibody, anti-LKM1, CYP2D6, is present not only in the endoplasmic reticulum but also is expressed on the membrane of hepatocytes and therefore readily accessible to the immune attack (Muratori et al., 2000).

Th17 cells contribute to autoimmunity by producing the proinflammatory cytokines IL-17, IL-22, and TNF- $\alpha$ , and inducing hepatocytes to secrete IL-6 (Zhao et al., 2011), which further enhances Th17 activation. The role of Th17 cells, which has been documented in PBC (Harada et al., 2009), is under investigation also in AIH, where an elevated level of Th17 cells has been reported in both blood and liver (Zhao et al., 2011; Thomas-Dupont et al., 2016). A possible role for T follicular helper (Tfh) cells in the pathogenesis of autoimmune diseases is increasingly been reported (Ma and Deenick, 2014). Tfh cells are specialized CD4+ T cells that induce the activation and differentiation of B cells into immunoglobulin secreting cells. This helper function is provided in the form of expression of molecules such as CD40L and cytokines such as IL-21. Tfh overactivation may result in autoimmunity. Tfh cells are located in secondary lymphoid tissues, but their counterparts can be found also in the circulation. Tfh secreted IL-21 cytokine has been reported to be elevated in AIH, its levels correlating with disease activity (Abe et al., 2016; Ma et al., 2014; Thomas-Dupont et al., 2016; Kimura et al., 2017).

Gamma/Delta T cells, which account for a low proportion of circulating lymphocytes, are relatively abundant in the liver (Wen et al., 1992) and might contribute to the pathogenesis of AIH, as they are elevated during active disease phases. Moreover, in AIH, gamma/delta T cells produce high levels of granzyme B and IFN-gamma, the expression of which correlates with biochemical indices of liver damage, suggesting a direct involvement of this cell population in hepatic injury (Ferri et al., 2010). The involvement of macrophages in AIH liver damage is supported by the finding that soluble CD163, a product of macrophage activation, is markedly elevated during the acute phase of the disease and in poor responders, normalizing with successful treatment (Gronbaek et al., 2016).

A deficiency of immunoregulation, enabling the autoimmune response to develop, has been repeatedly reported in AIH. Thus earlier, patients with AIH were reported to have low levels of circulating CD8+ T cells and impaired T-cell suppressor function which segregated with disease-predisposing HLA alleles B8/DR3 and was correctable by therapeutic doses of corticosteroids (Nouri-Aria et al., 1982). Furthermore, there was a defect in a subpopulation of T cells controlling the immune response to liver-specific membrane antigens (Vento et al., 1984). More recent evidence based on the now “genuine” regulatory T cells (Tregs) confirms an impairment of immunoregulatory function in AIH. Amongst T-cell subsets with potential immunosuppressive function, CD4 cells constitutively expressing the IL-2 receptor alpha chain (CD25) (Tregs) have emerged as the dominant subset. These cells, representing 5%–10% of all peripheral CD4 cells in health, control innate and adaptive immune responses by limiting the proliferation and effector function of autoreactive T cells (Sakaguchi, 2000). Their mechanism of action involves mainly a direct contact with the target cells, and to a lesser extent the release of immunoregulatory cytokines, such as IL-10 and tissue growth factor beta 1. In addition to CD25, which is also present on T cells undergoing activation, Tregs express a further markers such as the glucocorticoid-induced tumor necrosis factor receptor, CD62L, CTLA4, and the forkhead/winged helix transcription factor FOXP3, whose expression has been associated with the acquisition of regulatory properties, while they express little or no CD127—the IL-7 receptor. Treg impairment is linked with various human autoimmune diseases including AIH (Sakaguchi et al., 2010). In patients with AIH type 1 and type 2, Tregs are defective in number compared to normal controls and this reduction is disease stage related, being more evident at diagnosis and during relapses than during drug-induced remission (Longhi et al., 2005; Longhi et al., 2010; Ferri et al., 2010; Liberal et al., 2015). The percentage of Tregs inversely correlated with markers of disease severity, such as anti-SLA and anti-LKM1 autoantibody titers, suggesting that reductions in Tregs favor manifestations of autoimmune liver disease. Moreover, Tregs from AIH patients at diagnosis are impaired in their ability to control the proliferation of CD4 and CD8 effector cells compared to Tregs isolated from AIH patients at remission or from healthy subjects (Longhi et al., 2005; Ferri et al., 2010). Though most published literature indicates a numerical and functional Treg defect in AIH, these findings were disputed in a paper which, however, used a different methodological approach (Peiseler et al., 2012; Longhi et al., 2012).

The immunoregulatory defects described above have been complemented by findings that effector CD4 T cells in AIH are less susceptible to restraints exerted by Tregs. This defect is linked to reduced expression of the receptor molecule Tim-3 (inhibitory receptor T-cell-immunoglobulin-and-mucin-domain-containing-molecule-3), which upon ligation of galectin-9 expressed by Tregs induces effector cell death (Liberal et al., 2012). In AIH, CD39 $^{+}$  Tregs are decreased in number, fail to adequately hydrolyze proinflammatory nucleotides, and do not suppress efficiently IL-17 production by effector CD4 T cells. CD39 $^{+}$  Tregs show plasticity and are unstable upon proinflammatory challenge, suggesting that defective immunoregulation in AIH might result not only from reduced

Treg number and function but also from increased conversion of Tregs into effector cells (Grant et al., 2014). In AIH it has also been reported that low Treg responsiveness to IL-2 results in defective IL-10 production, contributing to Treg functional impairment (Liberal et al., 2015).

An increase of FOXP3-positive cells in the liver of patients with AIH, particularly during active disease, has been reported and interpreted as an enrichment of Tregs in the target tissue (Behairy et al., 2016; Diestelhorst et al., 2017; Taubert et al., 2014). However, these studies rely only on the expression of FOXP3 in tissue lymphocytes, this molecule being associated with activation of CD4 cells—including effector cells (Allan et al., 2007), without functional demonstration of regulatory properties.

If loss of immunoregulation were central to the pathogenesis of autoimmune liver disease, treatment should concentrate on restoring the ability of Tregs to expand, with consequent increase in their number and function. However, we must be mindful that further confirmatory data are needed. Moreover, it is essential to devise strategies preventing Tregs to become effectors of damage within an inflammatory milieu (Liberal et al., 2017; Holder et al., 2014).

Intestinal microbiome may also be involved in the pathogenesis of AIH. Alterations in the composition of the intestinal microbiota (dysbiosis) have been found in experimental AIH (Yuksel et al., 2015). Compared to healthy volunteers, the structural proteins binding intestinal epithelial cells are reduced in patients with AIH; plasma lipopolysaccharide levels are increased; and the number of intestinal anaerobes is decreased (Lin et al., 2015). Also in humans, AIH appears therefore to be associated with dysbiosis, increased gut permeability, and translocation of intestinal microbial products into the systemic circulation.

## ANIMAL MODELS

Research on the pathogenesis of AIH has been hampered by the lack of animal models reproducing faithfully the human condition. Findings in animal models of AIH have been reviewed by Hardtke-Wolenski et al. (2012) and by Christen and Hintermann (2016). Most animal models of AIH, though informative regarding single steps leading to liver inflammation and damage, do not mimic the chronic relapsing course of the human disease. In fact, they demonstrate the difficulty in breaking tolerance toward liver antigens, and the involvement of regulatory mechanisms in maintaining it.

A widely studied model of experimental hepatitis is that induced by concanavalin A (Tiegs et al., 1992). Though this model does not reflect accurately the pathological entity of AIH in humans, it has provided evidence that liver damage mainly occurs within a Th1 scenario, with the involvement of activated CD4 T cells and release of the proinflammatory cytokines interferon gamma and tumor necrosis factor alpha against a specific genetic background. Interleukin-4, a cytokine with mainly regulatory activity, is also required for the establishment of concanavalin A-induced hepatitis. This finding and those of Takeda et al. (2000), who have shown that natural killer T (NKT) cells, which secrete both IL-4 and interferon gamma, are critical to the development of concanavalin A-induced hepatitis in C57/B6 mice, suggest that both adaptive and innate immunity are involved. A distinct member of the interleukin 17 family, IL-17C, produced by hepatocytes, has been shown to have a key role in the liver damage in concanavalin A-induced hepatitis through the binding with its specific receptor IL-17RE present on liver resident T cells (Huang et al., 2017).

The ideal model for AIH should have a well-defined initiating event followed by chronic inflammation leading to fibrosis.

Researchers have been focusing on animal models of AIH type 2, since in this condition the autoantigens are well defined. The model produced by the group of Alvarez (Lapierre et al., 2004) is based on immunizing every 2 weeks for three times C57BL/6 female mice with a plasmid containing the antigenic region of human CYP2D6, the target of anti-LKM1, and FTCD, the target of anti-LC1, together with the murine end terminal region of CTLA-4. The latter was added to facilitate antigen uptake by APCs. In a parallel set of experiments, a plasmid containing the DNA encoding IL-12, a Th1 skewing proinflammatory cytokine, was also used. When autoantigens and IL-12 were used to break tolerance, antigen-specific autoantibodies were produced, a relatively modest elevation of transaminase levels at 4 and 7 months was observed, and a portal and periportal inflammatory infiltrate composed of CD4 and CD8 T cells and, to a lesser extent, B cells was demonstrated 8–10 months after the third immunization. When the same immunization protocol was used in different mouse strains, either a mild hepatitis or no inflammatory changes were observed indicating the importance of a specific genetic background. These authors have also shown, in the same animal model, that adoptive transfer of ex vivo expanded Tregs expressing the chemokine receptor CXCR3 targets efficiently the inflamed liver, restores peripheral tolerance to

FTCD, and induces disease remission (Lapierre et al., 2013). More recently, the same group has shown that liver damage can be controlled by the use of low-dose anti-CD3 (Marceau et al., 2015) or anti-CD20 (Beland et al., 2015) monoclonal antibodies, demonstrating the pathogenic involvement of both T and B cells in liver damage. Using FTDC as immunogen in an Adenovirus shuttle vector, Hardtke-Wolenski et al. (2013) describe a model of AIH evolving to portal and lobular fibrosis, in which the genetic predisposition afforded by the NOD background was the key to the development of the disease. That the development of the disease is genetically controlled was confirmed in a later paper by the same group, in which, however, tolerance breakdown was shown not to be dependent on the genetic background (Hardtke-Wolenski et al., 2017).

Recently, Yuksel et al. (2015) developed a model based on the HLA-DR3 transgenic mouse on the nonobese diabetic background by immunization with a DNA plasmid coding for human CYP2D6/FTCD fusion protein. Immunization leads to increased transaminase levels, development of autoantibodies, interface hepatitis, and fibrosis. Milder liver injury was observed by the same group using HLA-DR4 transgenic mice in the same animal model (Yuksel et al., 2016).

Another model of AIH type 2 uses CYP2D6 transgenic mice and aims at breaking tolerance with an Adenovirus-CYP2D6 vector (Holdener et al., 2008). While focal hepatocyte necrosis was seen in both mice treated with the Adenovirus-CYP2D6 vector and control mice treated with Adenovirus alone, only the former developed chronic histological changes, including fibrosis, reminiscent of AIH. The hepatic lesion was associated to a specific immune response to an immunodominant region of CYP2D6 and a cytotoxic T-cell response to Adenovirus-CYP2D6 vector-infected target cells. Recent data from the same group suggest that preexisting nonalcoholic fatty liver disease potentiates AIH in this mouse model (Muller et al., 2016).

A complex and somewhat artificial strategy, involving neonatal thymectomy to prevent Treg development and egress from the thymus, was used in PD-1-deficient mice to produce a fulminant hepatitis characterized by spontaneous and severe CD4 and CD8 T-cell liver infiltration, lobular necrosis, and elevated titers of ANA. Also in this model, adoptive transfer of Tregs was able to reverse progression to fatal hepatitis, providing support for a protective role of this cell population in AIH (Kido et al., 2008).

In view of the presence of AIH type 2 in some 20% of the patients with APECED, a monogenic autosomal recessive disorder caused by homozygous mutations in the *AIRE1* gene, Hardtke-Wolenski et al. (2015) generated a BALB/c mouse model, in which *AIRE* is truncated at exon 2. Twenty four percent of these mice developed liver damage similar to AIH, disease manifestations being dependent on specific *Aire* mutations and the genetic background of the mice.

Though these experimental approaches provide useful information on some of the possible pathogenic mechanisms leading to AIH type 2, a model closely representative of type 1 AIH in humans is still missing. In this context, of particular interest is the recently developed murine model reminiscent of AIH type 1 created by Bonito et al. (2013). The model is characterized by deletion of medullary thymic epithelial cells. These cells regulate T-cell tolerance by ectopically expressing self-antigens and eliminating autoreactive T cells in the thymus. Unexpectedly, these animals do not suffer from multiorgan autoimmune disease but develop a condition closely resembling human AIH type 1, with interface hepatitis, production of ANA, anti-SLA, and antibodies directed to liver-specific antigens.

## TREATMENT

The aim of treatment in AIH is to attain an early complete remission to prevent disease progression and to maintain it long term using the lowest possible dose of medications. In all types of presentation apart from a fulminant onset with encephalopathy, AIH responds well to immunosuppressive treatment whatever the degree of liver impairment with a reported remission rate of ~80% (Krawitt, 2006; Liberal et al., 2016).

### Standard Treatment

A combination of predniso(lo)ne and azathioprine has remained from the late 1960s, the basis of treatment for AIH (Mackay, 1968; Cook et al., 1971; Soloway et al., 1972; Murray-Lyon et al., 1973). The earlier unfounded suggestion of waiting for 6 months before starting immunosuppression has long been abandoned, since it is now clear that treatment should be started as soon as possible to avoid disease progression (Manns et al., 2010; European Association for the Study of the Liver, 2015).

The American Association for the Study of Liver Diseases (AASLD) practice guidelines, published in 2010, recommend for adult patients either an initial dose of 30 mg prednisolone combined with 1–2 mg/kg of azathioprine daily, or monotherapy with prednisolone at a starting dose of 40–60 mg daily (Manns et al., 2010). To avoid azathioprine hepatotoxicity, particularly in cirrhotic and jaundiced patients (Lohse and Mieli-Vergani, 2011; European Association for the Study of the Liver, 2015), the more recent guidelines by the European Association for the Study of the Liver (EASL) recommend to add azathioprine after 2 weeks of steroid monotherapy [prednisolone 1 mg/kg/day in adults], when partial disease control has been achieved. For children, a dose of 1–2 mg/kg prednisolone up to a daily dose of 60 mg is recommended in combination with azathioprine (1–2 mg/kg) or its parent drug 6-mercaptopurine (6MP) (1.5 mg/kg) (Mieli-Vergani et al., 2018). As children present frequently acutely with jaundice, they should be treated with high-dose prednisolone first and azathioprine should be added later when partial disease control is achieved and jaundice has subsided, to avoid potential hepatotoxicity. The most common side effect after prolonged steroid administration is Cushingoid changes, and recurrent cutaneous warts are also frequent. Less common but severe side effects include osteoporosis, vertebral collapse, diabetes, cataract, hypertension, and psychosis. However, only ~13% of the treated patients develop side effects that necessitate dose reduction or premature drug withdrawal, this being usually for cosmetic changes or obesity, osteopenia with vertebral collapse, and brittle diabetes (Czaja and Freese, 2002). Adverse effects of azathioprine (cholestatic hepatitis, veno-occlusive disease, pancreatitis, nausea and vomiting, rash, bone marrow suppression) affect less than 10% of the patients and usually subside upon drug withdrawal (Manns et al., 2010). Determination of erythrocyte concentrations of thiopurine methyltransferase (TPMT) activity may be advisable before institution of azathioprine therapy but does not invariably predict response to the drug or toxicity (Langley et al., 2002; Heneghan et al., 2006). TPMT genotyping predicts azathioprine hematological toxicity in those rare individuals with variant homozygosity with near-zero erythrocyte concentrations of the enzyme, while heterozygotes do not experience more toxicity than wild-type patients (Newman et al., 2011). Though immunosuppression is tolerated relatively well in AIH, some side effects, particularly cosmetic, are often a great concern for the patients and may lead to poor quality of life (Schramm et al., 2014) and nonadherence, with dangerous consequences for their disease control.

Criteria for complete remission are the disappearance of clinical symptoms, normalization of transaminase and IgG levels in adults and children, and, in addition, abrogation or reduction to a very low titer of the autoantibodies in children (Mieli-Vergani et al., 2018; Liberal et al., 2016). Histological resolution of inflammation lags well behind biochemical improvement (Manns et al., 2010; Sogo et al., 2006; Ustundag et al., 2008).

Response to immunosuppressive treatment in AIH is usually so swift that a lack of response should prompt investigation of other causes of liver disease.

Relapse is characterized by an increased level in serum transaminase enzymes and is common, occurring in 40%–80% of the patients usually during attempts to withdraw treatment or because of nonadherence, and requires a temporary increase in the steroid dose (European Association for the Study of the Liver, 2015; Krawitt, 2006; Manns et al., 2010; Gregorio et al., 1997; Czaja and Freese, 2002). Nonadherence is particularly common in young adults and adolescents (Kerkar et al., 2006) and should not be mistaken for inefficacy of the drugs. Most patients, including those with cirrhosis (Manns et al., 2010; European Association for the Study of the Liver, 2015), attain complete remission on the above treatment schedules.

In the presence of severe steroid side effects, remission can be maintained with azathioprine alone at a dose of up to 2 mg/kg daily (Johnson et al., 1995; Czaja, 2008). Treatment with both steroids and azathioprine can be safely continued during pregnancy (Heneghan et al., 2001; Candia et al., 2005; Terrabuio et al., 2009). Though azathioprine is classified as a category D drug by the Food and Drug Administration, it has no reported teratogenic effects in humans. If concerns remain about its use, women can be temporarily switched to steroid monotherapy.

Early identification of patients who do not respond satisfactorily to conventional treatment would allow tailored monitoring and early intervention with salvage therapy. Montano-Loza et al. (2007) reported that onset at an early age, acute presentation, hyperbilirubinemia, and presence of HLA DRB1\*03 characterize patients with poor response to corticosteroid treatment and that the model for end-stage liver disease (MELD) score (based on serum creatinine and total bilirubin levels, and international normalized ratio value) at presentation may help identifying these patients. In a large cohort presenting with icteric AIH, Yeoman et al. (2011) show that approximately 20% of the patients fail corticosteroid therapy and that failure is best predicted by changes in the MELD score and the United Kingdom end-stage liver disease (UKELD) score (which incorporates serum sodium and reduces the weighting of the creatinine level) at day 7 of treatment. Factors reported to be associated with poor short- and long-term outcome are young age at diagnosis (because of a higher risk of relapse), histological cirrhosis at first diagnosis, and presence of anti-SLA antibodies, while DRB1\*04:01 positivity is associated with a

favorable clinical outcome (Kirstein et al., 2015; Muratori et al., 2016). Interestingly, a recent paper reports alterations of the glucocorticoid receptor signaling pathway in patients who fail to respond to standard therapy (Eriksen et al., 2017).

For adult patients who are asymptomatic, paucisymptomatic or are identified incidentally, the benefit of therapy should be weighed against the adverse effects of corticosteroids, particularly in postmenopausal women or the elderly patients, with the histological severity of inflammation and liver damage being the best guide. In contrast, children, despite being rarely symptomatic, should start treatment promptly, even if the diagnosis is made incidentally, as they have a more aggressive and rapidly progressive disease (Floreani et al., 2013; Czaja et al., 2005).

Long-term immunosuppressive treatment could be associated with the development of malignancies since extrahepatic cancers, including non-Hodgkin lymphoma and skin cancer, are reported to be more frequent in patients with AIH than in age- and sex-matched normal populations (Wang et al., 1989; Werner et al., 2009; Danielsson Borssen et al., 2015; Arinaga-Hino et al., 2017). The risk of developing primary hepatocellular carcinoma (HCC) in AIH is associated with the presence of cirrhosis, akin to other chronic liver diseases (Yeoman et al., 2008; Wong et al., 2011; Werner et al., 2009; Danielsson Borssen et al., 2015; Tansel et al., 2017) though HCC has been anecdotally described also in the absence of cirrhosis (Maeda et al., 2010). Both the AASLD and EASL Autoimmune Hepatitis Guidelines recommend active surveillance for HCC (Manns et al., 2010; European Association for the Study of the Liver, 2015).

The management of AIH with severe acute or fulminant presentation is particularly delicate. In adults, corticosteroid therapy has been reported to be of little benefit and to favor septic complications (Ichai et al., 2007; De Martin et al., 2015), but recent papers show that steroid treatment in severe acute AIH does not jeopardize survival and can improve outcome, suggesting that these patients should be considered for a short trial of corticosteroids, while undergoing assessment for sepsis, and for liver transplant in case of clinical deterioration or development of encephalopathy (Yeoman et al., 2014; Zhu et al., 2014; Sonthalia et al., 2017; Mendizabal et al., 2015). In a pediatric cohort, prednisone treatment was successful in four of nine children with AIH presenting as fulminant hepatic failure, avoiding liver transplant (Di Giorgio A, et al., 2015). Similarly, good results with steroid therapy are reported in a paper from India, where 10 out of 13 children with severe acute presentation of AIH, including encephalopathy in 6, were rescued by prednisone treatment (Ramachandran et al., 2014). Appropriate diagnostic criteria for AIH presenting as severe acute hepatitis or fulminant hepatic failure are not available, though the IAIHG-modified score (Alvarez et al., 1999) performs better than the IAIHG-simplified score (Hennes et al., 2008) as autoantibodies and high IgG levels may not be detectable at presentation, to become detectable or rise during follow-up (Yilmaz et al., 2016; Fujiwara et al., 2015).

## Alternative Treatments

Cyclosporine and tacrolimus, calcineurin inhibitors, have been used as steroid-sparing agents in an attempt to induce remission whilst avoiding high-dose steroid adverse effects (Alvarez et al., 1999; Cuarterolo et al., 2006; Debray et al., 1999; Van Thiel et al., 1995; Zizzo et al., 2017; Marlaka et al., 2012), but whether the use of these toxic and expensive drugs confers any advantage over standard treatment remains to be evaluated in controlled studies.

A large European trial investigating the effect of a combination of budesonide and azathioprine in AIH reported remission in a higher proportion of noncirrhotic patients with less adverse effects than medium-dose standard prednisone and azathioprine (Manns et al., 2010). This study compared the effect of budesonide at a dose of 3 mg three times daily, decreased upon response, with prednisone 40 mg once daily reduced per protocol, irrespective of response. Six months after starting treatment, remission was observed in 60% of the budesonide group, but in only 39% of the prednisone group. When pediatric patients were considered separately, no difference in response was observed between the budesonide and prednisone groups at 6 months (16% vs 15%) and 12 months (50% vs 42%) (Woynarowski et al., 2013). Of note, the remission rate in the prednisone arm of this study is considerably less than that reported both in adults and children (~80%) when a higher starting dose of prednisone is used and tapered according to biochemical response (Gregorio et al., 1997; Kanzler et al., 2001). A controlled trial in treatment-naïve pediatric AIH patients, using drug schedules appropriate for the juvenile disease, is needed to establish whether budesonide has a role in the treatment of this condition (Mieli-Vergani and Vergani, 2013). A limitation of budesonide is that it is ineffective in patients with cirrhosis, who represent at least one-third of all AIH cases (Gregorio et al., 1997; Roberts et al., 1996; Manns et al., 2010; European Association for the Study of the Liver, 2015). Despite its limitations, budesonide could be a valid alternative in patients at selected

risk of adverse effects from prednisolone. Budesonide may also be effective in maintaining remission in patients who have achieved it with prednisolone but has been reported to be ineffective in those resistant to prednisolone, perhaps not surprisingly as prednisone and budesonide target the same receptor (Peiseler et al., 2017).

In patients with azathioprine intolerance, but not in poor responders, 6MP (Hubener et al., 2016) or 6-thioguanine (Legue et al., 2017) appear to be effective and relatively well-tolerated alternatives. As allopurinol, a xanthine oxidase inhibitor, shifts the metabolism of azathioprine from 6-methylmercaptopurine, hepatotoxic, toward 6-thioguanine, not hepatotoxic, the combination of allopurinol and a reduced dose of azathioprine might provide an alternative to more expensive and toxic second line-therapy to induce remission (de Boer et al., 2013; Deswal and Srivastava, 2017). A recent paper reports a beneficial effect of 6-thioguanine treatment (Legue et al., 2017).

Difficult-to-treat cases are reported to respond to mycophenolate mofetil at a dose of 20 mg/kg twice daily in association with prednisone (Richardson et al., 2000; Aw et al., 2009; Devlin et al., 2004; Jothimani et al., 2014; Zizzo et al., 2017; Efe et al., 2017), although this experience is not unanimous (Hennes et al., 2008). In adults, mycophenolate mofetil has been reported to be effective in patients intolerant of but not in those unresponsive to azathioprine (Hennes et al., 2008), though a recent paper from Australia does show a similar remission rate irrespective of intolerance or unresponsiveness to azathioprine (Gazzola et al., 2016).

Mycophenolate mofetil in association with prednisolone has been also used in AIH as first-line treatment and reported to be effective in inducing remission and possibly in achieving a higher rate of successful suspension of treatment than the conventional prednisolone/azathioprine combination (Zachou et al., 2016). However, it is unclear whether mycophenolate mofetil offers a real advantage over azathioprine, as a head-to-head comparison between the two drugs was not performed. Mycophenolate mofetil, moreover, has the major disadvantages of being much more expensive than azathioprine, and, most importantly, of being teratogenic, a highly relevant adverse effect, as AIH affects mainly young females (Janmohamed and Hirschfield, 2016).

For patients who do not respond to, or are intolerant to mycophenolate mofetil (headache, diarrhea, nausea, dizziness, hair loss, and neutropenia), a calcineurin inhibitor in combination with prednisone is suggested (Manns et al., 2010; European Association for the Study of the Liver, 2015; Zizzo et al., 2017; Efe et al., 2017). In patients particularly difficult to treat, the use of biologics has been reported. Rituximab, an anti-CD20 agent targeting B lymphocytes, has shown promising results in a small number of difficult-to-treat AIH (Barth and Clawson, 2010; Burak et al., 2013; D'Agostino et al., 2013), but its safety profile needs to be evaluated carefully, as the drug may have severe long-term side effects, including B-cell depletion (Pavanello et al., 2017). Infliximab, an anti-TNF- $\alpha$  agent (Weiler-Normann et al., 2009, 2013; Bovensiepen et al., 2017), has given promising results in treatment-resistant patients, but it is important to note that anti-TNF- $\alpha$  agents can induce hepatotoxicity resembling AIH (Rodrigues et al., 2015; Bjornsson et al., 2017), as well as other immune-mediated conditions, such as SLE. Moreover, an important risk of these biologic treatments is the occurrence of severe infections (Weiler-Normann et al., 2013).

A single recent paper reports a satisfactory response to methotrexate in 6 of 11 patients refractory or intolerant to first-line therapy. However, two patients developed methotrexate DILI, and the benefit of such treatment remains to be tested (Haridy et al., 2017).

Anecdotally, the m-TOR inhibitors sirolimus and everolimus have been used in difficult-to-treat AIH patients mostly with disappointing results (Chatrath et al., 2014; Kurowski et al., 2014; Ytting and Larsen, 2015).

All these still experimental second-line drugs should be reserved for very difficult to manage AIH cases in specialized centers.

## Duration of Treatment

No optimal length of treatment has been established. Most authors recommend at least 3 years of continuous therapy (Manns et al., 2010; European Association for the Study of the Liver, 2015) before considering withdrawal. Treatment withdrawal should be attempted only in patients with stably normal liver function tests and IgG levels over a period of 1–2 years (Mieli-Vergani et al., 2018; Deneau et al., 2014; Hartl et al., 2015) and when a follow-up liver biopsy shows resolution of inflammation (Manns et al., 2010; European Association for the Study of the Liver, 2015; Mieli-Vergani et al., 2018). Cessation should proceed with caution during or immediately before puberty, when relapses are more frequent, possibly because of poor adherence to treatment during adolescence (Kerkar et al., 2006).

During withdrawal, close monitoring is needed as relapse may be severe and even fatal. While a single relapse may not impact on disease progression, frequent relapses are associated with poor outcome (Bouma and van

Nieuwkerk, 2015). Successful stopping of immunosuppression should be followed up long term, as relapses can occur even several years later (Manns et al., 2010). Some 20% of the patients with juvenile type 1 AIH can stop treatment successfully and permanently, but treatment cessation is achieved only rarely for patients with type 2 AIH (Gregorio et al., 1997; Deneau et al., 2014). Levels of autoantibody and IgG (Luth et al., 2008; Gregorio et al., 2002) are important markers of disease activity and are useful to monitor response to treatment.

Most AIH patients who respond to immunosuppressive treatment have an excellent outcome and lead a normal life on low-dose medication.

## Liver Transplantation

Liver transplantation is the treatment of choice for patients who present with fulminant hepatic failure (grades II–IV encephalopathy) unresponsive to steroids, or who progress to end-stage liver disease despite immunosuppression (~10%–20% of patients) (Liberal et al., 2013). Recurrence of AIH, characterized by high transaminase levels, positive autoantibodies, interface hepatitis, and/or steroid dependence, occurs in ~20% of transplanted patients (Milkiewicz et al., 1999; Duclos-Vallee et al., 2003; Liberal et al., 2016) and can happen even years after transplantation. Prednisolone treatment long term and at a dose higher than that generally used after liver transplantation for other conditions is recommended to avoid recurrence. Besides recurrent AIH, there is a form of graft dysfunction characterized by chronic liver damage with interface hepatitis, high transaminase and IgG levels, and positive tests for autoantibodies that occurs in ~6%–10% of the patients transplanted for nonautoimmune disorders. It has been named “de novo AIH” (Kerkar et al., 1998; Liberal et al., 2013). This condition affects mainly young patients (Kerkar and Yanni, 2016). Early diagnosis is needed, as de novo AIH does not respond satisfactorily to antirejection regimens, but only to the addition of standard treatment for AIH (Liberal et al., 2013). However, despite the good response to AIH treatment, which avoids graft loss, the condition can herald progression to chronic liver disease (Ekong et al., 2017). In resistant cases, rapamycin has been used with success (Kerkar et al., 2005).

## Future Treatment Approaches

As loss of immunoregulation appears central to the pathogenesis of AIH, so treatment should concentrate on restoring the ability of Tregs to expand in number, with consequent increase in their function. The immunotherapeutic use of autologous CD4<sup>+</sup>CD25<sup>+</sup> Tregs derived from patients, however, is hindered by their limited ability to proliferate and by their propensity to apoptosis (Akbar et al., 2003), which usually precludes cell numbers adequate for treatment. The partial Treg restoration in patients during remission (Longhi et al., 2004; Longhi et al., 2005) indicates that Tregs in AIH, although impaired, can expand and regain function. Following in vitro exposure to polyclonal T-cell stimulation, Tregs can be expanded not only in healthy individuals but also in patients with AIH (Longhi et al., 2008). While maintaining the phenotypic features of original CD4<sup>+</sup>CD25<sup>+</sup>CD127<sup>-</sup> T cells, expanded Tregs express increased FOXP3 and display augmented suppressor function (Liberal et al., 2015).

Studies in mice show that Tregs with autoantigen specificity suppress immune effectors more efficiently than do their nonantigen-specific counterparts (Tarbell et al., 2004; Albert et al., 2005). In this regard, type 2 AIH is an excellent model for specific reconstitution of self-tolerance since not only known is the key autoantigen, CYP2D6, but also the specific autoepitope regions (CYP2D6<sub>217–260</sub> and CYP2D6<sub>305–348</sub>), targeted by B cells, CD4 cells, and CD8 T cells (Ma et al., 2006; Longhi et al., 2007; Kerkar et al., 2003). Antigen-specific Tregs have been obtained from patients with type 2 AIH and exert a more powerful immunosuppressive effect than polyclonally expanded Tregs (Longhi et al., 2011). The most efficient suppression of autoreactive T cells was achieved after Tregs were exposed to CYP2D6 peptides cocultured with semimature DCs loaded with the same peptide. Thus adoptive transfer of autologous CYP2D6-specific Tregs could become an effective and even curative therapy for AIH type 2, as suggested also in an animal model of this condition (Lapierre et al., 2013). In type 1 AIH, immune intervention based on SLA could be a possibility, since at least 50% of the patients have autoantibodies to this autoantigen. An even higher proportion of patients with type 1 AIH have cellular immune reactivity to HLA DRB1\*0301 (Meda et al., 2007) or HLA DRB1\*0401 (Zhao et al., 2011) restricted SLA epitopes. SLA-specific Tregs could, therefore, be considered for antigen-specific immune intervention in type 1 AIH as well.

Another possible therapeutic approach is exploitation of Treg response to low-dose IL2, since Saadoun et al. (2011) report encouraging results in the treatment of hepatitis C virus-associated vasculitis that was refractory to

conventional antiviral therapy and anti-CD20 monoclonal antibody, using repeated courses of low-dose IL2, which led to an increase in Treg number and also clinical improvement.

Recent observations on intestinal dysbiosis in AIH may influence future management strategies.

## PERSPECTIVES

AIH requires consideration in the differential diagnosis of any instance of increase in liver enzyme levels. Several pathogenic aspects of AIH have been elucidated, including predisposing genetic factors and (to a degree) disease-specific humoral and cellular immune responses. Prompt immunosuppressive treatment provides a good outcome with a mostly symptom-free long-term survival.

Even so, type 1 (but not type 2) AIH is one of those autoimmune diseases for which clear knowledge on initiation, immunopathogenic mechanisms, and effector processes remain quite lacking. The necessary better understanding of each of these aspects (Sebode et al., 2017) could facilitate our tasks for the future which include establishment of novel treatments aimed specifically at arresting liver autoaggression or, ideally, at reinstating failed tolerance to liver autoantigens, thereby abrogating our hitherto long reliance on nonspecific immunosuppression with all of its discomforts and hazards.

## INTRODUCTION

Primary biliary cholangitis (PBC), formally known as primary biliary cirrhosis, is a chronic cholestatic liver disease that can affect adult women of all ages but is most common in the middle years of life. It presents as a chronic nonsuppurative destructive cholangitis (CNSDC) with granuloma formation in the liver, and degeneration and necrosis of biliary epithelial cells (BECs) elicit destructive changes and disappearance of small- or

medium-sized intrahepatic bile ducts, leading to chronic and progressive cholestasis. Although the etiology of PBC has not been fully elucidated, robust evidence indicate that autoimmune reactions against intrahepatic BECs play a critical role in the pathogenesis of the disease. Indeed, PBC is considered a model autoimmune disease because of detection of disease-specific autoantibodies (i.e., antimitochondrial autoantibodies (AMAs)), dense infiltration of mononuclear cells into the bile ducts, and a high prevalence of autoimmune diseases as comorbidities. Whereas patients with PBC frequently lack subjective symptoms and the disease is incidentally detected during random blood testing, a substantial number of patients experience a variety of symptoms, including pruritus, fatigue, dryness, and body pain. Other autoimmune diseases such as rheumatoid arthritis, Sjogren's syndrome, and chronic thyroiditis frequently coexist in patients with PBC. Jaundice and other decompensating events of the liver develop as progressive features, eventually resulting in liver failure and the need for liver transplantation (LT). Until recently, ursodeoxycholic acid (UDCA) had been the only approved drug for PBC and clinical trials demonstrated that the administration of UDCA can extend LT-free survival. On the other hand, 30% of the patients with PBC are refractory to UDCA and second-line therapeutic options are strongly needed. In 2016, obeticholic acid (OCA), a farnesoid X receptor (FXR) agonist, was approved for UDCA-refractory or UDCA-intolerant patients; however, the efficacy and safety of OCA are still unsatisfactory. In the near future, an individualized treatment policy based on stratification of the risk for progression should be a goal in the treatment of PBC.

## CHANGING NOMENCLATURE FOR PRIMARY BILIARY CHOLANGITIS— FROM “CIRRHOSIS” TO “CHOLANGITIS”

In 1851 a patient presenting with symptoms resembling PBC was first described in the literature ([Addison and Gull, 1851](#)). The term “primary biliary cirrhosis” first appeared in the title of a published article in 1949 ([Dauphinee and Sinclair, 1949](#)) and was described by [Ahrens et al. \(1950\)](#). Most early descriptions of PBC involved patients at the cirrhotic stage, with jaundice, ascites, and variceal bleeding, and therefore the nomenclature of cirrhosis, which refers to an end-stage liver disease, was correct. However, [Sherlock \(1959\)](#) had already noted that this name should be changed because many patients were free of cirrhosis. In 1965 Hans Popper et al. also suggested that the term “primary biliary cirrhosis” is actually a misnomer, as neither septa nor nodules are present, and suggested “CNSDC” instead ([Rubin et al., 1965](#)). Thereafter, the introduction of biochemistry and AMA tests into clinical settings enabled diagnosing PBC at earlier stages, and the establishment of UDCA as a first-line treatment drug prevented progression to cirrhosis. The serious gap between the disease and its misnomer became wider, and the term “cirrhosis” became not merely an inaccuracy but an active stigma for patients. In 2014 during the 2nd European Association for the Study of the Liver (EASL) monothematic conference on primary biliary cirrhosis, experts gathering from different parts of the world agreed that (1) the name “primary biliary cirrhosis” should be changed and (2) the alternative should be “primary biliary cholangitis,” keeping the acronym “PBC.” The EASL and the American Association for the Study of Liver Diseases governing boards approved this agreement in 2014 and 2015, respectively ([Beuers et al., 2015a, 2015b, 2015c, 2015d, 2015e, 2015f, 2015g, 2015h](#)). The Asian Pacific Association for the Study of Liver (APASL) also officially approved this decision, and the new nomenclature “PBC” is currently used in the official journal of the APASL ([Tanaka et al., 2016](#)). The new name “primary biliary cholangitis,” although still imperfect, is therefore used for this disease worldwide.

## EPIDEMIOLOGY

A systematic review by [Boonstra et al. \(2012\)](#) identified 29 epidemiological studies of PBC and indicated that the incidence and point prevalence ranged from 0.39 to 5.8 per 100,000 populations and from 1.91 to 40.2 per 100,000 populations, respectively. Both the incidence and point prevalence greatly varied depending on the study, probably attributable to either a true epidemiological difference among regions or periods or the study design for case finding or ascertainment. In [Table 58.1](#), the results of epidemiological studies published after 2010 are summarized. It is of note that the epidemiological data of PBC are nearly exclusively limited to countries in Europe, Northern America, and Australia. A study from South Korea including a large number of patients provided a relatively low prevalence compared with those reported in Europe and North America, indicating that the Asian population may be genetically protected from PBC. Population-based studies from other Asian countries are awaited to solve this question. Furthermore, it is notable that the male-to-female ratio seems to be changing in recent decades and the number of male patients with PBC is increasing. Previous large-scale population-based studies demonstrated that the male-to-female ratio was almost 1:10 ([Danielsson et al., 1990; Hamlyn et al., 1983](#);

**TABLE 58.1** Incidence and Prevalence of Primary Biliary Cholangitis (Published After 2010)

Country	No. of patients	Incidence (95% CI)	Prevalence (95% CI)	Male (%)	Year
<b>EUROPE AND AMERICA</b>					
Iceland (Baldursdottir et al., 2012)	168	2.5	38.3	18	2012
Northeast England (McNally et al., 2014)	982	4.51 (4.11–4.91)	NA	10	2014
Netherlands (Boonstra et al., 2014)	992	1.1	13.2	14	2014
North Italy (Lleo et al., 2016)	2970	1.67 (1.44–1.91)	11.1 (10.9–11.3)	33	2016
Denmark (Lleo et al., 2016)	722	1.14 (1.06–1.23)	11.5 (11.3–11.8)	21	2016
USA (Wisconsin) (Kanth et al., 2017)	79	4.9	NA	5	2017
Greece (Gatselis et al., 2017)	482	NA	58.2	13.5	2017
<b>ASIA AND PACIFIC</b>					
Southern China (Liu et al., 2010a)	4	NA	49.2 (12.8–109.3)	25	2010
New Zealand (Ngu et al., 2012)	71	0.8 (0.1–1.6)	9.9 (7.1–12.7)	8	2012
South Korea (Kim et al., 2016)	2824	0.86	4.75	16	2016

CI, Confidence interval; NA, not applicable.

Kim et al., 2000; Myszor and James, 1990). However, recent data suggested that the proportion of male patients have increased to around 15%, indicating a male-to-female ratio of 1:6 (Boonstra et al., 2012; Baldursdottir et al., 2012; Gatselis et al., 2017; Kim et al., 2016). Surprisingly, Lleo et al. (2016) reported that male patients comprise 21% of PBC cases in Denmark, and even up to 33% in Lombardia, Italy. This alteration may be explained by either a true increase of male patients owing to environmental factors or the increased recognition of the disease even in the male population.

Another controversial issue concerning the epidemiology is whether the prevalence of PBC is increasing. Two serial epidemiological studies were performed in Australia. The first population-based study was published in 1995, giving an estimated prevalence of 1.91 per 100,000 persons in 1990 and 1991 (Watson et al., 1995). A second study was published in 2004, indicating a prevalence of 5.1 per 100,000 in 1990–2002 (Sood et al., 2004). The increased prevalence of PBC in recent years was also demonstrated by investigators from the Netherlands (Boonstra et al., 2014) and Lombardia, Italy (Lleo et al., 2016). In contrast, the prevalence remained stable in Iceland (Baldursdottir et al., 2012), Denmark (Lleo et al., 2016), and northeast England (McNally et al., 2014).

## ETIOLOGY

The first finding to unravel the etiological myth of PBC was the molecular identification of autoantigens targeted by AMAs, which are exclusively detected in patients with PBC, leading to the determination of T- and B-cell epitopes. PBC is a multifactorial disease and is considered to be caused by the interaction of both genetic background and environmental triggers. In other words, PBC results from a combination of “bad genes and bad luck,” that is, individuals with a genetic predisposition to the disease develop PBC as a consequence of environmental triggering effects. Recent innovative technologies including genome-wide association studies (GWAS) and traditional case-control studies have identified a number of genetic and environmental factors contributing to susceptibility. Knowledge on the biology of BECs, the major target cells in PBC, has helped in dissecting the interactions between immune cells and BECs. Finally, efforts to establish animal models of PBC have generated novel findings.

### Antimitochondrial Autoantibody Epitopes

AMAs are the most disease-specific autoantibodies in human immunopathology and are detected in 90%–95% of the patients with PBC (Van de Water et al., 1988; Oertelt et al., 2007). Although a high titer of autoantibody in the sera of patients with PBC was observed by Mackay (1958) more than 60 years ago, the

<sup>a</sup>K denotes lysine 173, which is the attachment site of lipoic acid.

<sup>b</sup>Identical amino acids to human PDC-E2 are denoted as “-”

immunodominant epitopes of AMAs were not determined until the identification by Gershwin et al. (1987) of the pyruvate dehydrogenase complex E2 subunit (PDC-E2) as the mitochondrial autoantigen of PBC by cDNA cloning. AMAs recognize a family of enzymes located at the inner membrane of the mitochondria, named as the 2-oxo-acid dehydrogenase complex (2-OADC), which mainly includes PDC-E2, branched-chain 2-OADC (BCOADC-E2), and 2-oxo-glutaric acid dehydrogenase complex (OGDC-E2), and dihydrolipoamide dehydrogenase-binding protein (E3BP) (Dubel et al., 1999). All of these E2 enzymes have a common structure consisting of an N-terminal domain with a single or multiple attachment sites to a lysine (<sup>173</sup>K in mammalian PDC-E2) of lipoic acid (LA) (Table 58.2). The dominant epitope sites recognized by AMAs are in contiguity with the LA attachment site(s) as the lipoyl domains of these target antigens (Leung et al., 1995; Moteki et al., 1996a; Surh et al., 1990). The amino acid residues critical to maintaining the structural integrity of the PDC-E2 lipoyl domain have been revealed by site-directed mutagenesis (Wang et al., 2013). The high specificity of AMAs for PBC suggests that AMAs are not simply serological markers for diagnosis but are important in the immunopathology of PBC.

### CD4+ and CD8+ T-Cell Epitopes

The histological signature of PBC includes dense infiltration of mononuclear cells in the portal tracts near small- or medium-sized bile ducts. Immunohistochemical examination of these lymphocytes reveals a predominance of CD4+ and CD8+ T cells with B and natural killer cells (Kita et al., 2002b; Shimoda et al., 2011). BECs and hepatocytes in the liver of patients with PBC also express large amounts of human leukocyte antigen (HLA) class I and II molecules (Bjorkland et al., 1991; Krams et al., 1990). Therefore both CD4+ and CD8+ autoreactive T cells play a crucial role in the pathogenesis of PBC. In the case of CD4+ T cells, Shimoda et al. (1995) established HLA DRB4 0101-restricted PDC-E2-specific T-cell clones from the peripheral blood of patients with PBC and mapped immunodominant T-cell epitopes as PDC-E2 peptide 163–176 (GDLLEIETDKATI), which overlapped with the B-cell epitope of human PDC-E2 (Table 58.2). Importantly, the frequency of PDC-E2-specific CD4+ T cells was 100- to 150-fold higher in the liver and hilar lymph nodes than in peripheral blood (Shimoda et al., 1998). Our laboratory also characterized an MHC class I (HLA-A2)-restricted epitope for CD8+ T cells as PDC-E2 peptide 159–167 (KLSEGDLA), which again mapped to the same region of the autoantigen PDC-E2 (Table 58.2) (Kita et al., 2002a). Taken together, AMAs and autoreactive helper and cytotoxic T cells contain a shared peptide sequence of the inner lipoyl domain of human PDC-E2.

### Why Biliary Epithelial Cells?—The “ABC” of Primary Biliary Cholangitis

PDC-E2 is a ubiquitous protein located in nearly all nucleated cells in the human body, and it remains unclear why autoreactive T cells specific for PDC-E2 elicit cytotoxicity against only BECs in the liver. In this regard, it should be noted that PBC recurs even after LT, indicating that the immunopathological susceptibility of BECs in PBC is not MHC specific but a general feature shared with autologous BECs. To answer this question, Lleo et al. demonstrated that only human intrahepatic BECs (HIBECs) could maintain PDC-E2 immunologically intact within apoptotic blebs (apoptoses) during apoptosis, but not control epithelial cells. This supports data showing that AMA-containing sera react with PDC-E2 on apoptotic BECs without permeabilization (Lleo et al., 2009). Lleo et al. (2010) then examined the ability of BECs to induce cytokine secretion from mature monocyte-derived macrophages, with and without AMAs, and observed intense inflammatory cytokine

production in the presence of a unique triad consisting of BEC apoptoses, macrophages from patients with PBC, and AMAs. Macrophages from healthy controls did not produce inflammatory cytokines, even when cocultured with apoptotic bodies from HIBECs and AMAs. Thus we propose that A (AMA, apoptote, and APC), B (blebs from apoptotic BECs), and C (complex formation and cytokine secretion) constitute the crucial triad in the inflammatory cascade of PBC.

## Genetic Predisposition

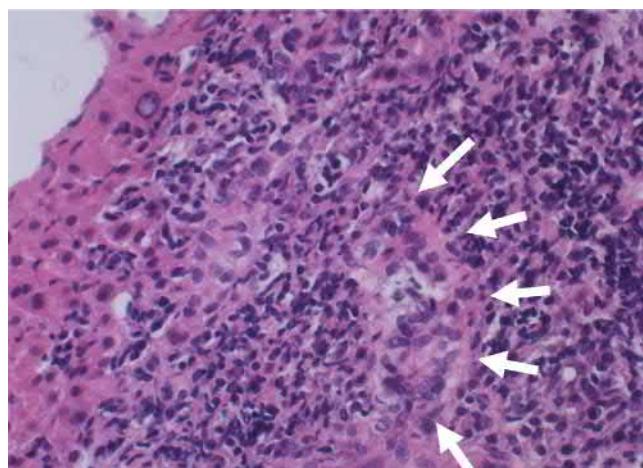

Robust evidence indicate a contribution of genetic background to the development of PBC. An increased prevalence of patients with PBC among first-degree relatives and siblings of an index patient has been repeatedly demonstrated, known as familial clustering of PBC (Abu-Mouch et al., 2003; Corpechot et al., 2010; Mantaka et al., 2012; Yanagisawa et al., 2010). The concordance rate of PBC is 63% in monozygotic twins, higher than that of other autoimmune diseases (Selmi et al., 2004b).

Concerning genetic predisposition, HLA class II alleles are found to be associated with the development of PBC by case-control studies, in particular *DRB1\*08*, *DRB1\*0801*, *DRB1\*0803*, *DRB1\*14*, and *DPB1\*0301* as susceptibility alleles and *DRB1\*11*, *DRB1\*13* as protective alleles, and, as expected, these associations vary depending on the populations studied (Donaldson et al., 2006; Invernizzi et al., 2012; Mella et al., 1995; Onishi et al., 1994). Recent GWAS from North America, European countries, Japan, and China have also identified that HLA alleles possess the strongest link with susceptibility of PBC and additionally demonstrated that more than 40 non-HLA alleles contribute to susceptibility to PBC (Cordell et al., 2015; Hirschfield et al., 2010, 2009, 2012; Juran et al., 2012; Kawashima et al., 2017; Liu et al., 2012, 2010c; Mells et al., 2011; Nakamura et al., 2012; Qiu et al., 2017; Tang et al., 2017). Although risk alleles differ among studies and populations, pathways that involve identified genes are largely shared among populations and are represented as antigen presentation and production of interleukin (IL)-12 (*IRF5*, *SOCS1*, *TNFAIP3*, *NFKB*, *IL-12A*), activation of T cells and interferon (IFN)- $\gamma$  production (*TNFSF15*, *IL12R*, *TYK2*, *STAT4*, *SOCS1*, *NFKB*, *TNFAIP3*), and activation of B cells and production of immunoglobulins (Igs) (*POU2AF1*, *SPIB*, *PRKCB*, *IKZF3*, *ARID3A*). These immune pathways are therefore assumed to be important in the pathogenesis of PBC. However, as with other autoimmune diseases, GWAS have remained disappointing and no “smoking gun” has been identified, leading to the suggestion that epigenetics may play a role.

## Environmental Triggering Factors

Although studies of monozygotic twins demonstrated a high concordance rate, recent epidemiological studies revealed a relatively low risk of developing PBC in first-degree relatives of the indicated patient during 8 years of follow-up, suggesting that genetic predisposition does not define the risk of PBC (Gulamhusein et al., 2016). Large-scale case-control studies have consistently found an association of urinary tract infections and cigarette smoking with PBC (Corpechot et al., 2010; Burroughs et al., 1984; Gershwin et al., 2005; Howel et al., 2000). Bacterial infection may have an impact on the etiology of PBC because PDC-E2, which is an immunodominant target of AMA, has a molecular mimic between human PDC-E2 and *Escherichia coli* PDC-E2 (Table 58.2). In particular, the ExDK sequence, which was reported to be the essential sequence of human PDC-E2 for recognition of CD4+ PDC-E2-specific T cells, is entirely shared by both human and *E. coli* PDC-E2 (Shimoda et al., 1995); thus *E. coli* infection may trigger the breaking of immunological tolerance against human PDC-E2. Another candidate bacterium that may be involved in the etiology of PBC through cross-reactivity is *Novosphingobium aromaticivorans*, a ubiquitous xenobiotic-metabolizing bacterium, because the sera of patients with PBC are highly reactive with lipoylated bacterial proteins from *N. aromaticivorans* (Selmi et al., 2003).

Case-control studies also suggest that frequent use of nail polish is associated with an increased susceptibility to PBC (Gershwin et al., 2005). Furthermore, a geographically uneven distribution of patients with PBC in a particular region is reported, especially near toxic waste sites (McNally et al., 2014; Ala et al., 2006; Prince et al., 2001). These epidemiological data, along with the known crucial role of AMAs in the immunopathology of PBC, prompted researchers to identify environmental mimotopes in the form of xenobiotics. A detailed, quantitative structure-activity relationship analysis with 107 potential xenobiotic mimics coupled to the lysine residue of the immunodominant 15-amino-acid peptide of the PDC-E2 inner lipoyl domain revealed that 2-octynamide, the conjugate derived from 2-octynoic acid (2-OA) present in cosmetics, lipsticks, and some chewing gums, was unique in both its quantitative structure-activity relationship analysis and reactivity with PBC sera (Amano et al., 2005).

**FIGURE 58.1** Chronic nonsuppurative destructive cholangitis in primary biliary cholangitis (arrow, hematoxylin, and eosin staining).

Furthermore, another xenobiotic, 2-nonyamide, provided an optimal chemical structure of the xenobiotics-modified epitope, which demonstrated enhanced recognition by AMA-positive PBC sera (Rieger et al., 2006). Indeed, significant molecular mimicry between lipoamide and 2-nonyamide was observed (Fig. 58.1). These findings illustrate that xenobiotic modification of PDC-E2 with chemicals abundantly found in daily life plays a role in generating immunogenic neoantigens and breaking tolerance in PBC. Cross-reactive monoclonal antibodies with both native PDC-E2 and 2-OA also recognize LA (Tanaka et al., 2017), further supporting the hypothesis that xenobiotically modified LA is the initial target of autoimmunity in PBC.

Genome-wide epigenetic analysis identified significant differences for methylation profiles, copy number variation, and gene expression in three monozygotic twins and eight sibling pairs discordant for PBC (Selmi et al., 2014). Moreover, aberrant demethylation on the CXCR3 promoter of the X chromosome was noted in patients with PBC (Lleo et al., 2015). These findings are still only descriptive, and further studies are needed to unravel the etiological implications of epigenetics. Finally, a role of the gut microbiota is now suggested, and dysbiosis was found in patients with PBC and, interestingly, partially resolved with UDCA treatment (Tang et al., 2017).

## ANIMAL MODELS OF PRIMARY BILIARY CHOLANGITIS

In addition to in vitro studies, murine models are important for understanding the etiology and natural history of PBC. Patients with newly diagnosed PBC are well past the onset of loss of tolerance, and there is likely a long latency period between the appearance of autoantibodies and clinical disease. Animal models that reflect many important aspects of the disease are therefore needed to explore the initiating events and interactions between genetic and environmental factors. The animal model should have the same physiological mechanisms observed in human PBC, such as female predominance, chronic cholestasis, AMA production, histological features including lymphocyte infiltration into the liver, and bile duct involvement. In particular, recognition of a strong sex predominance (females) is essential in understanding PBC. Sex hormones, X-linked genes, and sex-specific microbiota may contribute to the immune difference between males and females (Rubtsova et al., 2015; Fish, 2008; Markle et al., 2013; Rosser and Mauri, 2016). However, the physiological mechanisms accounting for the strong female predominance in PBC remain unclear (Sun et al., 2015). PBC risk factors may function synergistically in accelerating the loss of tolerance. One theory proposes that haploinsufficiency for specific X-linked genes leads to the susceptibility to PBC of women and that enhanced monosomy X in the peripheral lymphocytes of affected women induces PBC (Invernizzi et al., 2004; Selmi et al., 2004a). However, how these genetic and environmental factors interact with the immune system to elicit autoimmunity in PBC remains unclear.

To date, several murine models that develop autoimmune cholangitis resembling PBC have been established spontaneously or through xenobiotic induction (Table 58.3). These mice share some of the important clinical phenotypes of PBC (Katsumi et al., 2015).

**TABLE 58.3** Characteristics of the Primary Biliary Cholangitis Mouse Models

	Spontaneous model				Induced model	
	NOD.c3c4	dnTGF $\beta$ RII	IL-2R $\alpha^{-/-}$	ARE Del $^{-/-}$	2-OA–BSA immunized	
Female dominance	Yes	No	No	Yes	No	
Cholestasis	–	+	–	+	+	
AMA seropositivity	50%–60%	100%	100%	100%	100%	
Portal inflammation	++ +	++ +	++ +	Yes	+	
Granulomas	+	–	–	+	+	
Other features	Biliary polycystic lesions	Moderate colitis	Severe anemia, inflammatory bowel diseases, and short life span		Peritonitis	

2-OA, 2-Octynoic acid; BSA, bovine serum albumin; ARE, adenylate uridine-rich element; AMA, antimitochondrial autoantibody.

### Spontaneous Murine Models

There are three mice models that spontaneously develop autoimmune cholangitis: NOD.c3c4 mice, a dominant-negative form of transforming growth factor (TGF)- $\beta$  receptor type II (dnTGF $\beta$ RII) mice, and IL-2R $\alpha^{-/-}$  mice. The NOD.c3c4 mouse has multiple B6- and B10-derived insulin-dependent diabetes-resistant alleles on chromosomes 3 and 4, respectively. These mice are protected from autoimmune diabetes but spontaneously develop lymphocytic peribiliary infiltrates and AMA positivity (Irie et al., 2006; Koarada et al., 2004). Notably, AMAs were detected in female mice, indicating female predominance as in human PBC. However, pathological examination of the liver revealed biliary polycystic diseases in both the intra- and extrahepatic biliary ducts, and little evidence of CNSDC. The dnTGF $\beta$ RII mice also mimicked phenotypes of human PBC (Oertelt et al., 2006). These mice are transgenic for the expression of a dominantly negative form of TGF- $\beta$  receptor type II directed by the CD4 promoter. dnTGF $\beta$ RII mice spontaneously produce AMAs directed to the same mitochondrial autoantigens as human PBC. Lymphocytic liver infiltration with periportal inflammation is analogous to the histological profile of human PBC. The complexity of the IL-12/IL-23 cytokine milieu in autoimmunity in dnTGF $\beta$ RII mice was examined by generating a series of cytokine knockouts: IFN- $\gamma^{-/-}$ , IL-12p35 $^{-/-}$ , IL-12/IL-23p40 $^{-/-}$ , IL-23p19 $^{-/-}$ , and IL-17A $^{-/-}$  dnTGF $\beta$ RII mice. Collectively, our data indicated that the IL-12/T-helper type 1 (Th1) pathway is essential for biliary disease pathogenesis and IFN- $\gamma$  production is significant for triggering Th1-cell responses in this model (Ando et al., 2012; Tsuda et al., 2013; Wang et al., 2014; Yoshida et al., 2009).

The third spontaneous mouse model is the IL-2R $\alpha^{-/-}$  mice, which lack the IL-2R cytokine crucial for differentiation of regulatory T cells (Tregs) and eventual reduction in Tregs (Wakabayashi et al., 2006). These mice develop portal inflammation, biliary ductular damage, and a Th1 cytokine bias, resembling human PBC. In addition, AMAs are targeted to the inner lipoyl domain of PDC-E2. However, female predominance was not observed.

### Xenobiotics-Triggered Murine Models

We have also examined possible environmental triggers of autoimmune cholangitis in mice, particularly chemical xenobiotics. We immunized C57BL/6 mice with 2-OA, which has been suggested as a candidate xenobiotic present in the environment in our previous study (Amano et al., 2005), coupled to bovine serum albumin (BSA). We found that anti-PDC-E2 antibodies were seropositive as early as 4 weeks after immunization, indicating loss of tolerance to PDC-E2 with xenobiotic immunization. In addition, these mice demonstrated portal infiltration of CD4+ and CD8+ T cells, granulomas, and elevated tumor necrosis factor- $\alpha$  and IFN- $\gamma$  expression levels (Wakabayashi et al., 2008). By using several unique gene-deleted mice immunized with 2-OA–BSA (Kawata et al., 2013), we also found that both IL-12/Th1 and IL-23/Th17 were involved in autoimmune cholangitis. The IL-12/Th1 signaling pathway elicited the pathology, whereas deletion of IFN- $\gamma$  prevented autoimmune cholangitis.

### Adenylate Uridine-Rich Element Del $^{-/-}$ Mice as a Novel Primary Biliary Cholangitis Model

We are currently focusing on IFN- $\gamma$  by using a “designer” mouse with dysregulation of IFN- $\gamma$ , in which the adenylate uridine-rich element (ARE) of the IFN- $\gamma$  3'-untranslated region is deleted and IFN- $\gamma$  is constitutively

produced (Hodge et al., 2014). Through various assays, we found that IFN- $\gamma$  is crucial to the pathogenesis of autoimmune cholangitis in this model (Kawata et al., 2013; Yang et al., 2014). We should note that the activation of naïve CD4 T cells from healthy women produces higher levels of IFN- $\gamma$  and lower levels of IL-17 than in healthy men (Zhang et al., 2012). Increased IFN- $\gamma$  levels have also been observed in patients with autoimmune diseases (Rubtsova et al., 2015; Pelfrey et al., 2002).

ARE Del<sup>-/-</sup> mice spontaneously developed many symptoms similar to human PBC, including liver histology, AMA production, and elevated serum total bile acid levels (Bae et al., 2016). These features were also found predominantly in female mice. In male ARE Del<sup>-/-</sup> mice, portal inflammation was rarely observed and serum titers of AMA were elevated but not significantly compared with those in wild-type mice. The total bile acid levels were comparable. In addition, gene expression analysis revealed that upregulated genes in female ARE Del<sup>-/-</sup> mice specifically overlapped with the gene expression signature of BECs in human PBC. Therefore female ARE Del<sup>-/-</sup> mice closely mimic human PBC.

Female predominance occurs in ARE Del<sup>-/-</sup> mice likely because female hormones and genetics cause immune cells in female mice to favor production of additional IFN- $\gamma$ -producing cells. In contrast, male mice may be protected by androgens, which favor the upregulation of regulatory cells and downregulation of IFN- $\gamma$ -producing cells. Female hormones activate T lymphocytes to express higher levels of IFN- $\gamma$  in female mice in this mouse model. Although numerous murine spontaneous and induced models have been reported as PBC mouse models (Katsumi et al., 2015; Wang et al., 2014), no single model exhibits female dominance as observed in ARE Del<sup>-/-</sup> mice.

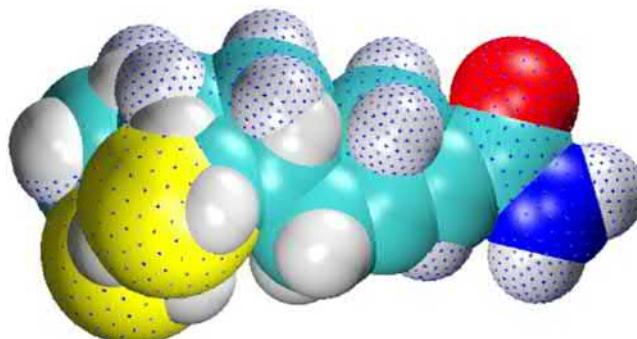

ARE Del<sup>-/-</sup> mice also provide clues about the immunopathology of PBC. IFN- $\gamma$  may play a pathogenic role in BECs during the initiation stage of PBC, and changes in expression levels of IFN- $\gamma$  are critical to the development of PBC in susceptible individuals. Furthermore, we demonstrated that transfer of CD4 T cells from ARE Del<sup>-/-</sup> mice to B5/Rag1<sup>-/-</sup> mice (an immune-deficient strain producing no mature T or B cells) induced moderate portal and parenchymal inflammation, indicating that CD4+ T cells contribute to the induction of cholangitis.

## DIAGNOSIS

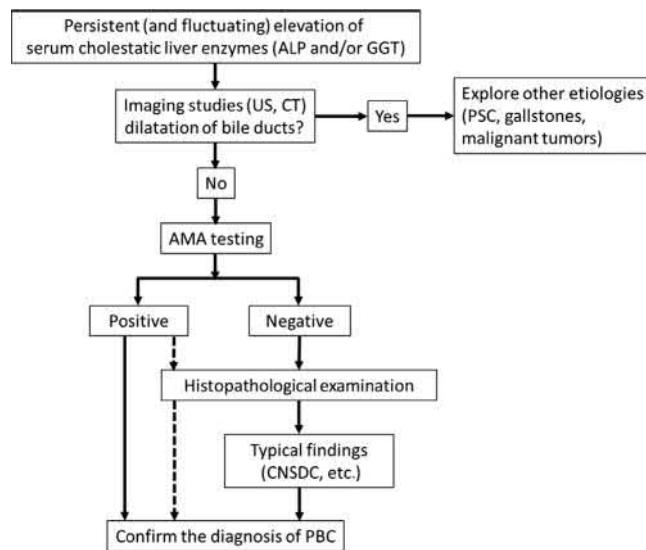

The diagnostic criteria of PBC include the following: (1) elevation of cholestatic liver enzymes, (2) AMA positivity, and (3) typical histopathological findings of the liver, that is, CNSDC of small- or medium-sized intrahepatic bile ducts (Fig. 58.2). The diagnosis of PBC is confirmed if two out of these three features are found (European Association for the Study of the Liver, 2017; Lindor et al., 2009). Because pruritus and fatigue, which are dominant symptoms in PBC, are not disease specific, most patients are suspected as having PBC when routine laboratory studies by chance demonstrate elevation of cholestatic liver enzymes. PBC is very unlikely to develop in childhood or adolescence but pediatric cases are exceptionally reported (Dahlan et al., 2003; Kitic et al., 2012).

### Serum Biochemistry and Imaging Studies

PBC should be suspected if the levels of the cholestatic enzymes alkaline phosphatase (ALP) and/or gamma-glutamylpeptidase are persistently elevated. In Fig. 58.3, a diagnostic flowchart for patients with elevated

**FIGURE 58.2** Molecular mimicry between lipoamide and 2-nonylamine. Superimposed models of lipoamide (dotted) versus 2-nonylamine in corkscrew conformation.

**FIGURE 58.3** Diagnostic flowchart of patients with PBC. *PBC*, Primary biliary cholangitis; *ALP*, alkaline phosphatase;  $\gamma$ -*GT*, gamma glutamyl transferase; *US*, ultrasonography; *CT*, computed tomography; *PSC*, primary sclerosing cholangitis; *AMA*, antimitochondrial autoantibody; *CNSDC*, chronic nonsuppurative destructive cholangitis.

cholestatic enzymes is presented. First, imaging studies of the liver and biliary tracts with ultrasonography or computed tomography scanning should be promptly carried out to rule out obstruction of the biliary tract resulting from gallstones or malignant tumors, which could be fatal and may require further urgent studies such as endoscopic procedures. Another chronic cholestatic liver disease, primary sclerosing cholangitis, is within the differential diagnosis if intra- or extrahepatic bile ducts are dilated. In contrast, PBC is suspected when imaging studies fail to detect abnormalities of the biliary tract in patients with elevated cholestatic liver enzymes. In most cases, cholestatic enzymes fluctuate. When cholestatic enzymes are consistently increasing, other etiologies including gallstones or malignant tumors obstructing the intra- or extrahepatic bile ducts should be explored.

Serum IgM (Kikuchi et al., 2005) and cholesterol levels are often elevated because of chronic cholestasis. Usually, elevation of aminotransferases—aspartate aminotransferase (AST) and alanine aminotransferase (ALT)—is mild and a marked increase of aminotransferases with elevated IgG raise the suspicion for a variant of PBC, such as PBC with features of autoimmune hepatitis (AIH), which requires corticosteroid treatment (Chazouilleres et al., 1998). In cases with advanced hepatic fibrosis, elevation of bilirubin and decreased levels of albumin are observed as cirrhosis due to other etiologies.

## Serological Testing

Serological testing, AMA testing in particular, is a necessary step for the diagnosis of PBC. If AMA is positive at a high titer, the diagnosis of PBC may be confirmed even without histopathological examination. Notably, the presence of other causes for chronic liver disorders (positive hepatitis B surface (HBs) antigen or antihepatitis C virus antibody, history of drug or alcohol use, or fatty liver) does not rule out the diagnosis of PBC in patients with detectable AMAs.

AMAs are highly specific for PBC and considered a hallmark of PBC. AMAs are detectable in about 95% of the patients with PBC and, in contrast, are very rarely found in individuals without PBC (Leung et al., 1997). As previously described, AMAs recognize a family of enzymes located at the inner membrane of the mitochondria (2-OADC), including PDC-E2, BCOADC-E2, OGDC-E2, PDC-E1 $\alpha$ , and E3BP (Table 58.4). The detection rate of AMAs is increased when enzyme-linked immunosorbent assay with recombinant mitochondrial autoantigens is used for AMA testing compared with conventional indirect immunofluorescence (Leung et al., 1992; Moteki et al., 1996b). There are, however, AMA-negative patients in a minority of patients with PBC (Oertelt et al., 2007; Miyakawa et al., 2001). “AMA-negative PBC” was once called “autoimmune cholangitis” as a variant of PBC (Taylor et al., 1994); however, it is identical to AMA-positive PBC and does not represent an independent clinical entity (Selmi et al., 2008) according to serological, immunological, and clinicopathological studies (Invernizzi et al., 1997; Kim et al., 1997; Nakanuma et al., 1997; Shimoda et al., 2008). Recent data indicate that AMA-negative PBC

**TABLE 58.4** Mitochondrial and Nuclear Autoantibodies and Their Frequencies

Antimitochondrial autoantibodies	
PDC-E2	95%
BCOADC-E2	53%–55%
OGDC-E2	39%–88%
PDC-E1 $\alpha$	41% – 66%
E3BP	95%
ANTINUCLEAR AUTOANTIBODIES	
Sp100	9%–27%
gp210	16%–26%

has a significantly worse outcome than conventional PBC; however, this observation was explained by a delay in the diagnosis (Juliusson et al., 2016). On the other hand, AMAs are occasionally detected in less than 1% of healthy individuals or patients without PBC (Mattalia et al., 1998; Shibata et al., 2004). A large-scale cohort study in France demonstrated that the prevalence of AMA-positive patients without evidence of PBC was 16.1 per 100,000, and only 1 in 6 patients with AMA positivity and normal ALP developed PBC in 5 years (Dahlqvist et al., 2017). This low number of patients with PBC raises a question about the relationship between the presence of AMA and the development of PBC, although 5 years of observation may be too short for the development of the disease.

Antinuclear antibodies (ANAs) are occasionally present in patients with PBC. Among them, anti-gp210 and/or anti-sp100 are of interest in both diagnosis and stratification of risk for progression. Two different antinuclear staining patterns with indirect immunofluorescence are observed in PBC: multiple nuclear dots (MNDs) and nuclear pore complex (NPC). Two nuclear proteins, Sp100 and promyelocytic leukemia antigen, are identified as major autoantigens in MND staining, and gp210 protein, the lamin B receptor, and nucleoporin p62 are targeted as autoantigens in NPC. Although the prevalence of anti-Sp100 and anti-gp210 is 9%–27% and 16%–26% in recent studies, respectively (Liu et al., 2010b; Muratori et al., 2008; Nakamura et al., 2007), and much lower than that of AMAs (Table 58.4), the specificities of these antibodies for PBC are very high (Invernizzi et al., 1997; Nakamura et al., 2007; Muratori et al., 2003). Thus these ANAs can be helpful for identifying patients with PBC when they are AMA negative (Bandin et al., 1996), and a novel commercially available assay kit (PBC screen) detecting AMAs against three major mitochondrial autoantigens (PDC-E2, BCOADC-E2, and OGDC-E2), anti-gp210, and anti-sp100 may serve as a first-line assay tool for the diagnosis of PBC (Liu et al., 2010b).

## Histopathology

In typical cases, dense infiltration of inflammatory cells including lymphocytes and mononuclear cells is found around small- or medium-sized intrahepatic bile ducts, coined as CNSDC (Fig. 58.1). Granulomas are occasionally observed and also diagnostic for PBC (Ludwig, 2000). As the disease progresses, the inflammatory infiltrates increase and later involves ductular proliferation, eventually resulting in septal fibrosis and cirrhosis.

Liver biopsy is not mandatory in patients with serologically confirmed PBC, positive AMA, and persistently elevated cholestatic enzymes. In addition, sampling errors and complications that could occur with liver biopsy may diminish the opportunities to carry out this invasive technique. Nevertheless, histological findings of the liver are required for establishing the diagnosis in atypical cases, such as with elevated cholestatic enzymes but negative AMA, and still remain the gold standard for the assessment hepatic fibrosis, which is associated with long-term prognosis. To avoid sampling errors, enough samples containing at least 10–15 portal tracts should be taken and multiple continuous sections should be examined to seek diagnostic findings of PBC.

Histologic lesions have been classically divided into four stages by Scheuer (1967) and Ludwig et al. (1978), as follows: stage 1, portal infiltration of lymphocytes; stage 2, portal/periportal ductular proliferation; stage 3, scarring and bridging fibrosis; and stage 4, nodular cirrhosis. This classification, although very simple and broadly applicable to clinical settings, does not overcome sampling errors in the assessment of stages and does not reflect necroinflammatory activity, which also contributes to the progression of hepatic fibrosis. Recently,

Nakanuma et al. (2010) proposed new histological assessment criteria for PBC, which consist of both staging (scoring of fibrosis, bile duct loss, and deposition of orcein-positive granules) and grading (cholangitis activity and hepatitis activity). These novel assessment criteria for histology, although more complicated, could stratify the risk for progression and outcomes of patients with PBC at baseline (Harada et al., 2013b).

## TREATMENT

### Ursodeoxycholic Acid

UDCA is now globally approved as a first-line therapy for PBC (European Association for the Study of the Liver, 2017; Lindor et al., 2009; Working Subgroup for Clinical Practice Guidelines for Primary Biliary Cirrhosis, 2014). UDCA is used at a dose of 13–15 mg/kg/day and is recommended for all patients with PBC with abnormal liver biochemistry. UDCA is a naturally occurring hydrophilic bile acid that, when orally administered, becomes the dominant bile acid in the enterohepatic circulation, exerting a protective effect to bile duct cells and hepatocytes through its choleretic and bicarbonate-secreting effects (Lindor, 2007). UDCA has been shown to improve serum biochemical abnormalities and also to delay the progression of histological progression and development of varices and to prolong transplant-free survival (Angulo et al., 1999; Combes et al., 1995; Corpechot et al., 2000; Heathcote et al., 1994; Lindor et al., 1996, 1997; Poupon et al., 1991, 1994, 1997, 2003). Indeed, patients who completely respond to UDCA treatment have been shown to have a comparable survival to the general population (Corpechot et al., 2008; Kuiper et al., 2009; Kumagi et al., 2010; Lammers et al., 2015; Pares et al., 2006). As discontinuation of UDCA frequently leads to elevation of serum liver enzymes, treatment with UDCA should be continued throughout life. Although the safety profile of UDCA is excellent in most cases, abdominal fullness, diarrhea, and constipation may infrequently occur and intolerance to UDCA may exist.

On the other hand, up to 30% of the patients with PBC exhibit incomplete responses to UDCA and the outcomes of these patients can be poor. Therefore it is extremely important to define nonresponders to UDCA with easy-to-use criteria. It is generally accepted that a variety of combinations of biochemical markers at 1 year after commencement of UDCA treatment are useful for this purpose, as will be discussed later.

### Obeticholic Acid

OCA is a selective ligand of the FXR. Bile acid toxicity against BECs and hepatocytes is decreased by FXR signaling through impairment of bile acid synthesis and stimulation of choleresis. The endogenous FXR ligand is chenodeoxycholic acid (CDCA), a primary bile acid. Compared with CDCA, OCA has approximately 100 times greater potency for activating FXR (Pellicciari et al., 2002). In 2016 the US Food and Drug Administration (FDA) officially approved OCA based on the results of the POISE trial (phase 3 clinical trial of OCA) (Nevens et al., 2016). In this international, prospective, randomized, placebo-controlled trial, 217 patients with PBC who showed an inadequate response (serum ALP level  $>1.67 \times$  upper limit of normal (ULN)) or an abnormal total bilirubin level ( $<2 \times$  ULN), or were intolerant to UDCA, were enrolled and received 5–10 mg OCA, 10 mg OCA, and placebo for 1 year. The primary end point was an ALP level of  $<1.67 \times$  ULN with  $>15\%$  reduction from the baseline and normal bilirubin level. Of the patients, 46%–47% achieved the primary end point (Nevens et al., 2016). With this result, OCA received accelerated FDA approval on May 27, 2016.

Thus OCA has become the long-awaited second-line drug officially approved for PBC. However, it is unsatisfactory for several reasons. First, the response rate was at most 50%, which means that half of the patients did not respond to OCA. Second, pruritus, a symptom frequently experienced by patients with PBC, appeared as an adverse effect in 56%–68% of the patients treated with OCA. Furthermore, whether the primary end points (ALP level  $<1.67 \times$  ULN with  $>15\%$  reduction from the baseline and normal bilirubin level) are associated with improvement of long-term outcomes has not been confirmed yet. In this regard, follow-up studies of the POISE trial were required by the FDA and a phase 3 study is currently ongoing (COBALT, NCT02308111). Finally, the appropriate treatment duration for OCA should be continued for patients refractory to UDCA; thus OCA may be prescribed lifelong along with UDCA. On the basis of the high cost of OCA (\$69,350 per year), this unlimited prescription of OCA places substantial economic burdens on both patients and societies and is not cost-effective. Samur et al. (2017) recently demonstrated that the price should be decreased to \$18,450 per year to make OCA cost-effective.

## Fibrates

Fibrates (fenofibrate and bezafibrate) were originally indicated for dyslipidemia and used for decreasing serum cholesterol and triglycerides. Fibrates are PPAR- $\alpha$  and PXR agonists, resulting in a reduction of de novo bile acid synthesis and upregulation of bile acid transporters (Honda et al., 2013). Bezafibrate was first reported as biologically effective for patients with PBC who are refractory to UDCA in 1999 (Iwasaki et al., 1999), and prospective, multicenter, randomized open-label studies in Japan demonstrated the significant biochemical efficacy of bezafibrate administered for 1 year (Iwasaki et al., 2008). A large-scale retrospective cohort study in Japan also indicated that patients with good response to bezafibrate (normalization of ALT) exhibited a comparable prognosis to those treated with UDCA alone and significantly better outcomes than those without good responses to bezafibrate (Tanaka et al., 2015). Recently, a prospective randomized study in Japan revealed that long-term outcomes were not significantly different between the UDCA plus bezafibrate and UDCA-only groups; however, the sample size in this study might be too small to establish enough statistical power (Hosonuma et al., 2015). Another prospective, randomized phase 3 study of bezafibrate for patients with PBC with incomplete responses to UDCA is ongoing in France (NCT01654731), and the addition of bezafibrate to UDCA for 2 years was significantly effective for improving liver biochemistries (Corpechot et al., 2017). Bezafibrate may also work for pruritus of PBC (Bolier et al., 2017). Fenofibrate was reported to decrease serum ALP levels in studies in Japan and China (Cheung et al., 2016; Dohmen et al., 2004), whereas adjunct use of fenofibrate with UDCA showed no association with decreased serum ALP levels in a UK cohort (Hegade et al., 2016). Participants are being recruited for a prospective randomized study in China (NCT02965911). However, these two prospective clinical trials provide improvements in liver enzyme levels notably at 12 or 24 months as the primary end point. Even after these trials are terminated, whether long-term outcomes are improved with additional treatment with fibrates is still unknown, and follow-up studies of these trials are needed.

## Ileal Bile Acid Transporter Inhibitors

Bile acids are essential to the human body, and 98% of bile acids excreted into the intestine are reabsorbed from the ileum bile acid transporter (IBAT) and returned to the liver via the portal tract, known as enterohepatic circulation. Therefore another strategy for reducing bile acids is blocking the inhibition of IBAT. One of these compounds, GSK2330672, did not significantly decrease serum ALP levels in patients with incomplete responses to UDCA but was demonstrated to significantly improve pruritus in comparison with placebo (Hegade et al., 2017). A prospective, randomized, placebo-controlled phase 2 study of GSK2330672 was launched in 2017 (NCT02966834).

## MANAGEMENT OF SYMPTOMS AND EXTRAHEPATIC MANIFESTATIONS

PBC is often diagnosed without any clinical symptom (asymptomatic PBC). The reported proportion of asymptomatic PBC at presentation greatly varies, from 13% to 80.7% (Jeffrey et al., 1990; Mahl et al., 1994; Nakano et al., 2002; Nyberg and Loof, 1989; Prince et al., 2002; Wong et al., 2007, 2008), probably owing to the difference of stages at diagnosis among studies or the lower recognition by physicians of the subjective symptoms of patients. The most dominant clinical symptoms at the early stage of PBC are fatigue and pruritus, followed by jaundice.

### Fatigue

Fatigue is the most common and debilitating symptom in PBC, experienced by approximately 50% (ranging from 20% to 80% depending on each study) of the patients (Prince et al., 2002; Huet et al., 2000; Mells et al., 2013). Objective assessment of fatigue can be carried out with the Fatigue Impact Scale (Fisk et al., 1994) or the PBC-40 questionnaire (Jacoby et al., 2005). Although it is difficult to define the cutoff clearly according to the presence of fatigue, it has been repeatedly shown that fatigue has a great impact on impairment of the quality of life of patients with PBC (Mells et al., 2013; Jopson and Jones, 2015). Fatigue is not associated with disease severity and staging but may be related to age at onset and sex (Carbone et al., 2013b).

The cause of fatigue remains unknown but appears to be complex in origin, probably multifactorial in most patients and associated with depression, autonomic dysfunction, and sleep disturbance (Jopson and Jones, 2015). Recent studies with magnetic resonance imaging revealed neuroimaging changes in the brain even in patients in

the early stage of PBC (Grover et al., 2016). Fatigue does not respond to UDCA treatment and there have been no established treatment. Fatigue may be improved by LT but still persists in a substantial part of patients even after LT, making the role of LT as a therapeutic option for severe fatigue questionable (Carbone et al., 2013a). Modafinil, which is officially approved by the FDA for wakefulness disorders, has been used; however, a recent randomized, placebo-controlled clinical trial failed to indicate beneficial effects of modafinil in terms of fatigue improvement in patients with PBC (Silveira et al., 2017).

## Pruritus

Pruritus is another important symptom in PBC, affecting 20%–80% of the patients. Pruritus can occur locally or diffusely, and its presence and severity fluctuate throughout the clinical course. It tends to become more pronounced along with the progression of PBC but could be present even at a very early stage. Pruritus could be highly bothersome and intolerable, such as causing sleep disturbance, and is an important indication for LT. Similar to fatigue, the severity of pruritus is objectively assessable with the PBC-40 questionnaire (Jacoby et al., 2005). The cause of pruritus remains unknown, although several substances are hypothesized to be related to pruritus in cholestatic liver diseases (Beuers et al., 2014). Most notably, lysophosphatidic acid (LPA) may be a potential candidate for the initiation of pruritus (Kremer et al., 2010a), and the activity of serum autotaxin, the serum enzyme converting lysophosphatidylcholine into LPA, is related to the severity of pruritus and responds to therapeutic interventions (Kremer et al., 2010b, 2012). Therefore LPA-autotaxin is an important candidate therapeutic target yet clinically unavailable. Very recently, an ileal bile acid transporter inhibitor compound (GSK2330672) that inhibits reabsorption of bile acids at the ileum was shown to effectively decrease pruritus of patients with PBC in a phase 2a study (Hegade et al., 2017), and the efficacy of this compound is now being further investigated in a global phase 2b study (NCT02966834). Moreover, bezafibrate, originally developed as an antihypertriglyceridemia drug, is now on clinical trial for the treatment of cholestatic pruritus (NCT02701166) (Bolier et al., 2017).

## DISORDERS ASSOCIATED WITH PRIMARY BILIARY CHOLANGITIS

### Primary Biliary Cholangitis With Features With Autoimmune Hepatitis

Although PBC typically presents as an elevation of cholestatic liver enzymes and detectable AMA, variant forms of PBC lacking one or more typical characteristics are occasionally encountered. In particular, some patients synchronously or consecutively present with features of AIH (i.e., elevation of transaminases, serum IgG levels, and positive ANAs). This variant type was formerly referred to as PBC–AIH overlap syndrome but is now termed PBC with features of AIH, because this atypical disorder is neither a single clinical entity nor a combination of PBC and AIH but rather a variant form of classic PBC (Boberg et al., 2011). The Paris criteria (Chazouillères et al., 1998) (Table 58.5) are most commonly used to define this variant, and patients who meet these criteria benefit from corticosteroid treatment in addition to UDCA (European Association for the Study of the Liver, 2017). Nevertheless, it must be kept in mind that the Paris criteria were not intended to define this variant as a single clinical entity.

**TABLE 58.5** The Paris Criteria for Primary Biliary Cholangitis (PBC) With Features of Autoimmune Hepatitis (AIH) (Chazouillères et al., 1998)

PBC criteria	Features of AIH criteria
1. ALP > 2 × ULN or γ-GT > 5 × ULN	1. ALT > 5 × ULN
2. Positive AMA	2. IgG > 2 × ULN or positive SMA
3. Florid bile duct lesion on histology	3. Moderate or severe periportal or periseptal lymphocytic piecemeal necrosis

The presence of at least two of three for each condition was required. ALP, Alkaline phosphatase; ULN, upper limit of normal; γ-GT, gamma glutamyl transferase; AMA, antimitochondrial autoantibody; SMA, smooth muscle antibody.

## Sicca Syndrome

The sicca complex is frequently present in patients with PBC, manifesting as dry eyes and/or dry mouth. External glands including the lachrymal or salivary glands are also affected in PBC. Indeed, a recent retrospective study revealed the prevalence of Sjogren's syndrome as up to 56% in patients with PBC ([Floreani et al., 2015b](#)); however, the sicca complex affects patients with PBC who do not meet the criteria of Sjogren's syndrome. Patients with sicca syndrome may experience a variety of complaints including burning, itching, or irritated eyes; blepharitis; dysphagia; stomatitis; dental caries; and dry cough, resulting in severe impairment of the quality of life. Early recognition of sicca symptoms and consultations to ophthalmologists or dentists are suggested.

## Osteopenia and Osteoporosis

Osteopenic bone disease, including osteopenia and osteoporosis, is a common disorder in PBC mainly affecting middle-aged women and is associated with an increased risk for fragility fracture. The decrease in bone mineral density found in PBC is multifactorial. Chronic cholestasis leads to malabsorption and deficiency of vitamin D, which is essential to bone metabolism. Other factors associated with bone diseases include age, sex, low body mass index, history of fragile fracture, and advanced stage of PBC ([Guanabens et al., 2005, 2010](#)). Intervention with a bisphosphonate for patients with osteoporosis and with a history of fragility fracture is safe and improves bone mineral density ([Guanabens et al., 2013](#)); however, it remains unclear whether it is associated with a decrease in fragility fractures.

## Hyperlipidemia and Metabolic Syndrome

Chronic cholestasis is a main feature of PBC, and therefore hyperlipidemia is common and affects up to 80% of the patients ([Sorokin et al., 2007](#)). Several prospective studies indicated that an increase in serum lipid levels is not associated with a higher risk for cardiovascular diseases related to atherosclerosis, and treatment for hyperlipidemia per se is not necessary. Notably, these studies were carried out in the 1990s when the metabolic syndrome was relatively rare in patients with PBC. A recent study in Italy demonstrated that cardiovascular events developed more frequently in patients with metabolic syndrome ([Floreani et al., 2015a](#)), indicating the importance of treatment intervention for patients with hyperlipidemia if metabolic syndrome exists.

## Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC), although previously very rare, is now occasionally encountered in patients with PBC in whom life expectancy is comparable to the general population with the introduction of UDCA. The reported incidences and risk factors for developing HCC from several large-scale retrospective cohorts are summarized in [Table 58.6](#). Surprisingly, the incidence rates (cases per 1000 patient-years) of HCC in all patients with PBC are similar across different regions: 3.6 in Barcelona, Spain; 3.7 in Padova, Italy ([Cavazza et al., 2009](#)); 3.6 in a nationwide study in Japan ([Harada et al., 2013a](#)); and 3.4 in an international cohort ([Trivedi et al., 2016b](#)). The

**TABLE 58.6** Incidence and Risk Factors for Hepatocellular Carcinoma (HCC) in Patients With Primary Biliary Cholangitis

Country/Region	Number		Incidence <sup>a</sup>			Risk factors
	Total	HCC	All	Male	Female	
Barcelona, Spain ( <a href="#">Cavazza et al., 2009</a> )	389	13	3.6	NA	NA	Advanced histological stage
Padova, Italy ( <a href="#">Cavazza et al., 2009</a> )	327	11	3.7	NA	NA	Advanced histological stage (all), male sex
Japan ( <a href="#">Harada and Nakanuma, 2014</a> )	2946	71	3.6	9.5	2.92.9	Male sex, advanced histological stage (in females)
International ( <a href="#">Trivedi et al., 2016b</a> )	4565	123	3.4	6.7	2.6	Advanced age, male sex, thrombocytopenia at 12 months, biochemical nonresponse
Beijing, China ( <a href="#">Rong et al., 2015</a> )	1865	70	6.6	NA	NA	Advanced age, male sex, coexistence of diabetes, Hx of HBV infection

<sup>a</sup>Cases per 1000 patient-years.

Hx, History; HBV, hepatitis B virus; NA, not applicable.

incidence rate was exceptionally high, 6.6, in a cohort from Beijing, China (Rong et al., 2015), presumably because of the high rate of the population with previous hepatitis B virus (HBV) infection. Indeed, a history of HBV infection was identified as an independent risk factor for HCC in this study. The incidence rate was higher in men than in women. In those studies, male sex and advanced histological stage independently contributed to the development of HCC (Cavazza et al., 2009; Harada et al., 2013a; Trivedi et al., 2016b; Rong et al., 2015). Treatment response was included among possible risk factors only in the international cohort study, and biochemical nonresponse at 1 year of UDCA treatment (Paris-II not fulfilled) significantly increased the future risk of HCC (adjusted hazard ratio, 3.44) (Trivedi et al., 2016b). Taken together, close monitoring of HCC is strongly recommended for high-risk patients with PBC, such as male patients, patients with advanced-stage disease, and nonresponders to UDCA. The mean survival of patients who developed HCC was 36 months after diagnosis, and another cohort indicated 5- and 10-year-survival rates of 49.5% and 31.7%, respectively (Imam et al., 2012).

## STRATIFICATION OF THE RISK FOR PROGRESSION

After the introduction of UDCA as the first-line drug, the prognosis of patients with PBC dramatically improved and now is comparable to those of the general population if the response to UDCA is favorable. On the other hand, a substantial proportion of patients who are already in the cirrhotic stage at presentation or are refractory to UDCA unavoidably progress to liver failure and require orthotopic liver transplantation (OLT). Therefore clinicians must stratify individual patients who are diagnosed as having PBC and estimate the risk of the patient for progression, both at presentation and at any time during treatment, especially at 1 year after the commencement of UDCA treatment (Trivedi et al., 2016a).

### Stratification at Baseline

Sex and age at diagnosis are reported to be associated with response to UDCA treatment and symptom development, and women who are younger than 50 years exhibited the lowest response rate to UDCA and the highest levels of symptoms (Carbone et al., 2013b). The AST/platelet ratio index at baseline is also a predictor of outcomes independent of the UDCA response (Trivedi et al., 2014). The presence of ANAs, especially anti-gp210, at baseline may be associated with a more severe clinical course (Nakamura et al., 2007; Muratori et al., 2003; Invernizzi et al., 2001). A recent retrospective study in China also reinforced the significance of anti-gp210 as a biomarker of worse outcomes (Yang et al., 2017). Advanced histological stages at presentation are obviously associated with poor prognosis. However, assessment of liver histology definitely requires liver biopsy as an invasive procedure, and sampling errors have always been a problem. In this regard, a variety of noninvasive techniques for the evaluation of liver fibrosis have been developed, including liver stiffness measurement by means of vibration-controlled transient elastography, magnetic resonance elastography, and serum biomarker measurements (Poupon, 2015). Recent studies indicated that serum levels of *Wisteria floribunda* agglutinin-positive mac-2-binding protein, soluble CD-14, IL-8, and IFN- $\gamma$ -inducible protein-10 are other candidate serum biomarkers for predicting liver fibrosis and the prognosis of PBC (Nishikawa et al., 2016; Umemura et al., 2015, 2017).

### Stratification During Treatment

It is important to stratify patients with PBC depending on responses to treatment. Different criteria for defining biochemical responsiveness to UDCA have been proposed (Table 58.7). A global consensus has been established to judge responsiveness to UDCA at 1 year after the commencement of UDCA treatment with liver biochemistry tests, which are easy to conduct. Furthermore, although several simple definitions of unresponsiveness (responder or nonresponder) have been established in a nationwide scale in earlier studies (Corpechot et al., 2008, 2011; Kuiper et al., 2009; Kumagi et al., 2010; Pares et al., 2006; Azemoto et al., 2009; Momah et al., 2012) and later in an international consortium (Global PBC Group) to take into account a very large-scale cohort (Lammers et al., 2014), these dichotomous definitions did not serve as predictors that could precisely and quantitatively assess the risk for progression in a given patient. Recently, two large-scale multicenter studies have developed continuous predictive models (GLOBE score, UK-PBC score) with age and liver biochemistries either at baseline or at 1 year after UDCA treatment (Lammers et al., 2015; Carbone et al., 2016). These scores are easy to use with computer-aided calculations and allow to continuously quantify the risk for progression over time in

**TABLE 58.7** Criteria Defining Biochemical Responses to Ursodeoxycholic Acid

Criteria	Number of patients	Duration	Definition
<b>QUALITATIVE DEFINITION</b>			
Barcelona (Pares et al., 2006)	192	1 year	Normal ALP or ALP reduction >40%
Paris-I (Corpechot et al., 2008)	292	1 year	ALP < 3 × ULN, AST < 2 × ULN, normal bilirubin
Rotterdam (Kuiper et al., 2009)	375	1 year	Normal bilirubin, normal albumin
Toronto (Kumagi et al., 2010)	69	2 years	ALP ≤ 1.67 × ULN
Ehime (Azemoto et al., 2009)	83	6 months	Normal γ-GT or γ-GT reduction ≥ 70%
Paris-II (Corpechot et al., 2011)	165	1 year	ALP < 1.5 × ULN, AST < 1.5 × ULN, normal bilirubin
Rochester (Momah et al., 2012)	73	1 year	ALP ≤ 1.67 × ULN, bilirubin ≤ 1 mg/dL
International (Global PBC) (Lammers et al., 2014)	4845	1 year	ALP < 2 × ULN, normal bilirubin
<b>QUANTITATIVE SCORES</b>			
GLOBE score (Lammers et al., 2015)	4119	1 year	Bilirubin, ALP, albumin platelet count at 1 year, age at baseline
UK-PBC score (Carbone et al., 2016)	3165	1 year	ALP, AST/ALT, bilirubin at 1 year, albumin, platelet count at baseline

ALP, Alkaline phosphatase; ULN, upper limit of normal; AST, aspartate aminotransferase; γ-GT, gamma glutamyl transferase.

a single patient. It is of note, however, that these scores were solely developed for a patient cohort treated with UDCA monotherapy, and whether these scores based on biochemical responses at 1 year treatment are also applicable to patients treated with additional drugs such as OCA or bezafibrate should be further validated.

## PERSPECTIVES

Clearly, the introduction of OCA in 2016 as an alternative therapeutic option was an epoch-making event in PBC, and it is very welcome that several new drugs are in clinical trials and under development. As the clinical characteristics of PBC may vary among patients and progression is not always predictable, it is an ultimate goal to stratify patients depending on the risk for progression and individualize the treatment with a variety of therapeutic agents including an option of no treatment. To accomplish this, more details about the etiology of PBC should be uncovered. Animal models of PBC that would allow scrutinizing the initial events of PBC should be established, the interaction between environmental triggers and genetic predispositions needs to be investigated, and the critical pathways in PBC that should be targeted by therapeutic interventions should be elucidated.

## GENERAL INTRODUCTION

### Gateway From Autoimmune Pancreatitis to Immunoglobulin G4–Related Disease

Immunoglobulin G4–related disease (IgG4-RD) is a currently proposed systemic disease that is characteristically associated with IgG4 and is considered to be caused by autoimmune mechanisms. The clinical features of IgG4-RD can be summarized as (1) systemic distribution; (2) imaging findings of swelling, nodules, and/or wall thickening; (3) high serum IgG4 concentration; (4) abundant lymphoplasmacytic and IgG4-bearing plasma cell infiltration in affected organs; (5) a favorable response to corticosteroid therapy; and (6) combination with other IgG4-RDs simultaneously or in a metachronous fashion.

The establishment of this disease concept was based on a culmination of specific discoveries, namely, (1) the proposal of autoimmune pancreatitis (AIP) presumably caused by autoimmune mechanisms, (2) a close association between AIP and high serum IgG4 concentration, (3) systemic other organ involvements (OOIs) in AIP, (4) abundant IgG4-bearing plasma cell infiltration in affected tissues of AIP and its extrapancreatic organs, and (5)

OOIs also exhibiting a favorable response to corticosteroid therapy. These findings led the way to the establishment of the concept of a systemic disease consisting of AIP and related extrapancreatic lesions, that is, IgG4-RD, and opened the gateway from AIP to this new disease entity (Kawa, 2016).

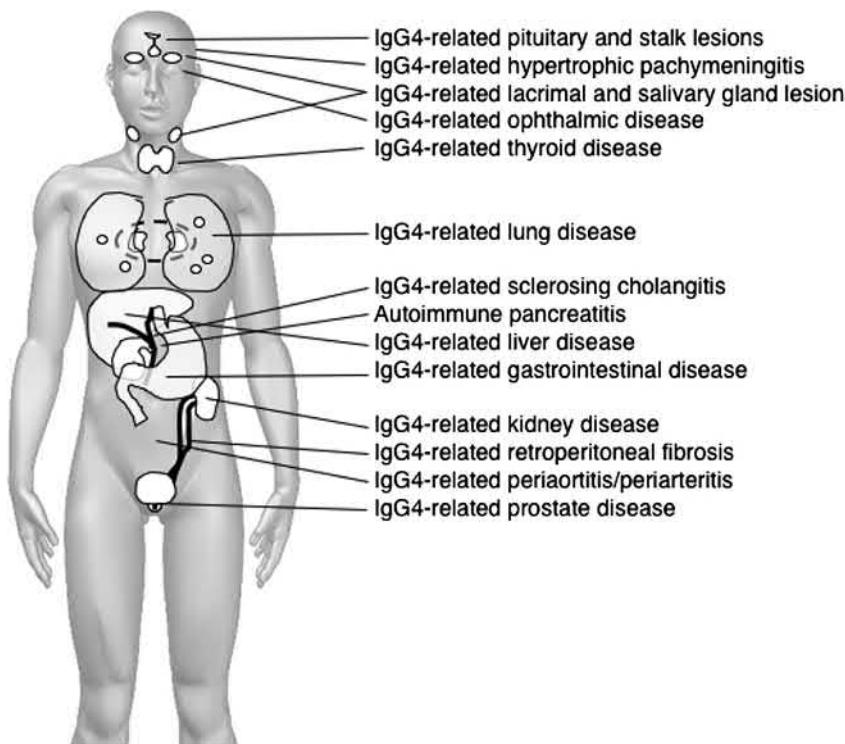

## HISTORICAL PROGRESSION FROM AUTOIMMUNE PANCREATITIS TO IMMUNOGLOBULIN G4–RELATED DISEASE

Although chronic pancreatitis is mainly caused by injury from alcohol abuse, there have long been reports of another type of chronic pancreatitis presumably caused by autoimmune mechanisms. Sarles et al. (1961) first reported a specific type of pancreatitis as chronic inflammatory sclerosis of the pancreas showing hyperglobulinemia and histologically marked lymphocytic infiltration. Nakano et al. (1978) described the first such case successfully treated with corticosteroids. Kawaguchi et al. (1991) designated this condition as lymphoplasmacytic sclerosing pancreatitis based on the detailed pathological study. Toki et al. (1992) reported chronic pancreatitis showing diffuse irregular narrowing of the entire main pancreatic duct (MPD). Yoshida et al. (1995) termed this condition as “AIP” based on the clinical findings of hypergammaglobulinemia, positive tests for autoantibodies and lymphoplasmacytic infiltration in the pancreas, and a favorable response to corticosteroid treatment. Since then, many cases of AIP have been diagnosed based on these characteristic features and a number of single cases and small case series have been published. In 2001 we reported that patients with AIP frequently and specifically exhibited high serum IgG4 concentrations that correlated closely with disease activity, suggesting that the disease was a discrete clinical entity different from ordinary chronic pancreatitis (Hamano et al., 2001). Protein electrophoresis of AIP patient sera revealed a polyclonal band in the rapidly migrating fraction of  $\gamma$ -globulins that was confirmed by the immunolectrophoresis to be caused by an elevated serum IgG4. We witnessed an increased IgG4 elevation in 90% of patients with AIP but scarcely in other conditions, which implicated IgG4 as a sensitive and specific marker for the disease. IgG4 levels also correlated closely with disease activity (Hamano et al., 2001). In 2002 we identified an abundant IgG4-bearing plasma cell infiltration in the pancreas and extrapancreatic sites of AIP, which have remained a histological hallmark of AIP and IgG4-RD (Hamano et al., 2002).

AIP is known to be accompanied by a variety of extrapancreatic lesions (Hamano et al., 2006). Investigation on the prevalence of extrapancreatic lesions in AIP based on the imaging modalities of computed tomography (CT), magnetic resonance imaging (MRI), and fluorodeoxyglucose position emission tomography showed dacryoadenitis/sialadenitis involvement to be the most common (48%), followed next by pulmonary lesions (54%), bile duct lesions (78%), kidney lesions (14%), retroperitoneal fibrosis (20%), and prostate lesions (10%) (Fujinaga et al., 2009). These additional manifestations shared many of the histopathological features of AIP, primarily IgG4-bearing plasma cell infiltration, and generally demonstrated a good clinical response to glucocorticoid treatment (Hamano et al., 2002). They also indicated a common pathophysiological background among the disorders and ultimately led to the proposal of a systemic disease linking IgG4, AIP, and related extrapancreatic lesions (Hamano et al., 2002; Kamisawa et al., 2003a). Elsewhere, experts in the field of rheumatology were proposing a similar systemic disease comprising IgG4, lachrymal and salivary gland lesions, and other extraglandular involvement (Yamamoto et al., 2006; Neild et al., 2006; Masaki et al., 2008). In 2010 the new disease concept of IgG4-RD was proposed for this condition by experts in Japan (Umeshara et al., 2012a), and in 2011 this entity was accepted at an international conference in Boston (Stone, 2012; Stone et al., 2012b). IgG4-RD now includes a wide variety of systemic lesions (Fig. 59.1) (Stone et al., 2012a), the number of which is increasing.

## EPIDEMIOLOGY

The precise epidemiology of IgG4-RD remains unclear due to a lack of large-scale surveys and the fact that most studies have dealt only with a specific disease subset, such as AIP, and not the entity as a whole. A nationwide survey of AIP in Japan revealed an overall prevalence rate of 4.6/100,000 individuals, annual incidence rate of 1.4/100,000 (Kanno et al., 2015). As AIP accounts for only a part of the total number of IgG4-RD cases, the true prevalence of IgG4-RD is certainly higher. Since the frequency of AIP among IgG4-RD cases was reported to be 60% (Inoue et al., 2015), the prevalence of IgG4-RD was estimated as 7.7/100,000 individuals. The genetic contribution to IgG4-RD remains incompletely described. To date, there has been only one reported familial case of IgG4-RD (Watanabe et al., 2013b).

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

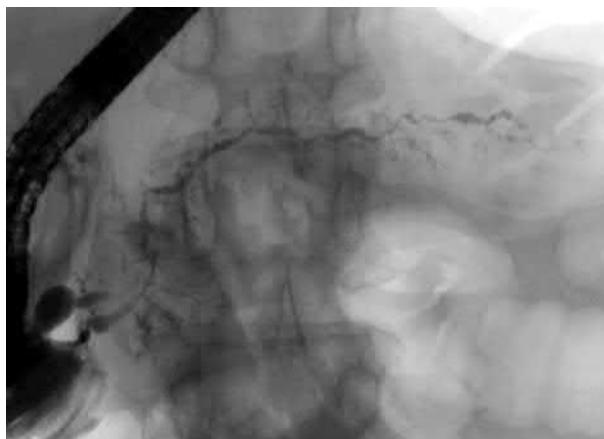

A host of systemic manifestations have been included in IgG4-RD (Fig. 59.1).

### Autoimmune Pancreatitis

The male ratio in AIP was found to be 77%, and the median age of occurrence was 63 years (range: 38–85 years), indicative of an elderly male preponderance. Few patients complained of severe pancreatitis attacks that were different from classical acute pancreatitis. A striking feature was obstructive jaundice in 70% of patients caused by stenosis or obstruction of the intrapancreatic common bile duct. Diabetes mellitus was often observed, the majority of which being type 2 (Yoshida et al., 1995; Kawa, 2016), and some patients improved after steroid therapy (Tanaka et al., 2000). Laboratory tests revealed several abnormal findings related to obstructive jaundice. The tumor-associated antigen CA19-9 was elevated in 50% of subjects, probably due to cholestasis rather than a malignant process. Elevated serum  $\gamma$ -globulin, IgG, and IgG4 were present in 60%, 70%, and 80% of patients, respectively. Although IgG4 was the most sensitive and specific immunological marker, decreased IgA and IgM concentrations were also detected in patients with increased IgG4 levels (Taguchi et al., 2009). Positivity for anti-nuclear antibody was 40% and that for other antibodies was 10%–30%, and serum immune complex (IC) values reflected disease activity as well. The decreased exocrine and endocrine function by the bentiromide test and HbA1c were found in 66% and 51% of cases, respectively (Kawa, 2016). Image finding disclosed a characteristic pancreatogram of diffuse but irregular narrowing (Fig. 59.2).

Patients with AIP sometimes receive an erroneous diagnosis of pancreatic cancer due to the preponderance of the disease in the elderly together with symptoms of obstructive jaundice, elevated serum CA19-9, and pancreatic swelling with irregular narrowing or obstruction of the pancreatic duct. The pathological analysis following pancreaticoduodenectomy (Whipple resection) for a diagnosis of pancreatic cancer disclosed results representative of AIP in 2.2% of patients (Hardacre et al., 2003). Also owing to similar pathological findings, AIP has been misdiagnosed as pancreatic lymphoma (Horiuchi et al., 1996).

Although AIP was initially believed to be an acute, nonprogressive condition (Yoshida et al., 1995), it became evident that some patients experienced pancreatic stone formation, pancreatic atrophy, and/or irregular dilatation of the MPD overtime (Takayama et al., 2004; Maruyama et al., 2012). During the long-term course, a number of AIP cases could progress to chronic pancreatitis with severe dysfunction (Maruyama et al., 2013, 2014; Kanai et al., 2016).

**FIGURE 59.2** Endoscopic retrograde cholangiopancreatography demonstrating the characteristic diffuse irregular narrowing seen in AIP. AIP, Autoimmune pancreatitis.

Recently, the long-term outcomes of AIP and IgG4-RD were described to include the complication of malignancy development (Yamamoto et al., 2012; Shiokawa et al., 2013), although this point is controversial (Hirano et al., 2014; Hart et al., 2014; Inoue et al., 2015). We identified a close association between IgG4-RD and malignancy formation within 12 years after diagnosis, particularly during the first year (Asano et al., 2015).

### **Immunoglobulin G4–Related Pituitary and Stalk Lesions**

IgG4-related pituitary and stalk lesions include hypophysitis presenting with compressive optic neuropathy, panhypopituitarism, pituitary hypothyroidism, adrenocortical insufficiency, and syndrome of inappropriate secretion of antidiuretic hormone (van der Vliet and Perenboom, 2004; Shimatsu et al., 2009; Shikuma et al., 2017). A review of 84 patients with IgG4-related hypophysitis demonstrated manifestations of anterior hypopituitarism in 26.2% of cases, central diabetes insipidus in 17.9%, and panhypopituitarism in 52.4% (Shikuma et al., 2017). IgG4-related hypophysitis should always be considered in the differential diagnosis of primary hypophysitis (Berreuther et al., 2017).

### **Immunoglobulin G4–Related Hypertrophic Pachymeningitis**

Hypertrophic pachymeningitis (HP) is a rare fibroinflammatory lesion that causes thickening of the dura in the cranium and/or spinal canal and presents as radiculomyopathy, headache, or cranial nerve palsy depending on the site of the involvement (Riku et al., 2009; Chan et al., 2009; De Virgilio et al., 2017). A nationwide survey of HP in Japan uncovered IgG4-related HP in 14 (8.8%) of 159 cases (Yonekawa et al., 2014).

### **Immunoglobulin G4–Related Lacrimal and Salivary Gland Lesions**

IgG4-related lacrimal and salivary gland lesions are major members of IgG4-RD including Mikulicz's disease and Küttner tumor and present as symmetrical swelling of lacrimal and salivary glands. Patients show no gender differences, which is different from other IgG4-RDs (Yamamoto et al., 2015). In contrast to Sjögren's syndrome, however, IgG4-related lacrimal and salivary gland lesions show milder exocrine dysfunction, are negative for anti-SS-A/Ro and SS-B/La autoantibodies, and have more frequent submandibular gland lesions (Yamamoto et al., 2005; Umehara et al., 2012a).

### **Immunoglobulin G4–Related Ophthalmic Disease**

IgG4-related ophthalmic disease includes lacrimal gland lesions (Mikulicz's disease) in 50% of cases and ocular adnexa lesions (trigeminal nerve branch enlargement, extraocular muscle enlargement, diffuse orbital fat lesions, orbital mass lesions, eyelid lesions, or nasolacrimal duct lesions) in another 50% (Wallace et al., 2014; Sogabe et al., 2014; Yamamoto et al., 2015). These lesions present as vision abnormalities from optic nerve disturbance, restriction of ocular movement, and exophthalmos (Sogabe et al., 2014) and should be differentiated from mucosa-associated lymphoid tissue (MALT) lymphoma (extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue), diffuse large B-cell lymphoma, and follicular lymphoma (Goto et al., 2015).

### **Immunoglobulin G4–Related Thyroid Disease**

Riedel's thyroiditis is a chronic fibrosing disorder of unknown etiology that is primarily known as a member of multifocal fibrosclerosis, with a portion of cases considered to be IgG4-RD (Dahlgren et al., 2010; Takeshima et al., 2015). AIP patients with complicating hypothyroidism had a significantly higher frequency of antithyroglobulin antibody than those without (Komatsu et al., 2005). The other series of Hashimoto's thyroiditis were classified as either IgG4 or non-IgG4 thyroiditis based on the immunostaining profiles (Li et al., 2012). IgG4 thyroiditis may represent IgG4-RD of the thyroid gland because it shares common histopathological characteristics with IgG4-RD in other organs (Kakudo et al., 2011). IgG4-RD is significantly associated with hypothyroidism that responds favorably to corticosteroid therapy as well, implicating the existence of an IgG4-related thyroid disease or an IgG4-related thyroiditis (Watanabe et al., 2013a).

### **Immunoglobulin G4–Related Lung Disease**

IgG4-related lung disease develops through the lymphatic routes of the lungs and exhibits various clinical characteristics. The Japanese diagnostic criteria for IgG4-related respiratory disease include the imaging findings of any of the following intrathoracic lesions of hilar/mediastinal lymphadenopathy, bronchial wall/bronchovascular bundle thickening, interlobular septal wall thickening, nodular shadow, infiltrative shadow, pleural thickening, and/or effusion (Matsui et al., 2016). There is a variety of IgG4-related respiratory lesions diagnosed with interstitial pneumonia (Taniguchi et al., 2004), inflammatory pseudotumor (Zen et al., 2005), hilar or mediastinal lymphadenopathy (Saegusa et al., 2003), or bronchial wall thickening (Ito et al., 2009).

### **Immunoglobulin G4–Related Sclerosing Cholangitis**

IgG4-related sclerosing cholangitis (IgG4-SC) is closely associated with AIP (60%–70% of AIP patients), and their cooccurrence often aids in diagnosis (Hamano et al., 2006; Tanaka et al., 2014). In contrast, solitary IgG4-SC without AIP closely resembles other conditions, such as primary SC (PSC) and bile duct malignancy (Hamano et al., 2005; Graham et al., 2014). IgG4-SC can be found in any part of the biliary system (Nakazawa et al., 2001, 2016). Lower bile duct lesions should be differentiated from pancreatic cancer and intrahepatic or hilar lesions from PSC and biliary malignancies (Nakazawa et al., 2005; Naitoh et al., 2009).

### **Immunoglobulin G4–Related Liver Disease**

IgG4-related liver disease consists of a variety of histological changes, including portal inflammation, interface hepatitis, large bile duct obstruction, portal sclerosis, lobular hepatitis, and canalicular cholestasis, all of which are collectively designated as IgG4 hepatopathy (Umemura et al., 2007b). Some of these lesions mimic those observed in autoimmune hepatitis (AIH) and have a similar clinical presentation; therefore they also fulfill the diagnostic criteria of AIH (Umemura et al., 2007a; Ishizu et al., 2016; Nakanuma et al., 2016).

### **Immunoglobulin G4–Related Kidney Disease**

Most cases of IgG4-related kidney disease involve the uriniferous tubules, with few being glomerular, and display tubulointerstitial nephritis with hypocomplementemia and deposits of ICs and C3 in tubular basement membranes (Takeda et al., 2004; Uchiyama-Tanaka et al., 2004; Saeki et al., 2010). Roughly, half of the patients have very mild proteinuria or hematuria, and urinalysis abnormalities are generally inconspicuous. However, nephrotic-range proteinuria may be observed when membranous glomerulonephritis or other glomerular lesions overlap. Some patients show an acute or progressive renal failure at presentation, while others are diagnosed based on incidental imaging abnormalities with normal renal function (Saeki et al., 2010; Raissian et al., 2011; Kawano and Yamada, 2016). CT depicts renal cortical lesions as areas of a decreased enhancement that appears as small peripheral cortical nodules and round or wedge-shaped lesions (Takahashi et al., 2007; Fujinaga et al., 2009).

### **Immunoglobulin G4–Related Retroperitoneal Fibrosis**

CT and MRI reveal soft tissue density or masses around the aorta and ureters (Fujinaga et al., 2009). Patients with periureteral lesions sometimes complain of lumbago or back pain due to hydronephrosis, which may result in renal atrophy and failure (Hamano et al., 2002).

### **Immunoglobulin G4–Related Periaortitis/Periarteritis**

Although IgG4-related periaortitis is a major member of IgG4-related retroperitoneal fibrosis, its disease spectrum extends to the thoracic aorta, coronary artery, and iliac artery, which has led to the proposal of the distinct systemic disease entity of IgG4-related periaortitis/periarteritis. Histopathologically, IgG4-related arterial lesions are characterized by arterial wall thickening corresponding to inflammation with IgG4-positive plasmacytes and fibrosis, both mainly in the adventitia (Kasashima et al., 2008; Inoue et al., 2011). Although IgG4-related periaortitis/periarteritis responds well to corticosteroid treatment, cases with prior luminal dilatation have shown exacerbation after therapy (Mizushima et al., 2014; Ozawa et al., 2017).

### **Immunoglobulin G4–Related Prostate Disease**

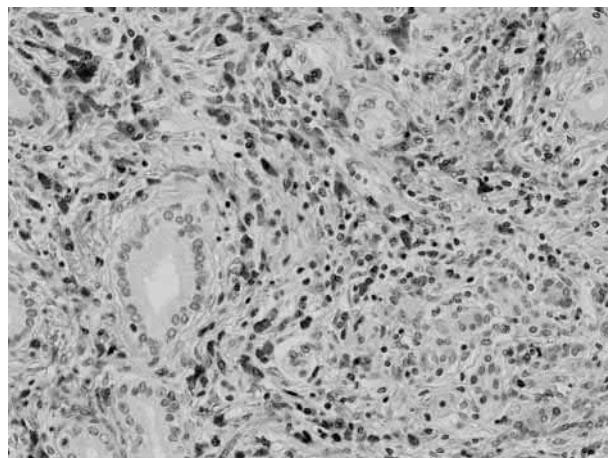

As prostate involvement might not be rare in IgG4-RD, the clinicians should consider this disease entity in patients with IgG4-RD accompanied with prostatic symptoms (Buijs et al., 2014). Patients present with a symmetrically, nontender, swollen prostate highlighted by an imaging analysis to have severe inflammatory lesions mainly in the central and transition zones (Uehara et al., 2008; Buijs et al., 2014).

## PATHOLOGICAL FEATURES

The diagnosis of IgG4-RD rests on the combined presence of a characteristic histopathological appearance and increased numbers of IgG4-bearing plasma cells. The critical histopathological features in IgG4-RD are dense lymphoplasmacytic infiltration, a storiform pattern of fibrosis, and obliterative phlebitis. A terminology scheme for diagnosing IgG4-RD is based primarily on its morphological appearance on biopsy, while tissue IgG4 count and IgG4/IgG ratio are of secondary importance (Deshpande et al., 2012).

The pathological features of IgG4-RD were first investigated intensely in AIP tissues (Kawaguchi et al., 1991; Kloppel et al., 2007). On gross examination, the involved pancreas appears glistening white, is firm or hard, and may be enlarged or shows mass lesions. Lymphoplasmacytic infiltration and fibrosis are the characteristic microscopic features of pancreatic lesions, and in some cases, result in the formation of lymphoid follicles. Infiltrating plasma cells characteristically bear IgG4 (Hamano et al., 2002) (Fig. 59.3). Cell infiltration is prominent around the pancreatic duct, resulting in its stenosis or obstruction, stasis of pancreatic secretions, and damage to the pancreatic lobules. Obliterating phlebitis is another characteristic feature, showing marked cellular infiltration of the venous wall and venous thrombosis (Kawaguchi et al., 1991).

The pathological findings of each type of IgG4-RD share common features that are also present in AIP (Hamano et al., 2002; Kamisawa et al., 2003b; Deshpande et al., 2009, 2012; Deshpande, 2015); however, there are subtle variations among some organs as well as organ-specific features (Zen and Nakanuma, 2010). The unique pathological features include numerous lymph follicles in lacrimal and salivary gland lesions, and obliterative arteritis in lung lesions (Zen and Nakanuma, 2010). Obliterative phlebitis is scarcely found in lacrimal gland

**FIGURE 59.3** IgG4 immunostaining of pancreatic tissue in AIP revealing abundant infiltration of IgG4-bearing plasma cells. AIP, Autoimmune pancreatitis; IgG4, immunoglobulin G4.

lesions. The semiquantitative analysis of IgG4-bearing plasma cells may help to distinguish IgG4-RD from other conditions (Deshpande et al., 2006; Dhall et al., 2010), and the ratio of IgG4-bearing plasma cells to IgG-bearing plasma cells further assists in diagnosing IgG4-RD, with a ratio of >50% being highly suggestive of a diagnosis. The closest histopathological mimics of IgG4-RD are lymphomas, for which clonality studies are necessary to differentiate among these two conditions (Stone et al., 2012b) and multicentric Castleman's disease (Terasaki et al., 2017).

## AUTOIMMUNE FEATURES

### Complement Activation System

Serum concentrations of complements C3 and C4 were reduced in 36% of patients with AIP, suggesting a role of the complement activation system in its pathogenesis. We uncovered a significantly higher serum IgG1 concentration and decreased C3 and C4 values in the elevated IC group. Since IgG4 did not bind to C1q, it appeared to have no contribution to complement activation, while IgG1 seemed strongly implicated via the classical pathway (Muraki et al., 2006). On the other hand, Sugimoto et al. observed that both the classical and mannose-binding lectin pathways might participate in the complement activation system (Sugimoto et al., 2016; Kawa, 2017).

### Innate Immunity

Recent investigations have highlighted the importance of innate immunity in preceding and/or augmenting IgG4 responses driven by adaptive immunity (Akitake et al., 2010; Arai et al., 2015; Fukui et al., 2015; Watanabe et al., 2012, 2013c, 2017). Antigens derived from intestinal microflora as part of the microbe-associated molecular pattern are thought to activate the host's innate immune system via pattern recognition receptors or pathogen recognition receptors (PRRs), such as the Toll-like receptors (TLRs), nucleotide-binding oligomerization-like receptors (NLRs), retinoic acid-inducible gene (RIG)-I-like receptors, or C-type lectin like receptors. Under sterile inflammatory conditions, endogenous nonmicrobial danger molecules, or damage-associated molecular patterns, released from dying and necrotic cells activate PRRs and have been implicated in the development of autoimmune diseases (Kono and Rock, 2008; Watanabe et al., 2017). Peripheral blood mononuclear cells, presumably B cells, isolated from patients with AIP show the enhanced production of IgG4 upon stimulation with NLR and TLR ligands that are associated with the release of B cell-activating factor (BAFF) (Yamanishi et al., 2011; Watanabe et al., 2012). The activation of basophils is also likely involved in the pathogenesis of IgG4-RD since TLR activation in basophils stimulates IgG4 production by B cells in a T-cell independent manner (Watanabe et al., 2013c). As described earlier, the mannose-binding lectin pathway, which is a member of innate immunity, may participate in the complement activation system in IgG4-RD (Sugimoto et al., 2016).

### Adaptive Immunity

#### Autoantibodies

Shiokawa et al. demonstrated that subcutaneous injection of IgG from AIP patients, but not control IgG, caused pancreatic and salivary gland injury in neonatal mice. Although pancreatic injury was also induced by the patient with IgG1 or IgG4, the potent pathogenic activity of IgG1 was significantly inhibited by simultaneous injection of IgG4, suggesting that circulating IgG4 in AIP patients had both pathogenic and protective roles. Moreover, the autoantibodies in AIP serum recognized molecules involved in cell-extracellular matrix adhesion, laminin 511 (Shiokawa et al., 2016, 2018).

*Helicobacter pylori* infection may also trigger AIP, possibly as a result of molecular mimicry. There is substantial homology between human CA II and *H. pylori* alpha-carbonic anhydrase: the homologous segments contain the binding motif of the human leucocyte antigen (HLA) molecule DRB1\*04:05, which is closely associated with AIP (Kawa et al., 2002). The HLA-DRB1\*04:05 allele was also an important risk factor for AIP in functional studies using a transgenic mouse model (Freitag et al., 2010). These data led to the hypothesis that the DRB1\*0405-restricted peptide of CA II was present in genetically predisposed subjects and that reactive T cells injured pancreatic tissue via interaction with the CA II of pancreatic ductal cells (Guarneri et al., 2005).

### Immunoglobulin G4

Since serum IgG4 and IgG4-type ICs are closely associated with disease activity (Hamano et al., 2001), they may play a major role in the pathogenesis of AIP and IgG4-RD. However, their exact nature, that is, whether they are beneficial or harmful, remains unclear. To date, the pathological effects of IgG4 and IgG4-type ICs have been reported in limited settings, such as pemphigus vulgaris (Rock et al., 1989), idiopathic membranous glomerulonephritis (Beck et al., 2009), acquired thrombocytopenic purpura (Ferrari et al., 2009), and muscle-specific kinase myasthenia gravis (Plomp et al., 2012). In AIP, IgG4-type autoantibodies may elicit an inflammatory response as described before (Shiokawa et al., 2016). Recent studies have demonstrated two outstanding characteristics of IgG4, Fab-arm exchange (van der Neut Kolfschoten et al., 2007) and rheumatoid factor (RF)-like activity (Kawa et al., 2008), which enable IgG4 to contribute to defense against disease progression. Specifically, dynamic Fab-arm exchange in the IgG4 molecule results in bispecific activity and the loss of monospecific cross-linking activity and ability to form ICs to impart antiinflammatory effects (van der Neut Kolfschoten et al., 2007; Aalberse et al., 2009; Rispens et al., 2011). IgG4 has also been reported to bind IgG and exert RF activity (Hennig et al., 2000). However, IgG4 Fc, but not IgG4 Fab, binds to IgG Fc, indicating that IgG4 binding to IgG Fc occurs via an Fc–Fc interaction and not RF per se (Kawa et al., 2008). Furthermore, the human IgG4 was seen to bind to the Fc portions of various animal IgGs (Ito et al., 2010). Although the exact role of this novel RF-like IgG4 activity remains unclear, different IgG4 molecules with the same antigen reactivity may associate via Fc–Fc interaction and then exchange half molecules of each IgG4, resulting in Fab-arm exchange with different epitope reactivity (Rispens et al., 2009).

### Cellular Immunity

In some cases of AIP, CD4 + Th1 cells predominate over Th2 cells, suggesting that Th1 cytokines are essential for the induction and maintenance of AIP while Th2 cytokines are involved in disease progression (Okazaki and Chiba, 2002). However, there is also evidence of a Th2-predominant immune response in AIP (Zen et al., 2007), and a deviation of Th1/Th2 balance toward Th2 was described in patients with IgG4-RD (Miyake et al., 2008). The expression profile of cytokines in salivary glands from patients with AIP, IgG4-related SC, and IgG4-related dacryoadenitis/sialadenitis suggested that Th2 immune reactions might play a key role in IgG4 production (Tanaka et al., 2012; Zen et al., 2007). In particular, interleukin (IL)-33 from CD163-positive M2 macrophages appeared to be strongly involved in the activation of a Th2 immune response (Moriyama and Nakamura, 2017). Several studies have observed that abnormal innate immune responses via TLRs expressed by monocytes/macrophages enhanced Th2 immune responses and the immunopathogenesis of IgG4-RDs (Watanabe et al., 2012; Fukui et al., 2015). Recent studies have indicated that particular Th subsets might be involved in the initiation of IgG4-RD (Moriyama and Nakamura, 2017).

Regulatory immune cells play an important role in several immune-related diseases. In particular, abnormalities in regulatory T cell (Treg) and regulatory B cell (Breg) number and function are implicated in multiple immune-related and autoimmune conditions, which has brought about investigation of their roles in IgG4-RD (Uchida and Okazaki, 2017). Transforming growth factor (TGF)- $\beta$  secreted from naïve Th0 cells can induce CD4 + CD25 + Tregs that have potent inhibitory function via the transcription factor forkhead box P3 (Foxp3). In the peripheral blood, Treg numbers were significantly increased in patients with AIP, and this rise was correlated with augmented serum concentrations of IgG4. In contrast, naïve Tregs are significantly decreased in patients with AIP, suggesting that the increased numbers of Tregs may influence IgG4 production and reflect disease progression while diminished numbers of naïve Tregs may be involved in AIP pathogenesis (Miyoshi et al., 2008). The ratio of Foxp3 + cells to infiltrating mononuclear cells (Foxp3/Mono) in AIP patients is significantly higher than in individuals with chronic alcoholic pancreatitis, and the Foxp3/Mono and IgG4/Mono ratios are positively correlated with each other (Kusuda et al., 2011). In the periphery, two functionally different subsets of effector Tregs [inducible costimulatory molecule (ICOS) + or ICOS – effector Tregs] actively produce the immunosuppressive cytokines IL-10 and TGF- $\beta$ , respectively. The levels of ICOS + Tregs and IL-10 + Tregs are significantly higher in patients with AIP, implying that ICOS + Tregs modulate IgG4 production via IL-10 in this disease (Kusuda et al., 2011) and supporting the notion that a decrease in the number of naïve Tregs is involved in AIP onset. Fibrosis may be regulated by TGF- $\beta$ , which is secreted by ICOS – Tregs (Uchida and Okazaki, 2017). The role of Tregs has been also confirmed in other IgG4-RDs, including IgG4-SC (Koyabu et al., 2010), IgG4-related sialadenitis (Tanaka et al., 2012), and IgG4-related kidney disease (Mizushima et al., 2012; Kawamura et al., 2015). Mechanisms underlying IgG4 production was proposed by Tanaka et al. (2012) and Takeuchi et al. (2014), showing that Th2 cell and Treg regulate the production of IgG4 via IL-4 and IL-10 cytokines, which may be initiated or controlled by M2 macrophage or mast cell.

Predominantly identified based on their ability to produce IL-10, Bregs play an important role in suppressing pathological immune responses (Mauri and Bosma, 2012). CD19<sup>+</sup>CD24<sup>high</sup>CD38<sup>high</sup> immature Bregs were significantly increased in the peripheral blood of AIP patients, whereas the CD19<sup>+</sup>CD24<sup>high</sup>CD27<sup>+</sup> B10 cell fraction of AIP patients was lower. The total number of IL-10-producing B cells was not significantly different between AIP patients and healthy controls. However, in untreated AIP patients, the number of CD19<sup>+</sup>CD24<sup>high</sup>CD38<sup>high</sup> immature Bregs did not correlate to IgG4 levels, which differed from findings for Tregs. These results imply that CD19<sup>+</sup>CD24<sup>high</sup>CD38<sup>high</sup> immature Bregs increase reactively to suppress disease activity, which is consistent with the hypothesis that CD19<sup>+</sup>CD24<sup>high</sup>CD27<sup>+</sup> B10 cells are involved in the development of type 1 AIP (Sumimoto et al., 2014; Uchida and Okazaki, 2017).

Taking the above observations into account, Uchida and Okazaki proposed that the decreased numbers of naïve Tregs and CD19<sup>+</sup>CD24<sup>high</sup>CD27<sup>+</sup> Bregs factored prominently in the induction of IgG4-RD. Moreover, effector/inducible Tregs and CD19<sup>+</sup>CD24<sup>+</sup>CD38<sup>high</sup> B10 cells increased in a reactive manner. Since Th2 immune responses promote disease progression, the elevated numbers of inducible Tregs and CD19<sup>+</sup>CD24<sup>+</sup>CD38<sup>high</sup> B10 cells may contribute to the development and progress of IgG4-RD as well. Both innate and adaptive immunity are believed to affect the production of IgG4 and fibrosis development. In adaptive immunity, ICOS + Tregs may regulate IgG4 production via secretion of IL-10. In innate immunity, basophils and monocytes are regulated via BAFF using the TLR and NLR signaling pathways. Fibrosis may in turn be modulated by TGF-β secreted from ICOS - Tregs and M2 macrophages to suppress inflammation. M2 macrophages are also known to accelerate the Th2 immune response (Uchida and Okazaki, 2017).

## GENETICS

As autoimmune diseases are multifactorial, their pathogenesis involves a complex interplay of multiple genetic and environmental factors. Although identifying responsibility genes is complex, two approaches, the candidate-gene approach by association studies and genome-wide association testing of the large numbers of single nucleotide polymorphisms (SNPs), have been employed to elucidate the genetic factors that influence disease susceptibility (Amos et al., 2011). In the candidate-gene approach, an association study is carried out using polymorphic markers (SNPs and microsatellites) that reside around or within biologically functional genes presumably involved in disease development. When the fundamental pathophysiology of a disease is unknown, however, genome-wide studies are better suited to hunt down causative genes (Ota et al., 2017).

### Association Studies Using Polymorphic Markers in Candidate Genes

The HLA serotypes DR4 and DQ4 are the markers most frequently associated with AIP among the major histocompatibility complex class I and class II molecules. Among the DR4 and DQ4 subtypes, the frequencies of *DRB1\*0405* and *DQB1\*0401* are significantly higher in AIP patients. In the Japanese population, *DRB1\*0405* is known to be in strong linkage disequilibrium with *DQB1\*0401*, resulting in the *DRB1\*0405-DQB1\*0401* haplotype. This haplotype is specifically associated with susceptibility to AIP and may play a functional role in antigen presentation and induction of an autoimmune response (Kawa et al., 2002). Moreover, *HLA-DR\*0405* transgenic mice displayed a high prevalence of AIP after sublethal irradiation and adoptive transfer of CD90+ T cells (Freitag et al., 2010). In a case-control study, using microsatellite markers distributed throughout the HLA region, we mapped AIP susceptibility to two areas of the telomeric region of HLA adjacent to the C3-2-11 marker and to HLA-DRB1-DQB1. The region adjacent to C3-2-11 contains the ATP-binding cassette subfamily F (*ABCF1*) gene that is regulated by TNF-α, a major cytokine involved in inflammatory and autoimmune reactions (Ota et al., 2007).

Polymorphisms in Fc receptor-like 3 (*FCRL*) genes alter the binding affinity of nuclear factor κB and regulate *FCRL3* expression. An analysis of genotype frequencies among *FCRL3-110* polymorphisms revealed a significant association between the -110A/A genotype and AIP; serum IgG4 concentrations were significantly and positively correlated with the number of susceptibility alleles (Umemura et al., 2006).

The cytotoxic T lymphocyte antigen (*CTLA-4*) gene product is an inhibitory receptor expressed on the surface of activated memory T cells and CD4+CD25+ Tregs to largely act as a negative regulator of T-cell responses. We observed that the frequency of the +6230G/G genotype was significantly higher in Japanese patients with AIP than in those without the disease and that the +49A/A and +6230A/A genotypes were associated with an

enhanced risk of AIP relapse (Umemura et al., 2008). The *CTLA-4* 49A polymorphism and the -318C/ + 49A/CT60G haplotype have also been linked to AIP in a Chinese population (Chang et al., 2007).

## Association Studies Using Genome-Wide Polymorphic Markers

An association analysis involving 400 microsatellite markers with an average spacing of 10.8 cm revealed an association of AIP with 7 SNPs within the 20 kb region around potassium voltage-gated channel, shaker-related subfamily, member 3 (*KCNA3*). Further analysis of *KCNA3* by SNP genotyping revealed four SNPs that were significantly related to AIP susceptibility (Ota et al., 2011). *KCNA3* is involved in the immunomodulation of auto-reactive effector T cell and memory T cell-mediated autoimmune diseases.

Several genes were implicated in the development of lachrymal/salivary gland lesions in AIP by genome wide association study (GWAS) using the Gene Chip Human Mapping 500K Array Set (Affymetrix, CA) and fine-tuned mapping of specific SNPs (Oguchi et al., 2016).

## ANIMAL MODELS

Several experimental models of AIP have been reported to date (Haruta et al., 2012). Inflammation was found in the pancreas of immunized mice and in all animals receiving whole spleen cells or CD4+ cells. CA II- and lactoferrin (LF)-immunized mice developed apoptotic duct cells and acinar cells, respectively (Uchida et al., 2002). The adoptive transfer of amylase-specific CD4+ T cells in rats also resulted in pancreatitis characterized by mononuclear cell infiltration and destruction of lobular tissue (Davidson et al., 2005). As for microorganism-related induction groups, virus-induced AIP models, such as C57BL/6 mice infected with the murine leukemia retrovirus LP-BM5, exhibited histological findings similar to those in human AIP (Watanabe et al., 2003). The spontaneous development of pancreatitis via an autoimmune mechanism in MRL/Mp mice was accelerated by the administration of polyinosinic:polycytidylic acid, a synthetic double-stranded RNA, and TLR 3 ligand (Qu et al., 2002; Soga et al., 2009; Asada et al., 2010; Nishio et al., 2011). Another animal model for AIP was developed by exposing C57BL/6 mice to heat-killed *Escherichia coli*, which produced the marked cellular infiltration with fibrosis in the exocrine pancreas and salivary glands (Haruta et al., 2010). One representative antigen reacting with the serum of *E. coli*-inoculated mice was identified as FliC (Yanagisawa et al., 2014). These findings indicate that avirulent bacteria and other silently infiltrating microorganisms can engage pathogen-associated molecular patterns and thereby activate the innate immune system so as to elicit a host immune response to the target antigen by molecular mimicry and lead to AIP (Oldstone, 1998; Haruta et al., 2010; Yanagisawa et al., 2014).

## DIAGNOSTIC PROCEDURES

Specific diagnostic criteria for individual organs involved in IgG4-RD have been established, including those for AIP (Pearson et al., 2003; Okazaki et al., 2006; Kim et al., 2006; Chari et al., 2006; Otsuki et al., 2008; Shimosegawa et al., 2011), IgG4-related sialadenitis and dacryoadenitis (Masaki et al., 2010), IgG4-related kidney disease (Kawano et al., 2011), IgG4-related SC (Ohara et al., 2012), and IgG4-related respiratory disease (Matsui et al., 2016). The framework of these criteria is based largely on that of AIP to include combinations of the following: (1) characteristic radiological findings, (2) elevation of serum IgG4 levels, (3) histopathological findings of abundant IgG4-positive plasma cell and lymphocyte infiltration, storiform fibrosis, and/or obliterative phlebitis, (4) association with other IgG4-RDs, and (5) a favorable response to steroids. The diagnostic criteria for AIP are not suitable for identifying other involved organs (Stone et al., 2012a), which requires specialized training often unknown to general clinicians.

The comprehensive diagnostic criteria for IgG4-RD including the involvement of various organs are intended for the practical use of general physicians and nonspecialists (Umehara et al., 2012b). Although many patients with IgG4-RD have lesions, either synchronously or metachronously, in several organs and the pathological features of each organ differ, a consensus has been reached on two diagnostic criteria for a definite diagnosis of IgG4-RD: (1) serum IgG4 concentration >135 mg/dL and (2) >40% of IgG+ plasma cells being IgG4+ and >10 IgG4+ cells per high-power field of biopsy sample. It is also important to differentiate IgG4-RD from malignant tumors affecting individual organs (cancer or lymphoma) and mimicking conditions by additional

histopathological examination. As it can be difficult to obtain tissue samples from certain organs, such as the pancreas, organ-specific diagnostic criteria are available for such lesions in the form of diagnostic algorithms. Together, the comprehensive diagnostic criteria combined with organ-specific diagnostic criteria and algorithms have remarkably increased detection sensitivity (Umehara et al., 2012b). For accurate diagnosis of the overall condition, the international consensus has been achieved for the nomenclature, management, treatment, and pathology of IgG4-RD (Stone et al., 2012a; Khosroshahi et al., 2015; Deshpande et al., 2012).

## TREATMENT

Corticosteroid treatment is regarded as the therapeutic standard for patients with AIP (Ito et al., 2007; Okazaki et al., 2009). According to the international guidance statement on the management and treatment of IgG4-RD, glucocorticoids are the first-line agent for remission induction in all patients with active, untreated IgG4-RD unless contraindications are present. Following a successful course of induction therapy, certain patients benefit from maintenance therapy (Khosroshahi et al., 2015).

A set regimen for corticosteroid treatment has been established for AIP. Aggressive intervention is advocated when vital organs are involved or serious organ dysfunction or failure is likely. However, not all forms of IgG4-RD require immediate treatment but simple observation is justified in some cases (Stone et al., 2012b). Most patients with obstructive jaundice, diffuse enlargement of the pancreas, associated extrapancreatic involvement, and abdominal pain are good candidates for steroid therapy, although spontaneous remission has been observed in patients with low disease activity (Kamisawa et al., 2009). Pancreatic tissue samples obtained by needle biopsy after corticosteroid therapy have shown marked histological improvement (Song et al., 2005; Ko et al., 2010). Some patients with high disease activity may continue maintenance therapy for as many as 3 years.

Azathioprine, mycophenolate mofetil, 6-mercaptopurine, methotrexate, tacrolimus, and cyclophosphamide have all been adopted as steroid-sparing agents for IgG4-RD (Ghazale et al., 2008; Raina et al., 2009; Hart et al., 2013). However, the efficacies of these agents have not been evaluated in prospective trials, and there is little evidence to support the notion that conventional steroid-sparing drugs are effective (Hart et al., 2013).

B-cell depletion with rituximab (RTX) was effective for IgG4-RD, even in patients refractory to conventional steroid-sparing agents (Topazian et al., 2008; Khosroshahi et al., 2010, 2015; Hart et al., 2013). Hart et al. (2013) reported an 83% rate of complete remission following RTX therapy in a group of patients with AIP whose disease had been resistant to, or who had contraindications for, steroids or conventional steroid-sparing agents. CD19<sup>+</sup>CD27<sup>+</sup>CD20<sup>-</sup>CD38<sup>high</sup> plasmablasts, which are largely IgG4<sup>+</sup>, play an important role in IgG4-RD disease activity. The number of CD19<sup>+</sup>CD27<sup>+</sup>CD38<sup>high</sup> plasmablasts decreased sharply after RTX treatment, presumably due to depletion of CD20<sup>+</sup> precursors since CD19<sup>+</sup>CD27<sup>+</sup>CD38<sup>high</sup> plasmablasts did not express CD20 (Mattoo et al., 2014; Wallace et al., 2015; Lanzillotta et al., 2017; Uchida and Okazaki, 2017).

## PERSPECTIVES

The intense study of AIP has opened the door to the new disease concept of IgG4-RD, an intriguing disorder presenting features never before encountered. Researchers need to clarify the following issues in IgG4-RD: (1) pathogenesis based on abnormal immune responses and genetics, (2) the role of IgG4, (3) the detailed characteristics and real global prevalence, (4) a rational treatment strategy, and (5) long-term outcome with respect to structure and function and the predisposition to malignancy. Many affected patients worldwide have been overlooked or categorized as having other diseases. Expanding the awareness of IgG4-RD will result in enhanced diagnosis and the scope for larger international studies in the future.

## INTRODUCTION

Autoimmune bullous diseases are rare disorders affecting skin and mucous membranes. These diseases are mediated by pathogenic autoantibodies directed against keratinocyte adhesion molecules (Diaz and Giudice, 2000). In the epidermis, neighboring keratinocytes adhere to each other through organelles known as desmosomes, whereas dermal–epidermal junction adhesion is mediated by hemidesmosomes. The majority of antigens

**FIGURE 60.1** Diagram of the desmosome and the hemidesmosome.

recognized by these autoantibodies are desmosomal and hemidesmosomal transmembrane glycoproteins involved in epidermal cell–cell and epidermal–dermal adherence.

The desmosome contains two parallel intracellular plaques, which are located just beneath the cell membranes of neighboring cells (Fig. 60.1). Transmembrane glycoproteins emerge from the desmosomal plaques and meet in the narrow extracellular space shared by the two cells, constituting the desmosomal core. The desmosomal plaques are composed of plakin family proteins and serve as insertion sites for intracellular keratins, whereas the core is composed of transmembrane calcium-dependent cell adhesion molecules known as desmosomal cadherins. The desmosomal cadherins include desmogleins (Dsgs)1–4 and desmocollins (Dscs)1–3 (Getsios et al., 2004), the isoforms of which vary in expression throughout the epidermis and in different squamous epithelial tissues. For example, in the skin Dsg1 is expressed throughout the epidermis with predominance in the upper layers of this tissue, whereas Dsg3 is expressed mainly in the suprabasal layers of the epidermis.

The hemidesmosomes, located on the dermal pole of the epidermal basal keratinocytes, also contain an intracellular plaque and an extracellular core structure (Fig. 60.1). The hemidesmosomal plaque, linked to the keratin network, contains the intracellular proteins BP230 and plectin (forming the inner plaque) and the transmembrane proteins BP180,  $\alpha 6\beta 4$  integrin (forming the outer plaque). The extracellular space termed the lamina lucida contains the ecto-domains of BP180,  $\alpha 6\beta 4$  integrin as well as laminin 5. The lamina lucida (corresponding to the desmosomal core) separates the basal keratinocytes from the underlying lamina densa (composed of collagen IV) (Diaz and Giudice, 2000). The sublamina dense region contains other matrix molecules and the anchoring fibrils (collagen VII).

The pemphigus group includes diseases that are characterized by autoantibodies against desmosomal cadherins (Dsg and Dsc) (Anhalt and Diaz, 2001; Beutner and Jordon, 1964), and intraepidermal cell–cell detachment known as acantholysis (Civatte, 1943). There are two classic forms of pemphigus: pemphigus vulgaris (PV) and pemphigus foliaceus (PF). PV is characterized by suprabasilar acantholysis and anti-Dsg3 IgG autoantibodies, whereas PF is characterized by subcorneal acantholysis and anti-Dsg1 IgG autoantibodies. Other less common forms of pemphigus include paraneoplastic pemphigus (PNP), drug-induced pemphigus, and IgA pemphigus (Table 60.1).

The pemphigoid group includes bullous pemphigoid (BP) and other rare subepidermal autoimmune blistering diseases (Table 60.1). The pemphigoid group is characterized by autoantibodies against hemidesmosomal proteins and separation of the epidermis from the dermis. BP is the most common autoimmune bullous disease and is the prototypic subepidermal blistering disorder (Lever, 1965). BP is characterized by subepidermal blisters and autoantibodies against the hemidesmosomal proteins BP180 and BP230 (Labib et al., 1986; Mutambo et al., 1985; Stanley et al., 1981). Other subepidermal blistering diseases such as cicatricial pemphigoid (CP), herpes

Dsg, Desmoglein; BP, bullous pemphigoid.

gestationis (HG), and linear IgA dermatosis (LAD) exhibit distinctive clinical, histological, and immunologic features, yet share a humoral autoimmune response to BP180 and occasionally other antigens. The rest of acquired subepidermal blistering diseases show autoantibody responses to the structural molecules of the dermal extracellular matrix. They include epidermolysis bullosa acquisita (EBA) with a target antigen of collagen VII and dermatitis herpetiformis (DH) with a target antigen of epidermal transglutaminase.

While the autoantibody response in most of these autoimmune skin diseases belongs to the IgG class, there are exceptions. For example, IgE autoantibodies have been detected in endemic PF and BP, and IgA is found in IgA pemphigus, LAD, and DH.

In this chapter we shall review the current clinical, histological, and immunological features of the most common forms of autoimmune bullous diseases (PV, PF, and BP) (Fig. 60.2) and briefly discuss other less common forms of pemphigus and subepidermal bullous diseases.

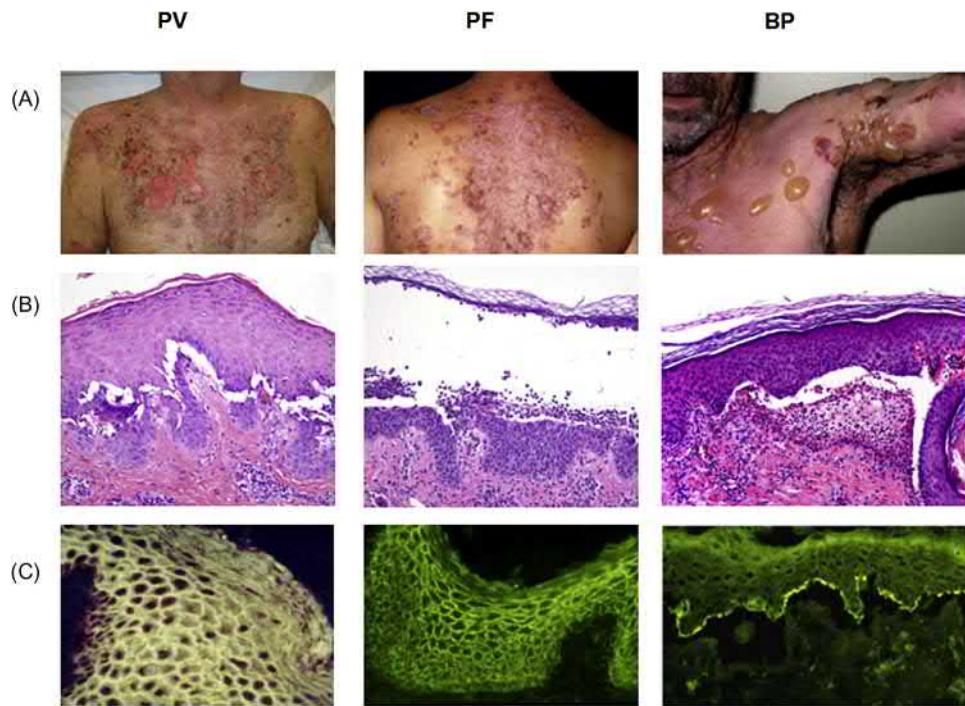

## PEMPHIGUS VULGARIS

### Clinical, Pathologic, and Epidemiologic Features

PV is the most severe and common form of pemphigus (Lever, 1965). The disease usually begins with painful erosions of the oral mucosa (mucosal PV), which may last for several months. Oral lesions are typically followed by involvement of the skin as well (mucocutaneous PV) where the disease produces flaccid blisters and erosions. Other squamous epithelial tissues (e.g., nasal, esophageal, larynx, pharynx, conjunctival, vaginal, and rectal) may also be involved.

Histologically, the lesions of PV show intraepidermal separation just above the basal cell layer of the epidermis with acantholysis, or rounding up of individual cells (Fig. 60.2, left panel). The basal cells remain attached to the dermis but laterally detached from each other producing the histological sign known as “row of tombstones” (Civatte, 1943). Inflammatory infiltration is usually mild and consists of a variable superficial and perivasular mixed infiltrate as well as lymphocytes, eosinophils, and occasionally neutrophils in the epidermis and blister cavity.

The incidence of PV ranges but is on average 1–7 new cases per million persons per year, with a mean age of onset of 50–60 years of age (Chams-Davatchi et al., 2005; Langan et al., 2008; Alpsoy et al., 2015; Shah et al., 2015). Although found in all ethnic and racial groups, the disease is more prevalent in patients harboring certain

The clinical (A), histological (B), and immunofluorescent (C) features of PV (left panel), PF (middle panel), and BP (right panel) are shown. *BP*, Bullous pemphigoid; *PF*, pemphigus foliaceus; *PV*, pemphigus vulgaris.

human leukocyte antigen (HLA) class II alleles (see the “Genetic features” subsection of “Pemphigus vulgaris” section).

## Autoimmune Features

### Autoantibodies

The serum of PV patients contains IgG autoantibodies that stain the epidermal intercellular spaces (ICS) by indirect immunofluorescence (IF) producing titers that roughly correlate with disease activity (Beutner and Jordon, 1964). Direct IF of perilesional skin reveals IgG bound to keratinocyte cell surfaces. These autoantibodies are predominantly of the IgG4 subclass (Jones et al., 1988; Futei et al., 2001). Interestingly, nonpathogenic autoantibodies have been detected in the first-degree relatives of PV patients, which are mainly IgG1 subclass (Bhol et al., 1995; Kricheli et al., 2000; Torzecka et al., 2007).

The target antigen recognized by PV autoantibodies is Dsg3, a 130-kDa desmosomal core glycoprotein (Amagai et al., 1991). While patients with limited mucosal lesions have autoantibodies to Dsg3 exclusively, patients who develop skin lesions possess autoantibodies against Dsg1 as well (Ding et al., 1997). It is well established that about 60% of the PV patients have autoantibodies against Dsg3 and Dsg1.

Dsg1 and Dsg3 belong to the cadherin family of calcium-dependent cell-adhesion molecules and share high-sequence homology (Getsios et al., 2004). The ectodomain of these glycoproteins is composed of four cadherin repeats (EC1-4) and a variable extracellular anchor (EC5). The six putative calcium-binding motifs of the ectodomain are involved in maintaining the conformation and adhesive function of Dsg3. A putative adhesion site (amino acid sequence RAL) is located on the EC1 domain. The ectodomain of Dsg3 has been expressed in the baculovirus system and can be used to adsorb pathogenic autoantibodies from PV serum. These Dsg3 affinity-purified autoantibodies are sufficient to induce suprabasilar acantholysis when passively transferred to neonatal mice (Amagai et al., 1992; Ding et al., 1999). These pathogenic autoantibodies recognize conformational and calcium-dependent epitopes located on the EC1 and EC2 domains of Dsg3.

([Sekiguchi et al., 2001](#)), which are believed to be involved in the *trans* and *cis* adhesive functions of the molecule ([Di Zenzo et al., 2012](#)).

The autoantibody response in PV is thought to be oligoclonal in nature. Indeed, studies utilizing antibody phage display indicate that a limited set of anti-Dsg3 B-cell clones persist in patients over time and through relapsing disease ([Hammers et al., 2015](#)).

### **T-Cell Activation**

Induction of anti-Dsg3 autoantibodies is T-cell dependent as supported by several lines of evidence. In vitro anti-Dsg3 antibody production by autoreactive B cells is abolished upon depletion of CD4<sup>+</sup> T cells ([Nishifuji et al., 2000](#)). In addition, T-cell clones derived from PV patients proliferate when stimulated with various Dsg3 peptides ([Lin et al., 1997; Veldman et al., 2004; Wucherpfennig et al., 1995](#)). The HLA restrictions and cytokine profiles of the T-cell clones have been characterized. CD4<sup>+</sup> T cells from PV patients responsive to three polypeptides (residues 145–192, 240–303, and 570–614) were restricted to HLA-DR and exhibit a Th2-like cytokine profile ([Lin et al., 1997](#)). These studies suggest that Th2 cells are relevant in the induction of Dsg3-specific autoantibodies. Not only autoreactive Th2 cells, but also Th1 cells are found in PV patients ([Veldman et al., 2004](#)). Both Th1 and Th2 cells may be involved in the production of PV autoantibodies, since the ratio of Dsg3-specific Th1/Th2 cells in PV patients correlated well with the serum autoantibody titers of the patients. In addition, recent studies have shown that an imbalance of Dsg3-specific type 1 regulatory T cells and Th2 cells may be critical for the loss of tolerance against Dsg3 in PV ([Veldman et al., 2009](#)).

Interestingly, Dsg3-specific T cells are not only detected in PV patients, but also detected in healthy individuals who carry PV susceptible HLA alleles ([Veldman et al., 2004](#)). However, in contrast to PV patients, Dsg3-responsive T-cell clones from the healthy donors exhibit exclusively Th1 cytokine profiles.

Recent studies have shown that Dsg3-specific CD4<sup>+</sup> T cells can induce PV in mice, further underscoring the importance of T cells in initiation of disease ([Takahashi et al., 2011](#)).

### **Genetic Features**

HLA alleles may play an important role in the development and progression of PV ([Delgado et al., 1997; Sinha et al., 1988; Sinha, 2011](#)). Two haplotypes, HLA-DR4 and HLA-DR6, are strongly associated with PV in different ethnic groups ([Todd et al., 1988](#)). In the non-Jewish population, DRB1\*0402 and DQB1\*0503 are the two candidate alleles most likely associated with disease susceptibility, whereas in the Ashkenazi Jewish population DRB1\*0402 seems to be singularly associated with PV ([Lee et al., 2006; Sinha, 2011](#)).

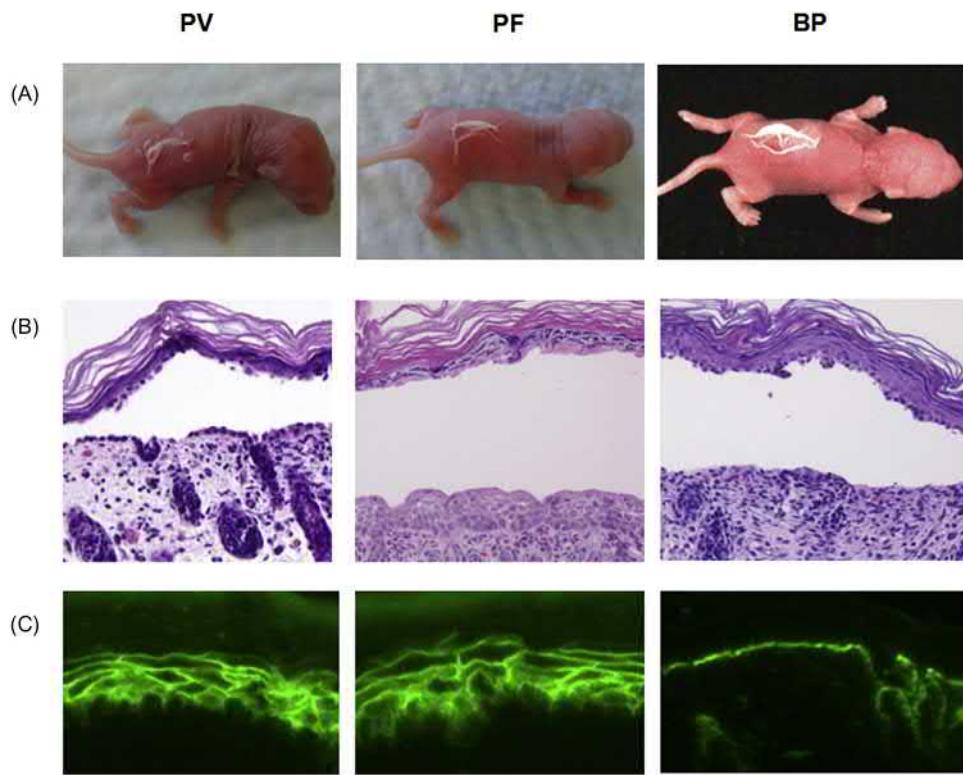

### **In Vivo and In Vitro Models**

#### ***In Vitro Models***

Normal human keratinocytes or keratinocyte cell lines cultured to a confluent monolayer have been used in pathogenicity assays for many years. Sera, purified IgG, or monoclonal anti-Dsg3 antibodies are added to the keratinocyte monolayer and allowed to incubate for a period of time. Dispase treatment releases the monolayer from the culture dish, and the keratinocyte sheets are subjected to mechanical stress. Pathogenic autoantibodies induce the monolayer to dissociate leading to fragmented cell sheets ([Ishii et al., 2005](#)). Human skin explants can also be used in vitro for testing. These assays are frequently used for the testing pathogenicity of monoclonal antibodies, which are often available in limited quantities ([Payne et al., 2005; Yamagami et al., 2010](#)).

#### ***Autoantibody Passive Transfer Model***

As described in the previous sections, neonatal mice have been used for passive transfer experiments of PV IgG ([Anhalt et al., 1982](#)). The small size of the animals and the lack of hair allow the use of smaller amounts of IgG and the lesions are easily visible on the hairless skin. PV IgG transferred to neonatal mice reproduces the clinical, histological, and immunological features of human disease within the first 24 hours postinjection ([Fig. 60.3, left panel](#)). Similarly, IgG from patients with mucosal PV can be passively transferred to the buccal mucosa of adult mice. Interestingly, mucosal PV IgG only induce blister formation in human Dsg3 transgenic mice (not WT mice), suggesting that the pathogenic epitopes targeted in mucosal PV are unique to human Dsg3 ([Culton et al., 2015](#)). The disease induced in these passive transfer animal models is dose dependent and correlates with the titers of PV autoantibodies detected in the sera of the injected mice.

**FIGURE 60.3** Clinical, histologic, and immunofluorescent features of the murine models of pemphigus vulgaris, pemphigus foliaceus, and bullous pemphigoid. The clinical (A), histological (B), and immunofluorescent (C) features of PV (left panel), PF (middle panel), and BP (right panel) murine models are shown. The animals passively transferred with human IgG (and IgG4) develop skin lesions (A), which histologically (B) are similar to the human disease. The human autoantibodies are detected bound to lesional skin (C) and circulating in the mouse serum. *BP*, Bullous pemphigoid; *PF*, pemphigus foliaceus; *PV*, pemphigus vulgaris.

### Murine Models of Pemphigus Vulgaris

The efforts to induce PV in adult mice by conventional active immunization with human Dsg3 have been largely unsuccessful. While the immunized animals produce anti-Dsg3 antibodies that were able to induce skin blisters when passively transferred into neonatal mice, the animals themselves do not develop disease (Fan et al., 1999). Amagai et al. (2000) developed an active mouse model of PV using a novel strategy to overcome the barrier of self-tolerance. Dsg3 knockout mice (Koch et al., 1997) were immunized with murine Dsg3, and splenocytes were subsequently harvested and adoptively transferred from these immunized animals to immunodeficient Rag-2<sup>-/-</sup> mice which express Dsg3 in their epidermis. The recipient mice produce anti-Dsg3 antibodies and show mucosal suprabasilar acantholysis histologically. Rag-2<sup>-/-</sup> mice that receive naïve Dsg3 knockout splenocytes also produce anti-Dsg3 IgG and develop the PV phenotype (Aoki-Ota et al., 2004). This active disease model has allowed for the characterization of anti-Dsg3 antibodies and Dsg3 reactive CD4<sup>+</sup> T-cell clones (Tsunoda et al., 2003; Takahashi et al., 2008).

Immunization of humanized HLA DRB1\*0402 transgenic mice with human Dsg3 induces human Dsg3-specific autoantibodies. Sera from these mice induce loss of adhesion in human keratinocyte dissociation assays, suggesting autoantibody pathogenicity. Although these antihuman Dsg3 antibodies are detected in the sera of immunized mice, they show very little reactivity with murine Dsg3 and, thus, do not induce the PV phenotype in these animals. This model has provided evidence that the HLA-DRB1\*0402 restricted T-cell recognition of human Dsg3 epitopes leads to activation of anti-Dsg3 B cells and subsequent anti-Dsg3 antibody production but also highlights the differences between human and murine Dsg3 in terms of both B and T-cell dominant epitopes (Eming et al., 2014).

## Pathologic Effector Mechanisms

### ***Pathogenic Role of Autoantibodies***

Several studies demonstrate the correlation of PV autoantibody titers and disease extent and activity. In vitro studies also show that PV IgG can induce acantholysis in skin organ cultures and cell detachment in primary keratinocyte cell cultures. The in vivo passive transfer studies demonstrate that PV IgG is able to faithfully reproduce the disease in neonatal mice and attribute a pathogenic role for PV autoantibodies (Fig. 60.3, left panel) (Anhalt et al., 1982). These pioneer studies were extended to demonstrate that PV autoantibodies are able to induce disease by passive transfer in a process that is independent of complement or plasminogen activator (Anhalt et al., 1986; Mahoney et al., 1999; Mascaro et al., 1997).

While it is well established that PV IgG cause disease, the current research is addressing the molecular mechanisms of how PV autoantibodies trigger acantholysis and cell detachment. A long-standing theory for autoantibody-mediated pathogenesis is the steric hindrance theory, in which binding of the autoantibodies to Dsg3 directly impairs the adhesive ability of the molecules, thereby causing cell separation (Diaz and Marcelo, 1978). PV autoantibodies bind Dsg3 on the keratinocyte cell surfaces forming clusters of that are internalized and fused with lysosomes (Calkins et al., 2006; Mao et al., 2009) and subsequent Dsg3 degradation. Thus, it seems that PV IgG may alter the assembly/disassembly of desmosomes by impairing the dynamics of the soluble and insoluble pools of Dsg3, which, in turn, may lead to acantholysis (Jennings et al., 2011).

Substantial evidence is accumulating in support of a complimentary hypothesis in which binding of PV autoantibodies to Dsg3 leads to that activation of intracellular signaling pathways that may augment acantholysis. Several signaling pathways have been shown to be activated upon autoantibody binding to Dsg3 including p38MAPK/HSP27 (Jolly et al., 2010; Berkowitz et al., 2008a; Berkowitz et al., 2008b), epidermal growth factor receptor (EGFR), Rho family GTPase (Waschke et al., 2006), c-myc (Williamson et al., 2006), and caspases (Li et al., 2009; Luyet et al., 2015). While modulation of certain signaling pathways can prevent autoantibody-induced acantholysis, the induction of individual signaling pathways is not sufficient to cause disease.

## Autoantibodies as Potential Immunologic Markers

As PV autoantibodies are the direct effectors of keratinocyte dissociation and blister formation, anti-Dsg3 and anti-Dsg1 autoantibodies are not merely immunologic markers of PV but are critical for the diagnosis.

---

## PEMPHIGUS FOLIACEUS

---

### Clinical, Pathologic, and Epidemiologic features

Unlike PV, PF affects skin only and the disease is manifested by superficial blisters and erosions, which may lead to crusting and formation of keratotic plaques (Fig. 60.2, middle panel). The skin lesions initially involve the central areas of the face, scalp, the mid chest, and the upper back. From these areas, the disease may spread to involve the entire body, occasionally producing an exfoliative erythroderma. Histological examination of these lesions reveals subcorneal vesicles and acantholysis, predominantly in the upper layers of the stratum spinosum (Lever, 1965).

The classic form of PF is seen sporadically in different parts of the world with an incidence of less than one case per million persons per year. A second form of PF is endemic and originally described in certain states of Brazil with the name of *fogo selvagem* (FS) and a prevalence of 1%–3% (Diaz et al., 1989). Endemic forms of PF have also been reported in Colombia and Tunisia. Epidemiological studies suggest environmental triggers for FS development (Aoki et al., 2004).

## Autoimmune Features

### ***Autoantibodies***

Similar to PV, PF patients are also characterized by antiepidermal ICS autoantibodies, predominantly of the IgG4 subclass (Rock et al., 1989). These autoantibodies are detected bound to diseased epidermis and circulating in the serum of the patients, with titers that roughly correlate with disease extent and activity.

Dsg1, expressed mostly in the superficial layers of the epidermis, is the target antigen of PF autoantibodies. Affinity-purified anti-Dsg1 antibodies from PF serum are able to induce disease in neonatal mice (Amagai et al., 1995). The majority of PF autoantibodies recognize conformational and calcium-dependent epitopes residing in the NH<sub>2</sub>-terminal amino acid 1-161 of Dsg1 (Sekiguchi et al., 2001). In the preclinical stage of FS, during disease-remission, and in some normal individuals, the anti-Dsg1 autoantibodies recognize the EC5 domain only. On the contrary, FS anti-Dsg1 autoantibodies from patients with active disease or during disease relapses recognize the EC1/EC2 domains (Li et al., 2003). Although the majority of PF/FS autoantibodies are of IgG4 subclass, it appears that epitope specificity, rather than the subclass of IgG, is the driver of the pathogenicity of the autoantibodies (Li et al., 2002). Considering these findings, we hypothesize that an environmental agent(s) cross-reacts with the EC5 domain of Dsg1 and triggers an initial nonpathogenic anti-EC5 autoimmune response (Diaz et al., 2004). In genetically predisposed individuals, the autoimmune response may undergo intramolecular epitope spreading toward pathogenic epitopes on the EC1/EC2 domains of Dsg1, which leads to disease onset (see the “Environmental factors involved in fogo selvagem” section).

### T-Cell Activation

It has been demonstrated that CD4<sup>+</sup> T-cell lines and clones derived from peripheral blood of FS patients show a proliferative response when incubated with the Dsg1 ectodomain (Lin et al., 2000a). The stimulation of these CD4<sup>+</sup> T cells is HLA-DR restricted. Moreover, these cells secrete Th2-like cytokines.

### Genetic Features

HLA alleles strongly associated with FS are DRB1\*0404, \*1406, \*1402 (relative risk = 14), and \*0102 (relative risk = 7.3) (Moraes et al., 1997). A common epitope of LLEQRRAA, the residues 67–74 of the third hypervariable region of the DRB1 molecule, is shared by these susceptibility alleles. Similarly, a strong association of DRB1\*0102 and DRB1\*0404 is also found in nonendemic PF patients in France (Loiseau et al., 2000). Interestingly, two susceptible alleles in PV, the DRB1\*1401 and DQB1\*0503, have been also reported with high frequencies in Italian and Japanese PF patients (Lombardi et al., 1999; Miyagawa et al., 1999).

### In Vivo and In Vitro Models

Keratinocyte cell culture and human skin explants have been utilized for in vitro testing PF autoantibody pathogenicity as described for PV. The classic animal model of PF was developed by passively transferring IgG from patients into neonatal mice (Roscoe et al., 1985). The animals develop skin blisters, which show the typical histological features of the human disease, that is, subcorneal vesicles (Fig. 60.3, middle panel). The extent of the disease correlates well with the indirect IF titers of human autoantibodies detected in the mouse. These animals develop classic subcorneal acantholysis (Futamura et al., 1989). The disease is complement-independent and can be induced by monovalent PF IgG fragments as well (Espana et al., 1997). Despite the availability of recombinant human and murine Dsg1, the studies on inducing disease by active immunization have been unsuccessful.

### Pathologic Effector Mechanisms

The IgG4 autoantibodies are pathogenic as demonstrated by passive transfer studies (Fig. 60.3, middle panel) (Rock et al., 1989). Activation of the complement cascade and plasminogen activator is not required for the induction of acantholysis by these autoantibodies in the mouse model (Espana et al., 1997; Mahoney et al., 1999).

### Autoantibodies as Potential Immunologic Markers

The importance of anti-Dsg1 autoantibodies as markers of disease has been illustrated in the FS population, where IgG4 anti-Dsg1 autoantibodies serve as a novel classifier/predictor that identifies FS patients with high sensitivity and specificity (92% and 97%, respectively). In an FS prone population with an incidence of 3%, detection of IgG4 anti-Dsg1 autoantibodies has a positive predictive value of 49% and a negative predictive value of 99.7% (Qaqish et al., 2009).

## Environmental Factors Involved in Fogo Selvagem

A remarkable characteristic of FS is its epidemiology. Several independent lines of evidence indicate that FS is precipitated by exposure to an environmental factor(s) (Aoki et al., 2004). Anti-Dsg1 autoantibodies are detected in 55% of the normal individuals living in an area exhibiting a high prevalence (3.4%) of FS (Warren et al., 2000). Remarkably, anti-Dsg1 autoantibodies are also detected in FS patients from one to several years before the clinical onset of disease (Qaqish et al., 2009). These preclinical antibodies are mixture of IgG1 and IgG4 subclasses and recognize the EC5 domain of Dsg1 (Li et al., 2003; Warren et al., 2003).

Early case-control epidemiological studies point to a hematophagous insects as a prime etiological agent of FS (Aoki et al., 2004). For example, anti-Dsg1 EC5 antibodies have been detected in the sera of patients with onchocerciasis, leishmaniasis, and Chagas disease, though the patients exhibit no skin lesions of FS (Diaz et al., 2004). Recent studies have revealed that FS patients harbor anti-Dsg1 IgG4 and IgE antibodies that cross-react with LJM11, a sand fly salivary gland antigen (Qian et al., 2012, 2015, 2016b). It is hypothesized that LJM11 induces an anti-Dsg1 autoantibody response through cross-reactivity/molecular mimicry. Genetic analysis confirms that these cross-reactive antibodies evolve from the same naïve B-cell clones. The cross-reactive antibodies may be pathogenic or may evolve via epitope spreading to a pathogenic autoantibody response in genetically susceptible individuals leading to FS disease onset (Diaz et al., 2008; Qian et al., 2011, 2016a).

## OTHER TYPES OF PEMPHIGUS

### Paraneoplastic Pemphigus

PNP is a rare, severe mucocutaneous disease that runs a usually lethal course in patients with underlying lymphoproliferative malignancy, that is, non-Hodgkin's lymphoma, chronic lymphocytic leukemia, and Castleman's diseases (Anhalt, 2004; Anhalt et al., 1990). Patients exhibit severe stomatitis that is often hemorrhagic and skin lesions that may be vesiculobullous in some patients or show erythema multiforme or lichen planus features in other patients. Approximately 30% of the PNP patients will also develop bronchiolitis obliterans with severe respiratory insufficiency.

Histological examination of the skin lesions reveals keratinocyte necrosis, lichenoid interface dermatitis, basal cell vacuolization, and suprabasilar acantholysis. Direct IF shows deposition of IgG and C3 in the epidermal ICS (as in pemphigus) but also along the basement membrane zone (BMZ). The unique and characteristic immunological finding in PNP patients is the polyclonal autoantibody response against structural antigens of the desmosome and hemidesmosome. The antigens that have been characterized besides Dsg3 and Dsg1 are members of the plakin family of proteins that includes desmoplakin I and II, BP230, envoplakin, periplakin, and plectin. Removal of anti-Dsg3 autoantibodies from PNP sera abrogates the pathogenicity of the IgG fraction (Amagai et al., 1998). Affinity-purified anti-Dsg3 antibodies and monoclonal anti-Dsg3 antibodies derived from PNP patients (Saleh et al., 2012) are able to induce skin lesions in neonatal mice further confirming anti-Dsg3 pathogenicity. The relevance of the antiplakin antibodies is not known. However, autoantibody-mediated disease explains only part of the complex epithelial injury found in these patients. Other mechanisms of tissue-injury are those mediated by cytotoxic T cells.

It has been proposed that the autoantibody response in PNP is primarily directed against tumor antigens that cross-react with epithelial structural proteins. In addition the tumor may produce cytokines that modulate the autoimmune response. Interestingly, Wang et al. (2004) have demonstrated recently that tumor B cells are able to produce antiepidermal antibodies. In those patients that receive rituximab, the B cell-mediated aspect of the disease and therefore autoantibodies wane. In these cases, the T cell-mediated aspect predominates and the disease takes on a distinct lichenoid pattern with absent or low PNP autoantibodies (Cummins et al., 2007).

The diagnosis of PNP is made clinically, histologically, and immunologically. By indirect IF, the serum of PNP patients typically stains plakin-rich rat bladder epithelium, which produce negative results when stained with the serum of PV or PF. Immunoprecipitation using radiolabeled keratinocyte extracts reveal reactivity with the plakin proteins, but this technique is rarely used in the clinical setting. Multivariant enzyme linked immunosorbent assay (ELISA) and biochip assays are now available to detect antiplakin autoantibodies (van Beek et al., 2017a; Probst et al., 2009).

## Drug-Induced Pemphigus

Certain drugs, particularly thiol-containing drugs, such as penicillamine and captopril, may induce clinical and histological features of PF and less commonly PV (Feng et al., 2011; Yoshimura et al., 2014). The majority of drug-induced pemphigus patients exhibit circulating autoantibodies to the epidermal ICS and epidermal-bound IgG. In cases of drug-induced PF the autoantibodies recognize Dsg1. Some of these drugs have been shown to cause acantholysis in vitro directly. Drug-induced pemphigus may be transient and usually resolves upon withdrawal of the medication, although in rare cases the disease may run a chronic course. The mechanisms involved in the induction of the autoimmune response by drugs in pemphigus remain obscure (Brenner and Goldberg, 2011).

## IgA Pemphigus

This variant of pemphigus is unique because of its clinical and histological phenotype. Clinically, the patients show superficial clusters of small vesicles and pustules, in some cases producing annular patterns. The Nikolsky sign is positive and the great majority of patients show no mucosal lesions. The histological features show, in addition to the acantholysis, an intense neutrophilic infiltrate in the epidermis. This infiltrate may be subcorneal [subcorneal pustular dermatosis (SPD)-type] or located in the mid-epidermis [intraepidermal neutrophilic (IEN)-type]. The immunological hallmark of this form of pemphigus is the presence of IgA class autoantibodies directed to the epidermal ICS. The antigen recognized in the SPD-type has been shown to be another desmosomal cadherin, Dsc1, whereas for the IEN-type, the target antigen appears to be a nondesmosomal cell-surface protein (Hashimoto, 2001). The pathogenic role of these IgA autoantibodies has not been demonstrated. Further, the intense neutrophilic infiltrate of the epidermis and a rapid response of the disease to dapsone (a neutrophilic targeted drug) might indicate a unique IgA-mediated pathway of tissue damage (Tsuruta et al., 2011).

# BULLOUS PEMPHIGOID

## Clinical, Pathologic, and Epidemiologic features

BP is the most common autoimmune bullous disease affecting the skin (Lever, 1965). The incidence of disease is 7–14 cases per million per year in Germany and Scotland (Gudi et al., 2005; Zillikens et al., 1995). Recent studies suggest that the incidence is increasing and may be as high as 22–24 per million per year in the United States and France and 43 cases per million per year in the United Kingdom (Langan et al., 2008; Joly et al., 2012; Brick et al., 2014). BP occurs most frequently in elderly (60 years of age and older) and affects men and women equally. The skin lesions usually begin as urticarial plaques or erythematous papules, which evolve into large, tense bullae filled with clear fluid (Fig. 60.2, right panel). The lesions are frequently associated with significant itch. Histological examination shows subepidermal blister formation with detachment of the epidermis from the dermis. The upper dermis exhibits an inflammatory infiltrate including eosinophils, neutrophils, lymphocytes, and monocytes/macrophages, and these cells may also be present in the blister cavity. The predominant inflammatory cells in early lesions are usually eosinophils and eosinophilic spongiosis may be present. Histological evidence of mast-cell degranulation has also been reported.

## Autoimmune Features

### Autoantibodies

BP is characterized by circulating and tissue-bound IgG autoantibodies directed against the BMZ. While these autoantibodies were originally detected by IF techniques (Jordon et al., 1967), molecular studies have demonstrated that the autoantibodies are directed against two hemidesmosomal proteins (Mutusim et al., 1985) known as BP180 (BPAG2, type XVII collagen) and BP230 (BPAG1) (Jordon et al., 1967; Labib et al., 1986; Stanley et al., 1981).

BP180 antigen is a hemidesmosomal transmembrane protein belonging to collagen family (Giudice et al., 1992). The BP180 protein shows a type II orientation, with its amino-terminal region toward the intracellular hemidesmosomal plaque and its carboxy-terminal half projecting into the extracellular space of the BMZ. The anti-BP180 autoantibodies from BP patients recognize multiple epitopes that cluster within the noncollagen (NC)

16A domain of the BP180 ectodomain (Giudice et al., 1993). The serum levels of autoantibodies to BP180 NC16A in patients directly correlate to disease severity (Haase et al., 1998; Tsuji-Abe et al., 2005). The BP230 antigen is an intracellular hemidesmosomal plaque protein belonging to plakin family (Tanaka et al., 1991). Intra- and intermolecular epitope spreading has been reported in BP and may shape the course of individual disease (Di Zenzo et al., 2011). Only antibodies to BP180 have been demonstrated to be pathogenic in neonatal mice (Fig. 60.3, right panel) (Liu et al., 1993).

The autoantibodies in BP sera are predominantly of IgG1 and IgG4 subclasses (Laffitte et al., 2001). Recent evidence suggests that BP autoantibodies of the IgG1 subclass are pathogenic, while the IgG4 subclass may be inhibitory (Zuo et al., 2016). Epitope specificity is also thought to play a role in autoantibody pathogenicity (Wada et al., 2016). In addition to IgG autoantibodies IgE autoantibodies to BP180 are found in the majority of untreated BP patients (Dimson et al., 2003). Anti-NC16A autoantibodies of both the IgG and IgE class correlate with disease activity as measured by the BP disease activity index (van Beek et al., 2017b).

### **T-Cell Activation**

BP180-specific autoreactive T cells recognize epitopes located predominantly on the NC16A domain of the molecule (Budinger et al., 1998; Lin et al., 2000b). These T lymphocytes express CD4 memory T-cell surface markers and exhibit a Th1/Th2 mixed cytokine profile. Regulatory T cells may also play a role in suppressing inflammation in BP (Bieber et al., 2017; Gambichler et al., 2017).

### **Genetic Features**

Early HLA studies involving American, Japanese, and British BP patients showed no significant association between the disease and HLA-A, B, C, and DR loci, while a marked increase in the HLA-DR5 allele was found in BP patients from France. Recent studies have demonstrated that HLA-DQB1\*0301 is associated with several ethnic groups including Caucasian, Chinese, and Iranian (Delgado et al., 1996; Gao et al., 2002; Esmaili et al., 2013), whereas DRB1\*0403, 0406, or DRB1\*1101 have high frequency in Japanese BP (Okazaki et al., 2000).

### **In Vivo and In Vitro Models**

Early studies on passive transfer of human BP IgG containing anti-BP180 and anti-BP230 autoantibodies to neonatal mice were unsuccessful. It was later found that human anti-BP180 antibodies did not react with the murine BP180 protein due to differences at the amino acid level of the NC16A region of the molecule. This problem was overcome by raising rabbit antibodies against a segment of murine BP180 homologous to the human epitope. It was demonstrated that this anti-BP180 antibodies were pathogenic if passively transferred into neonatal mice. The animals recapitulate the key clinical and histological features of the human disease, (Fig. 60.3, right panel) (Liu et al., 1993).

In contrast to PV and PF mouse models, the subepidermal blistering in mice induced by anti-BP 180 antibodies depends on complement activation and a subsequent cascade of inflammatory events including mast-cell degranulation and neutrophil infiltration. Proteolytic enzymes released from recruited neutrophils are the final effector molecules that cause the epidermal–dermal separation seen in skin lesions (Liu, 2004).

To directly test the pathogenicity of anti-BP180 IgG autoantibodies from BP patients, humanized BP180 mice were generated which harbor the human BP180 or NC16A domain in place of the murine protein (Liu et al., 2008; Nishie et al., 2007). Injection of BP patient anti-BP180 IgG into these humanized mice leads to subepidermal blister formation in process dependent on complement, mast cells, and neutrophils (Liu et al., 2008; Nishie et al., 2007).

IgE purified from BP patient sera was also shown to be pathogenic upon passive transfer into athymic nude or SCID mice with human skin grafts. The human skin grafts developed urticarial plaques and subepidermal splitting at higher doses (Fairley et al., 2007; Zone et al., 2007).

### **Pathologic Effector Mechanisms**

As opposed to the pemphigus group where the autoantibodies directly induce blister formation, BP is the result of autoantibody deposition leading to a complex inflammatory cascade. In addition to autoantibody deposition at the BMZ, inflammatory cells are present in the upper dermis and bullous cavity, including both intact

and degranulating eosinophils, neutrophils, and mast cells (Borrego et al., 1996; Czech et al., 1993; Dvorak et al., 1982; Wintrob et al., 1978). Proteinases including plasmin, matrix metalloproteinase (MMP)-9, collagenase, and elastase are present in blister fluid (Ujie et al., 2011). Animal models of BP demonstrate that anti-BP180 IgG-induced subepidermal blistering requires mast cells and neutrophils. Plasmin, MMP-9, and neutrophil elastase work in concert to degrade BP180 and other extracellular matrix proteins, causing dermal–epidermal separation (Chen et al., 2001; Liu et al., 1997, 1998, 2000a, 2000b, 2005). The deposition of complement components at the BMZ of the lesional/perilesional skin of BP is common, but whether the complement activation is actively involved in BP or a bystander remains controversial.

## Autoantibodies as Potential Immunologic Markers

The detection of anti-BP180 autoantibodies by direct immunofluorescence (DIF), indirect IF, and/or ELISA is critical for the diagnosis of BP. IgG antibodies against BP180 NC16A correlate with disease activity (Schmidt et al., 2000; van Beek et al., 2017b; Amo et al., 2001). Interestingly, a study of 337 patients with various non-BP dermatologic disorders suggests that 4% of the individuals without BP show a low positive level of anti-BP180 by ELISA (Wieland et al., 2010).

## OTHER SUBEPIDERMAL BULLOUS DISEASES

### Herpes Gestationis (Pemphigoid Gestationis)

Pemphigoid gestationis (PG), formerly known as herpes gestationis (HG), is a variant of BP affecting pregnant women or women immediately postpartum. The incidence is about 1 in 50,000 pregnancies (Ambros-Rudolph et al., 2006). The disease usually develops during the second or third trimester of pregnancy or in the immediate postpartum period. PG has also been associated with underlying trophoblastic tumors, hydatidiform mole, and choriocarcinoma (Jenkins et al., 1999). Similar to BP, PG patients develop subepidermal blisters and linear deposition of IgG and C3 at the BMZ (Provost and Tomasi, 1973). The sera of these patients is usually negative by conventional indirect IF assays but become positive when fresh complement fixation to the skin is assayed (HG factor) (Provost and Tomasi, 1973). The HG factor was found to be a complement fixing autoantibody against the BP180 antigen (Giudice et al., 1993; Jordon et al., 1976; Katz et al., 1976; Morrison et al., 1988). While indirect IF is frequently negative in PG, the BP180 NC16A ELISA shows a high sensitivity and specificity for the diagnosis of PG (97% and 100%, respectively) and may be a useful test to distinguish between PG and other pregnancy-related dermatoses (Powell et al., 2005; Al Saif et al., 2017). Autoantibodies are predominantly IgG4 and recognize the same epitope (within the BP180 NC16A domain) as BP autoantibodies (Patton et al., 2006). BP180-specific T cells also recognize the BP180 NC16A and express a CD4<sup>+</sup> Th1 memory phenotype (Lin et al., 1999). PG is associated with maternal HLA-DR3 and/or HLA-DR4 (Shornick et al., 1981). The mechanism of autoimmunity in PG and the role of pregnancy in the pathogenesis of this unique form of pemphigoid are not fully understood (Sadik et al., 2016).

### Cicatricial Pemphigoid

CP, also known as mucous membrane pemphigoid, is a group of heterogeneous diseases characterized by subepithelial blistering involving mucous membranes predominantly (Korman and Cooper, 2000; Chan et al., 2002). The oral and ocular surfaces are most commonly involved, while skin lesions occur only in one-third of CP patients. A striking clinical feature of CP is that healing of the lesions leads to scarring and dysfunction of the affected organs. For example, ocular involvement may cause blindness due to corneal scarring and fibrosis. Direct IF reveals linear deposition of IgG, IgA, or C3 along the epithelial BMZ (Egan et al., 2003). CP is also associated with DQB1\*0301 (Delgado et al., 1996; Chan et al., 1997).

There are several antigenic targets in CP including BP180 NC16A, C-terminal domain of BP180, laminin 5 (also known as laminin 332 or epiligrin), integrin subunits  $\alpha$ 6 and  $\beta$ 4, and NC1 domain of collagen VII. Patients with primarily oral disease often show circulating IgG autoantibodies against BP180 NC16A antigen (Balding et al., 1996), but some show autoantibodies that recognize the C-terminal domain of BP 180, which is different from BP. A subset of CP patients exhibit circulating autoantibodies against laminin 5 (also known as laminin 332 or epiligrin) (Domloge-Hultsch et al., 1994; Egan et al., 1999). Experimentally, it was shown that antilaminin 5 antibodies are able to induce subepidermal blisters in neonatal mice (Lazarova et al., 1996). An association of

cancer with some of CP with antilaminin 5 autoantibodies has been reported (Egan et al., 2003). Many patients with ocular involvement have autoantibodies against  $\alpha 6\beta 4$  integrin (Tyagi et al., 1996). The pathogenic role of the various autoantibodies found in CP and their link to scarring remains to be elucidated (Kurosh and Yancey, 2011).

### Linear IgA disease

LAD is a subepidermal blistering disorder characterized by pruritic lesions and linear deposition of IgA autoantibodies at the BMZ (Nemzer et al., 2000; Venning, 2011). Mucosal membrane involvement is common and can be predominant (60%–80%). LAD can be subdivided into adult-onset, childhood-onset (also known as chronic bullous disease of childhood), and drug-induced LAD (Zone et al., 2004). The histology of lesional and perilesional skin reveals subepidermal vesicles with neutrophilic infiltration along the BMZ and in the superficial dermis in all forms of the disease. In drug-induced LAD, vancomycin is the most frequently implicated drug (Venning, 2011; Fortuna et al., 2012).

IgA autoantibodies in LAD serum react with multiple antigenic peptides derived of the BP180 ectodomain. The most common antigenic peptides for the major type of LAD (lamina lucida type), detected by immunoblotting using epidermal extracts, are the 97-kDa protein (LABD97) and the 120-kDa antigens (LAD-1), which are considered to be the proteolytic fragments of the BP180 polypeptide (Zone et al., 2004). These findings suggest that the majority of LAD autoantibodies recognize epitopes on LABD97 and LAD-1, which are different from those bound by BP autoantibodies on the intact BP180 molecule.

### Epidermolysis Bullosa Acquisita

EBA is an acquired subepithelial blistering disease of the skin and mucous membranes mediated by IgG autoantibodies against type VII collagen (O'Toole and Woodley, 2000). Lesions occur predominantly in areas of trauma and often heal with scarring, like CP. There are two clinical forms of the disease: inflammatory and non-inflammatory (or mechanobullous). Subepidermal blisters are formed as a result of detachment of the epidermis at the level of the sublamina densa area as demonstrated by ultrastructural studies (Fig. 60.1). EBA is associated with HLA-DR2 (Gammon et al., 1988).

The target antigen of EBA is type VII collagen (C-VII), which is confined to anchoring fibers of the sublamina densa region of the skin. EBA autoantibodies react with four major epitopes within the amino-terminal noncollagenous NC1 domain of C-VII. It is hypothesized that binding of these autoantibodies may interfere with dimer formation of the C-VII molecule or may impair the association of C-VII with its ligands, laminin 5, and fibronectin. It has also been suggested that complement activation by the autoantibodies induces inflammation and blistering in a process that is Fc-dependent (Sitaru et al., 2005). Rabbit antihuman type VII collagen NC1 domain IgG induced EBA-like lesions in adult hairless mice and nude mice bearing human skin grafts (Chen et al., 2004). Furthermore, rabbit antibodies specific to a murine portion of type VII collagen induced subepidermal blistering when passively transferred into adult mice, thereby reproducing the clinical, histological, and immunopathological features of human disease in a complement-dependent fashion (Sitaru et al., 2005). Neutrophils are the key effector cells in the pathogenesis of EBA, particularly in the inflammatory form of the disease (Chiriac et al., 2007).

### Dermatitis Herpetiformis

DH is an IgA-mediated skin blistering disease characterized by intensely pruritic erythematous papules and vesicles symmetrically distributed over extensor surfaces (Bagheri and Hall, 2000). The skin rash is gluten-dependent and responsive to gluten-free diet. Skin biopsies from DH lesions show a characteristic neutrophilic infiltration in the upper dermis involving the dermal papillae. Perilesional and normal skin in DH show a granular deposition of IgA along the BMZ with accentuation in the dermal papillae. Recently it has been shown that DH patients possess in their sera IgA autoantibodies that recognize epidermal transglutaminase (Sardy et al., 2002; Donaldson et al., 2007). It is unknown if these antitransglutaminase autoantibodies are pathogenic or an epiphenomenon, but the autoantibodies can be used as a sensitive serologic marker for DH. A remarkable feature of DH is its high association with celiac disease, another IgA-mediated gluten-sensitive disorder involving small intestine. Patients with DH and gluten sensitive enteropathy (GSE) share an increased expression of the HLA-A1, HLA-B8, HLA-DR3, and HLA-DQA1\*0505 and DQB1\*02 genes (Sollid, 2000) and a humoral response to transglutaminases. Both diseases

are exacerbated by the intake of gluten-containing food. The mechanisms of gluten-induced autoimmunity and the relationship of the IgA autoantibody response to transglutaminase in DH remain unclear (Cardones and Hall, 2011).

## TREATMENT OF AUTOIMMUNE BULLOUS DISEASES

The aim of the therapy in all autoimmune blistering diseases of the skin is to abrogate the pathogenic autoantibodies and to decrease the tissue inflammatory response triggered by these autoantibodies. The elimination of pathogenic autoantibodies from the patient is accomplished by a variety of approaches ranging from general immunosuppression to B cell–directed therapies to reduction/elimination of the autoantibodies themselves. In addition, the resultant inflammatory response in the skin may be modulated by using topical or systemic steroids or drugs that are known to impair the effector function of infiltrating inflammatory cells (e.g., dapsone-modulating neutrophils). It is understood that systemic steroids may modulate the antibody production and also benefit the local inflammatory response in the skin.

Systemic corticosteroids are the first line of therapy for patients with most clinical forms of pemphigus and pemphigoid. Doses of prednisone in the range of 1.0 mg/kg daily are used initially. If patients continue to develop new lesions, the dose of prednisone can be increased incrementally to 2.0 mg/kg; however, in our practice we rarely exceed a total prednisone dose of 80 mg daily. The use of azathioprine, cyclophosphamide, methotrexate, or mycophenolate mofetil, as adjunctive therapy, is beneficial in controlling the disease of these patients (Frew et al., 2011). The use of these drugs enhances the chances of inducing a prolonged remission of the disease. These immunomodulatory agents have shown excellent steroid sparing ability, thereby reducing severe complications that arise from long-term use of systemic corticosteroid therapy, that is, osteoporosis, diabetes, hypertension, obesity. The doses and side effects of these drugs are described in detail in dermatological textbooks.

Some patients are resistant to or develop serious side effects to these therapeutic modalities. These patients may benefit from plasmapheresis or parenteral infusions of human immunoglobulin aimed at eliminating/reducing autoantibodies. B cell–targeted therapy with anti-CD20 humanized monoclonal antibodies has been shown to induce clinical and serological remissions in severe cases of pemphigus and CP/MMP (Maley et al., 2016; Joly et al., 2007) and is effective as a first-line agent in pemphigus with high rates of disease remission (Joly et al., 2017).

Dapsone is the drug of choice in DH; it exerts its antiinflammatory effects by direct action on the neutrophil by interfering with the myeloperoxidase–hydrogen peroxide–halide-mediated cytotoxic system in neutrophils. Not only patients with DH, but also LAD and IgA pemphigus show a remarkable clinical response to dapsone. In addition, CP and certain cases of BP respond favorably to dapsone. Dapsone can cause hemolysis and methemoglobinemia; therefore it is mandatory to assay the levels of the enzyme glucose 6-phosphate dehydrogenase (G6PD) prior to beginning dapsone as G6PD deficient patients may experience severe hemolysis.

Therapy for patients with EBA is limited since most of the drugs used to control other autoimmune blistering diseases do not change the course of the disease in EBA patients, particularly in the noninflammatory mechanobullous subtype of EBA. The use of systemic steroids, immunosuppressive drugs, or dapsone may be individualized in each patient. Treatment of underlying malignancy, steroids, immunosuppressive drugs, and supportive therapy has been attempted in PNP patients. The prognosis of these patients however is poor.

## CONCLUDING REMARKS

The autoimmune blistering disorders represent classic antibody-mediated organ-specific autoimmune diseases that can serve as models for understanding the development and pathogenesis of antibody-mediated autoimmune disease in general. New treatments continue to emerge based on our current understanding of disease pathogenesis. Furthermore, unique disease responses to some of these treatments have led investigators back to the bench to further explore the immunologic aberrations present in these patients.

### ALOPECIA AREATA

#### Clinical, Pathologic, and Epidemiologic Features

Alopecia areata (AA) is perhaps the most common autoimmune disease, affecting 5.3 million Americans including males and females across all ethnic groups (Petukhova et al., 2011), with a lifetime risk of 1.7% (Safavi et al., 1995). The most common presentation of AA is reversible loss of one or a few patches of hair called transient AA. More extensive persistent hair loss is classified as patchy persistent AA (Fig. 61.1). Loss of all hair of the scalp is called alopecia totalis (AT), and loss of all scalp and body hair is termed alopecia universalis (AU).

**FIGURE 61.1** Patchy persistent, extensive alopecia areata.

Loss of hair localized to the retroauricular area and occipital areas is called ophiasis and has a poor prognosis. Onset early in life, severe and long-lasting course (Chu et al., 2011), extensive disease, and associated nail dystrophy (pits, ridges, or trachonychia) also indicate poor prognosis.

In AA a mononuclear cell infiltrate attacks the hair follicle (HF) bulb, the factory which produces the hair shaft. T-cell (Tc) cytokines and cytotoxic Tcs produce cytotoxic damage (Whiting, 2003) and disrupt the normal function of the HF. This leads to the production of thin, fragile hairs, which easily break off or detach from the follicle and fall out. Since the hairs which fall out in AA are in actively growing anagen follicles, AA is classified as a form of anagen effluvium.

AA is commonly associated with atopy, especially in severe forms, where the incidence of atopy may be 50% or more (Barahmani et al., 2009). AA is highly associated with other autoimmune diseases, the most common being hypothyroidism, especially autoimmune thyroiditis (Goh et al., 2006). Because the immune damage is localized to the hair bulb, the stem-cell populations are preserved and normal cycling HF can be regenerated, and the regrowth of the hair can occur even years after total hair loss.

## Autoimmune Features

There are multiple observations supporting the concept that AA is an autoimmune disease:

1. AA HFs are surrounded by an immune infiltrate of activated T helper(h) cells, cytotoxic Tcs, natural killer (NK) cells, and a Th1-type cytokine profile (Petukhova et al., 2011).
2. The target of the immune response in AA appears to be the pigmented anagen HF. Anagen is the growing phase of the hair cycle. Neither resting HFs (telogen phase) nor white hair-containing follicles are affected in AA.
3. Autoantibodies are common both in human AA and in the C3H/HeJ mouse model of AA, and their specificities are quite different from the antibody specificities in human vitiligo (Cui et al., 1992; Tobin et al., 1997) where melanocytes are the targets. Antibodies in the C3H/HeJ mouse and in human AA appear to react to proteins of 40–46 kDa, possibly HF-specific keratins (Tobin et al., 1997).

4. Other candidate targets are trichohyalin, an HF keratin-associated protein, and keratin 16 (Tobin, 2003; Leung et al., 2010). Attempts to identify antibodies specific for HF melanocytes have not been successful.
5. Autoreactive Tcs and NK cells are necessary for hair loss in AA, as demonstrated in a xenograft model in which hair-bearing skin from AA patients is grafted onto the severe combined immunodeficiency mouse. This is followed by injection into the graft of leukocytes from the AA patient stimulated in vitro with various melanocyte antigens (Gilhar et al., 1998). In this model CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes transferred the disease after they were primed in vitro by the melanocyte antigens gp100, MART-1, or tyrosinase (Gilhar et al., 2001). In a report on this model leukocytes from AA patients were first stimulated with interleukin (IL)-2 (not melanocyte antigens), producing hair loss dependent on NK cells, CD8<sup>+</sup>NG2D<sup>+</sup>, and CD8<sup>+</sup>CD56<sup>+</sup> cells (Gilhar et al., 2012, 2013).
6. CD8<sup>+</sup> Tcs are necessary for local HF cytotoxicity, while CD4<sup>+</sup>CD25<sup>+</sup> Tcs can transfer the disease systemically in the C3H/HeJ mouse (McElwee et al., 2005).
7. The adhesion pair Cadm-1/class 1-restricted Tc-associated molecule (CRTAM)-1 appears to be necessary to mediate CD8<sup>+</sup> Tc cytotoxicity in AA. Cadm-1 is expressed by epidermal cells and mediates heterotypic adhesion to lymphocytes expressing the CRTAM.
8. The overexpression of Cadm-1 in a mouse model of alopecia favored the progression of alopecia (Giangreco et al., 2012).
9. It has been hypothesized that low expression of class I and II major histocompatibility complex (MHC) molecules in the HF, together with local expression of potent immunosuppressants, maintains a state of immune privilege of HF, in which the cytotoxic immune attack on the HF is suppressed (Ito et al., 2008). Several reports indicated that AA occurs because of the breakdown in this immune privilege in the follicle (Paus et al., 2003; Ito et al., 2008; Kang et al., 2010). According to this hypothesis, proinflammatory signals such as interferon (IFN)- $\gamma$  and substance P cause upregulation of class I MHC molecules and allow the presentation of previously sequestered HF antigens to preexisting autoreactive CD8<sup>+</sup> Tcs. Costimulatory signals from the CD4<sup>+</sup> Tcs and mast cells also facilitate the attack of lymphocytic infiltrates on the HF (Gilhar et al., 2012).
10. Whole genome gene expression analysis of 96 human scalp skin biopsy specimens from AA or normal control subjects revealed distinct expression clusters based on the presence or absence of disease as well as disease phenotype (patchy disease compared with AT or AU). This approach demonstrated the graded immune activity in samples of increasing phenotypic severity, leading to a quantitative gene expression scoring system (alopecia areata disease severity index (ALADIN)) that classified samples based on IFN and cytotoxic T lymphocyte immune signatures critical for disease pathogenesis (Jabbari et al., 2016).
11. High-throughput T cell receptor (TCR) sequencing in the C3H/HeJ mouse model of AA and in human AA patients revealed clonal CD8<sup>+</sup> Tc expansions in lesional skin (de Jong et al., 2018). In the C3H/HeJ model there was interindividual sharing of TCR $\beta$  chain protein sequences, which strongly support a model of antigenic drive in AA. The overlap between the lesional TCR repertoire and a population of CD8<sup>+</sup>NKG2D<sup>+</sup> Tcs in skin-draining lymph nodes identified this subset as pathogenic effectors. In AA patients the treatment with the oral janus kinase inhibitor tofacitinib resulted in a decrease in clonally expanded CD8<sup>+</sup> Tcs in the scalp. However, many expanded lesional Tc clones did not completely disappear from either skin or blood during the treatment with tofacitinib, which may explain in part the relapse of disease after stopping treatment (de Jong et al., 2018).

## Genetic Features

As the approaches to studying the genetics of AA have broadened from observed heritability in first-degree relatives, twin studies, and family-based linkage studies (Martinez-Mir et al., 2007) to genome-wide association studies or deep sequencing of key areas of the genome, it has been increasingly clear that genetic control of innate and acquired immunity is the most powerful factor in determining the susceptibility to all variants of AA, from patchy disease to AU. The two genome wide association study performed in AA to date (Petukhova et al., 2010; Jagielska et al., 2012) provided compelling evidence for the implication of numerous individual genes, most of them with immune function, and have established the major determinants of autoimmunity in AA (Table 61.1) (Petukhova et al., 2010).

The first metaanalysis in AA confirmed that the strongest region of association is the MHC, containing 4 well-mapped independent effects, all implicating human leukocyte antigen (HLA)-DR as a key etiologic driver.

**TABLE 61.1** Alopecia Areata Major Susceptibility Genes With Role in Innate or Acquired Immunity

Mechanism	Genes
<b>INNATE IMMUNITY</b>	
NK cell activation	NKG2D ligands: <i>ULBP6</i> , <i>ULBP3</i> , <i>MICA</i>
Cytokine	<i>IL-2</i> , <i>IL-21</i> , <i>IL2RA</i>
<b>ACQUIRED IMMUNITY</b>	
Antigen presentation	<i>HLA-DRA</i> , <i>HLA-DQA1</i> , <i>HLA-DQA2</i> , <i>HLA-DQB2</i> , <i>HLA-DOB9</i>
T cell proliferation	<i>CTLA4</i> , <i>ICOS</i> , <i>IL-21</i> , <i>IL-2</i> , <i>IL2RA</i> , <i>IKZF4</i> , <i>BTNL2</i>
T cell differentiation	<i>NOTCH4</i>
Tregs	<i>CTLA4</i> , <i>IKZF4</i> , <i>IL-2</i> , <i>IL2RA</i>
B cell proliferation	<i>IL13</i>
<b>END ORGAN</b>	
Antioxidant	<i>PRDX5</i>
Premature graying	<i>STX1</i>
With supposed immune function	<i>KIAA0350/CLEC16A</i>

NK, Natural killer; *IL*, interleukin; Tregs, regulatory T cells.

Outside the MHC, there were two novel loci that exceed statistical significance, containing acyl-CoA oxidase like/BCL2L11(BCL2-interacting protein) (2q13); GARP (LRRC32) (11q13.5), as well as a third nominally significant region SH2B3 (lymphocyte-specific adapter protein)/ATXN2 (12q24.12). Candidate susceptibility gene expression analysis in these regions demonstrates expression in relevant immune cells and the HF. This work uncovered new molecular pathways disrupted in AA, including autophagy/apoptosis, transforming growth factor - $\beta$ /regulatory T cells (Tregs), and JAK kinase signaling, and supported the causal role of aberrant immune processes in AA (Betz et al., 2015).

## In Vivo and In Vitro Models

Since AA is a complex immune process attacking the human anagen HF, and since the exact targets of autoimmune damage are not known, in vitro experiments based on single-cell populations have not been very useful. However, both naturally occurring and engineered animal models have been extremely useful in defining disease mechanisms in AA, in identifying potential drug targets, and more recently, in testing new drugs for future use in human experimentation.

The C3H/HeJ mouse has been an indispensable tool in defining the immunoregulatory AA genes (Sundberg et al., 2004). As in humans the alopecia developed in these mice is strongly IFN- $\gamma$  and IL-2 dependent (Freyschmidt-Paul et al., 2005) and is characterized by a diffuse inflammatory hair loss, which closely mimics in terms of histology, gene expression, and response to treatment, the human disease AA. The AA phenotype could be adoptively transferred to a whole colony of other syngeneic C3H/HeJ mice by transplanting involved alopecic skin, providing the ability to synchronize AA development in large cohorts of mice, and an exciting basic and clinical research platform (Sun et al., 2008). Newer engineered mouse models promise to validate Tc and NK cell roles in AA pathogenesis (Alli et al., 2012; Gilhar et al., 2012).

The xenograft mouse model using hairy skin from AA patients and autologous peripheral blood mononuclear cells (PBMC) sensitized in vitro has already been described in a review by Gilhar et al. (1998). This model has been instrumental in showing that melanocyte-specific CD4 $^{+}$ , CD8 $^{+}$ , and NK cells are effectors of hair loss in AA.

**TABLE 61.2** Inflammatory Response Underlying Alopecia Areata

Type of response	Cells and signaling molecules
Innate/NKG2D response	Alarms: hair follicle TNF- $\alpha$ , IL-15, IFN- $\gamma$ , MICA, UBLP-3, UBLP-6, Rae-1 First responders: DETC, NK, NKT, $\gamma$ /8T
APC/Sentinel	Cellular sentinels: Langerhans cells, dermal dendritic cells, dermal macrophage, mast cells Determinants: HLA, TAP, IFN- $\gamma$
Adaptive immunity	Immune cells: CD4+ T cells, CD8+ T cells, Tregs, B cells, CTLA4, ICOS, IL-2, IL-2R, IL-21 Cytokine network: IL-2, IL-6, IL-17, IL-21, IFN- $\gamma$ , IFN- $\alpha$ Downstream signaling pathways: JAK 1/2, Syk

NK, Natural killer; IL, interleukin; IFN, interferon; TAP, transporter associated with antigen processing; ICOS, inducible T cell co-stimulator; TNF, tumor necrosis factor; Tregs, regulatory T cells.

## Pathologic Effector Mechanisms

At the recent AA Research Summit “From Basepairs to Bedside: Innovations in the Immunology and Clinical Science of Alopecia Areata,” Raphael Clynes and Angela Christiano presented their recent investigations on the inflammatory cascade in AA. As summarized in Table 61.2, the effector cascade in AA encompasses danger signals, NK/innate immune first responders, antigen-presenting cell (APC)/sentinel presentation of HF antigens and adaptive responses dependent on the interplay of multiple T and B-cell populations, and a complex cytokine network (Petukhova et al., 2011). Their studies on gene expression in AA lesions show that 16 of the top 20 signals are IFN- $\gamma$  response genes.

Targeting the IFN- $\gamma$  response genes in AA with JAK inhibitors is one of the great clinical success stories in medicine. The impressive array of case reports and now ongoing clinical trials using multiple JAK inhibitors in AA are summarized in a recent review in the proceeding of the Montagna Symposium on the Biology of Skin (Wang et al., 2018).

## Autoantibodies as Potential Immunologic Markers

There is preliminary evidence that autoantibodies to hair keratins and trichohyalin are commonly found in AA serum (Tobin, 2003). Research is under way to use validated techniques to identify and quantitate autoantibodies in AA.

## Concluding Remarks—Future Prospects

Until recently, the treatments for AA have been inadequate. As stated in a previous Cochrane review, “There is no good trial evidence that any treatments provide long-term benefit to patients with alopecia areata, totalis and universalis” (Delamere et al., 2008). Initial studies of biologics that are highly effective in psoriasis were stunningly unsuccessful in AA. The National Alopecia Areata Foundation has organized a program to develop and test new treatments in the AA. This includes an intensive effort to design and validate a uniform clinical research platform for testing effectiveness of the new treatments. Multiple new approaches using drugs effective in other autoimmune diseases are being developed and deployed: anti-CTLA4, anti-JAK (1/2), anti-Syk, anti-IL-15, anti-NKG2D (Colonna et al., 2010; Petukhova et al., 2011).

It is unknown whether it is necessary to purposefully reactivate affected HF in AA.

Future research programs will determine the effectiveness of direct HF stimuli to reactivate hair growth in the AA.

## VITILIGO

### Clinical, Pathologic, and Epidemiologic Features

Vitiligo is the most common acquired type of leukoderma, causing significant social and psychological difficulties in people with darker skin phototypes. The hallmark of the disease is the white patch with well-

**TABLE 61.3** Classification of Vitiligo

Types and subtypes of disease	Features
1. NSV	
1.1. Generalized/vulgaris	Presents as multiple scattered lesions over the body
1.2. Acrofacial	Begins typically on the fingers and feet and around facial orifices
1.3. Universalis	Depigmentation over the whole body
2. SV	
2.1. Uni/plurisegmental	Follows a dermatomal distribution; stops at the midline; most common type in childhood
2.2. Mucosal	
2.3. Focal	One/few macules in one site. Lesions on multiple sites
3. Mixed	NSV + SV
4. Unclassified	
4.1. Focal	At onset; an earlier stage of generalized type
4.2. Multifocal asymmetrical NSV	Becomes generalized/mixed overtime
4.3. Mucosal	Lesions on one site

NSV, Nonsegmental vitiligo; SV, segmental vitiligo.

Modified from Taieb, A., Alomar, A., Böhm, M., Dell'Anna, M.L., De Pase, A., Eleftheriadou, V., et al., 2013. Guidelines for the management of vitiligo: the European Dermatology Forum consensus, In: Vitiligo European Task Force (VETF); European Academy of Dermatology and Venereology (EADV); Union Européenne des Médecins Spécialistes (UEMS). *Br. J. Dermatol.* 168, 5–19.

defined borders, affecting the skin and mucous membranes (Birlea et al., 2012). Based on the lesions' distribution, extension, and number, the disease is divided into nonsegmental vitiligo (SV) (NSV), SV, mixed, and unclassified (Taieb et al., 2013) (Table 61.3).

In general, NSV is characterized by symmetrical depigmentation (Fig. 61.2) with earlier onset and progression overtime. SV is characterized by a unilateral distribution that may be dermatomal, rapid in onset, and with the involvement of both epidermal and HF melanocytes (Taieb et al., 2013). Vitiligo often occurs in photodistribution and commonly affects body folds and periorificial areas. The most common triggers include sunburn, physical trauma, repeated rubbing of the skin (so-called Koebner phenomenon), psychological stress, and pregnancy. The clinical course of vitiligo is unpredictable; in general, NSV is gradually progressive, while the most SV cases rapidly stabilize.

In atypical cases of vitiligo, the pathologic exam of lesional skin is necessary to confirm the diagnosis. It shows an epidermal basal layer completely devoid of melanocytes in the center of the lesions (Le Poole et al., 1993a); cells expressing melanocyte markers are observed at the margins of lesions. In early vitiligo or in episodes of progression, the dermis at the margin of lesions may contain sparse perivascular and perifollicular infiltrates, consistent with the cell-mediated immune processes destroying melanocytes in situ (Kim et al., 2008).

Vitiligo affects all races and geographic areas with a frequency of 0.3%–0.5% (Birlea et al., 2012). Generalized vitiligo (GV), the most common subtype, occurs with equal frequency in males and females and may manifest at any time in life, with the average age of onset of 24 years (Spritz, 2010).

## Autoimmune Features

Several clinical and experimental observations support the autoimmune basis of vitiligo:

1. In GV subjects of white European ancestry, there is a 15%–25% incidence of at least one additional concomitant autoimmune disease, particularly autoimmune thyroid disease, pernicious anemia, rheumatoid arthritis, psoriasis, type 1 diabetes, Addison's disease, or systemic lupus erythematosus. These diseases also occur at increased frequencies in first-degree relatives of patients with GV (Spritz, 2010), indicating a heritable autoimmune diathesis in vitiligo. In contrast with GV, in SV the occurrence

**FIGURE 61.2** Generalized symmetric vitiligo of the anterior forearms with perifollicular repigmentation process (*brown dots*).

of other autoimmune diseases is uncommon (el-Mofty and el-Mofty, 1980; Koga and Tango, 1988; Park et al., 1988).

2. Circulating antimelanocyte antibodies (antityrosinase, antityrosinase-related protein-1, antidopachrome tautomerase) have been described in GV. Vitiligo antibodies were initially described by immunoprecipitation studies using melanoma cell extracts; they were most commonly directed against antigens with the molecular weights of 35, 40–45, 75, 90, and 150 kDa; the antigens of 35 and 90 kDa were preferentially expressed on melanocytes (Cui et al., 1992). Antigens of 45, 65, and 110 kDa have been identified in immunoblotting studies with melanocyte extracts (Hann et al., 1996b; Park et al., 1996), while the vitiligo-associated antibodies have been demonstrated to recognize melanoma cell proteins of 68, 70, 88, 90, 110, and 165 kDa (Hann et al., 1996a; Rocha et al., 2002). The other vitiligo-associated antibody targets have been reported (lamin A, MCHR-1, PMEL-17, SOX-9, SOX-10, tyrosine hydroxylase).
3. The presence of circulating skin-homing cytotoxic Tcs (Ogg et al., 1998) and infiltrates containing activated cytotoxic Tc and macrophages was described at the margins of active vitiligo lesions (Gross et al., 1987; Badri et al., 1993; Le Poole et al., 1993b, 1996). The Tcs were shown to target melanocyte-specific antigens [including Melan-A (MART-1), gp100 (Pmel-17), and tyrosinase] (Ogg et al., 1998; Lang et al., 2001; Palermo et al., 2001) and to express high levels of the skin-homing receptor cutaneous lymphocyte-associated antigen. The frequency of Tc correlated with both the extent and activity of the disease (Lang et al., 2001). In progressive disease the CD4/CD8 ratio was reported decreased among the skin-infiltrating Tcs, which exhibited a predominant Th1 cytokine secretion profile (Wankowicz-Kalinska et al., 2003). It is accepted that skin-homing, autoreactive, melanocyte-specific Tcs cause melanocyte destruction in vitiligo and that regulatory cells ineffectively restrain autoreactive Tcs in GV (Klarquist et al., 2010).
4. Recent evidence suggests that immune responses may also contribute to the pathogenesis of SV, in which the melanocyte loss, which remains more localized, seems to be related to a lymphocytic infiltrate of IFN- $\gamma$ -producing CD8 $^{+}$  and of some CD4 $^{+}$  Tcs found at the lesional margin of early stages, similar to those observed in GV (van Geel et al., 2011).

5. An immune mechanism in vitiligo was also implied by the experimental observations in occupational vitiligo ([Manga et al., 2006](#)). So-called chemical leukoderma can initially occur on upper extremities of subjects coming in contact with cleaning solutions containing phenolic compounds (such as 4-tertiary butyl phenol). It was hypothesized that these agents are directly toxic to melanocytes, in the context of a possible genetic susceptibility of patients' melanocytes to chemical injuries, which can lead to melanocyte death, release of intracellular proteins, and subsequent autoimmunity.
6. Vitiligo-like depigmentation occurring during IL-2 immunotherapy for malignant melanoma was proposed to follow an autoimmune mechanism. Since some melanoma-associated antigens (such as MART-1, gp100, and tyrosinase) are shared by normal melanocytes and melanoma; the onset of vitiligo suggests that the cytotoxic Tcs activated by IL-2 ([Feliciani et al., 1996](#); [Verheyen et al., 2001](#)) can also attack normal tissue ([Phan et al., 2001](#)), producing vitiligo-like depigmentation.
7. Lymphocyte-mediated destruction of melanocytes can occur in other nonvitiligo scenarios: (1) intratumor depigmentation during melanoma regression, (2) leukoderma acquisitum centrifugum around melanoma and nevi (the latter defining the "halo nevi" phenomenon), and (3) vitiligo-like depigmentation, observed at distant sites from primary melanoma ([Birlea et al., 2012](#)).
8. Immunosuppressive drugs may induce repigmentation in vitiligo. As such, topical calcineurin inhibitors (tacrolimus or pimecrolimus) are first-line therapy in vitiligo and exert an immunosuppressive effect on Tcs by blocking the action of the cytokine gene-activating cofactor calcineurin ([Homey et al., 1998](#); [Boone et al., 2007](#); [Hartmann et al., 2008](#)). Topical corticosteroids have antiinflammatory and immunosuppressive effects and are recommended typically in children and adults with SV or NSV of recent onset ([Abu Tahir et al., 2010](#); [Gawkroger et al., 2010](#)). Systemic corticosteroids, which represent a second-line alternative, can halt the progression of the rapid-spreading vitiligo. Unfortunately, well-established depigmented vitiligo lesions often do not repigment in response to immunosuppressives or corticosteroids. In these circumstances, ultraviolet light-based therapies are necessary to trigger repigmentation ([Fig. 61.2](#)), through a regenerative process involving HF melanocyte precursors ([Birlea et al., 2012, 2018](#)).

## Genetic Features

Epidemiologic studies showed that 15%–20% of the vitiligo patients have one or more affected first-degree relatives, although the most vitiligo cases occur sporadically. A single-locus Mendelian pattern of transmission was not supported for vitiligo. Most reports favored a polygenic, multifactorial model involving multiple genes and also environmental risk factors, features that define a "complex trait" ([Spritz, 2011](#)). In addition to the genetic factors, a considerable effect of nongenetic, environmental triggers has been implicated by the observation of a low concordance rate of 23% in monozygotic twins ([Alkhateeb et al., 2003](#)). Different earlier approaches, such as candidate gene association studies ([Birlea et al., 2011](#)) or genome-wide linkage studies ([Spritz, 2011](#)), tested the involvement of susceptibility genes in vitiligo pathogenesis, some of which could not be confirmed to date. More successful in gene identification were the genome-wide association studies; they have produced a rich yield of validated GV susceptibility genes that encode components of biological pathways reaching from immune cells to the melanocyte ([Birlea et al., 2010, 2013](#); [Jin et al., 2010a,b, 2012a](#); [Quan et al., 2010](#)). Among the most informative signals in Caucasians ([Jin et al., 2010a](#)) were those within MHC class I single-nucleotide polymorphisms rs12206499 which tags the HLA-A\*02a marker that was associated with a favorable response to melanoma therapy. Also significant, and within the tyrosinase gene locus, was the R402Q polymorphism which is associated with susceptibility to malignant melanoma ([Spritz, 2011](#)). Currently, the corresponding underlying causal variants for the two abovementioned signals have already been identified by next generation resequencing ([Jin et al., 2012b](#)).

## In Vivo and In Vitro Models

Several animal models of naturally occurring vitiligo (the Smyth line chicken, the gray horse, the vitiligo mouse, and the Sinclair swine) were identified and described ([Boissy and Lamoreux, 1988](#)). Of these, the Smyth line chicken has been studied extensively because it recapitulates the entire spectrum of clinical and biological manifestations of the human disease (mainly, an inherent defect in the melanocytes in feathers and ocular tissue, and an associated autoimmune response that eliminates pigment cells). A spontaneous mouse model for autoimmune vitiligo was created by introducing a human Tc receptor to human tyrosinase (h3T) into mice, combined

with transgenic expression of the associated human HLA-A\*0201 molecule (Mehrotra et al., 2012; Mosenson et al., 2013). The ensuing h3TA2 mice develop rapid, symmetrical, and progressive depigmentation of the pelage during adolescence.

Research in vitiligo using in vitro models has greatly advanced over the past two decades, providing a range of methodological options to study discrete mechanistic questions, as cited by Dell'anna et al. (2012):

1. Histological, immunofluorescence, and molecular techniques to test the destruction of melanocyte in vitiligo, and the migration of melanocytes to the interfollicular epidermis during vitiligo repigmentation.
2. Monolayer cell culture studies from vitiligo skin to characterize the response of vitiligo melanocytes to various pharmacological agents, and to study melanocyte differential susceptibility to noxious stimuli (UVB, cumene, hydroperoxide, and *tert*-butylphenol).
3. Three-dimensional skin models, such as reconstructed epidermis with keratinocytes and melanocytes on dead deepidermized dermis offer the possibility of reproducing the epidermal melanin unit.
4. The analysis of PBMC in vitiligo consists in characterization of the immunological status of such cells, their ability to recognize specific melanocyte antigens, their cytotoxic effects to melanocytes or melanoma cell lines, and their redox status and responses to DNA damage.
5. Computer simulation models where structural and functional features can be reproduced to define better the sequence of events that possibly lead to functional defects.
6. Fluorescence-based assays, such as microscopy and flow cytometry, represent easy methods to study some functional parameters and cell morphology.
7. A new mouse model of vitiligo has at last provided an experimental platform for demonstrating the molecular details of vitiligo pathomechanisms (Riding et al., 2018). This genetically engineered mouse has epidermal melanocytes that can be killed by immune mechanisms like those in human vitiligo. Adoptive transfer of melanocyte-specific CD8+ Tcs into recipient mice and the subsequent activation of these Tcs using a viral vector produces depigmentation of the epidermis within 5–7 weeks in a patchy pattern similar to patients with vitiligo.
8. New understanding of the mechanisms of vitiligo repigmentation has been possible using a new research platform using narrow band UVB to repigment human vitiligo skin (Goldstein et al., 2015, 2016). This model of repigmentation of human vitiligo by narrow band ultraviolet B treatment is associated with proliferation, migration, and differentiation of melanocyte precursors in the HF bulge, infundibulum, and interfollicular epidermis. The primary melanocyte germ was present in the untreated and treated HF bulge, whereas a possible secondary melanocyte germ composed of C-KIT+ melanocytes was found in the infundibulum and interfollicular epidermis of UV-treated vitiligo. This is an exceptional model for studying the mobilization of melanocyte stem cells in human skin. The improved understanding of this process is essential for designing better treatments for vitiligo, ultimately based on melanocyte stem-cell activation and mobilization (Birlea et al., 2018).

Using careful microdissection and RNA-sequencing to measure gene activation, it has been shown that the repigmentation of human vitiligo skin by narrow band ultraviolet B is controlled by transcription of GLI1 and activation of the  $\beta$ -Catenin pathway in the HF bulge stem cells (Goldstein et al., 2018).

## Pathogenetic Mechanism

One of the most important factors in vitiligo pathogenesis is the unique nature of the human melanocyte as a target of cytotoxic damage. Melanocytes are factories for melanin, a heterogeneous protein product that absorbs light over a broad range of wavelengths. The melanization apparatus is enclosed in the melanosome, an organelle that separates the toxic intermediates of melanization from the cytoplasm of melanocytes. These melanocytes are transferred to surrounding keratinocytes to produce an intact pigment network. Melanocytes are terminally differentiated cells of neuroendocrine lineage. They have limited regenerative capacity and are highly resistant to apoptotic cell death because of high expression of Bcl-2, Bcl-X, and Mcl-1 (Bowen et al., 2003). As discussed in the "Autoimmune features" Section, melanocyte-specific Tc can cause the progressive depigmentation seen in vitiligo (van den Boorn et al., 2009). Moreover, vitiligo-associated antibodies are able to destroy melanocytes and melanoma cells in vitro and in vivo by complement-mediated damage and antibody-dependent cellular cytotoxicity (Fishman et al., 1993; Gilhar et al., 1995; Norris et al., 1988a; Gottumukkala et al., 2006). However, the current opinion is that these autoantibodies reflect a humoral response secondary to melanocyte destruction,

rather than a primary cause of GV (Kemp et al., 2007). There is also extensive evidence that other mechanisms participate in the development and progression of disease and the induction of autoimmunity (Le Poole et al., 1993a; Norris et al., 1994). In vitro studies have connected cellular oxidative stress (Schallreuter et al., 1991, 2001, 2005; Dell'anna and Picardo, 2006) with the immune response in vitiligo; stressed melanocytes were found to mediate dendritic-cell activation with the consequent dendritic cell effector functions playing a role in the destruction of melanocytes (Kroll et al., 2005). These experimental observations suggest that, like other autoimmune diseases, intrinsic damage to melanocytes could be the initiating event in vitiligo, followed by a secondary immune response by Tc lymphocytes which exacerbates the destruction of melanocytes (Le Poole and Luiten, 2008; Hariharan et al., 2010; van den Boorn et al., 2011).

The observation that depigmented lesions develop at a site previously exposed to a physical trauma (Le Poole and Luiten, 2008) suggests that immune response follows melanocyte damage. Cryptic epitopes of several vitiligo-associated intracellular melanocyte autoantigens such as tyrosinase and gp100 could be released during apoptosis and lead to the Tc activation (Namazi, 2007; Westerhof and d'Ischia, 2007; Kemp et al., 2007). Antibodies could then be produced following the stimulation of B lymphocytes by the activated helper Tc (Namazi, 2007); the activated Tc could directly attack melanocytes that express antigenic peptides on their surface in the context of MHC class I molecules (Le Poole et al., 1993b; Hedley et al., 1998; Kemp et al., 2007). The selective destruction of melanocytes in vitiligo might occur because they are intrinsically more sensitive to immune-mediated injury than other skin cells (Norris et al., 1988b).

The use of a new genetically engineered mouse that closely mimics human vitiligo has demonstrated that autoimmunity in vitiligo is driven by the IFN- $\gamma$ -CXCL10 cytokine signaling pathway. Activated melanocyte-specific CD8+ Tcs secrete IFN- $\gamma$ , which signals through the IFN- $\gamma$  receptor to activate JAK1/2 and STAT1. This induces the production of CXCL9 and CXCL10, which signal through their receptor CXCR3 to recruit more auto-reactive Tcs to the epidermis, resulting in widespread melanocyte destruction. Targeting this cytokine pathway represents an emerging treatment strategy for vitiligo (Rashighi and Harris, 2017; Richmond et al., 2017).

There is great enthusiasm to use inhibitors of these mechanistic pathways to treat vitiligo, following the lead of the application of JAK inhibitors to treat AA. The initial experience with one JAK inhibitor suggests that ultraviolet radiation might be necessary as a partner treatment with the JAK inhibitors to treat vitiligo (Liu et al., 2017). Other treatments such as IL-15 inhibition are also under active consideration, based on the mechanistic studies done using this new engineered mouse model (Richmond et al., 2017).

## Autoantibodies as Potential Immunologic Markers

The use of melanocyte antibodies as markers of vitiligo activity is a controversial subject. While a recent study reported no correlation between the presence of antibodies and recent disease activity or different clinical parameters (e.g., age, gender, extension, and duration of vitiligo) (Kroon et al., 2012), other reports found the incidence and/or level of melanocyte antibodies linked to the activity and extent of vitiligo (Naughton et al., 1986; Aronson and Hashimoto, 1987; Hanning et al., 1991; Yu et al., 1993; Kemp et al., 2007).

Following treatment with systemic steroids, a reduction in antimelanocyte antibody levels and in antibody-mediated antimelanocyte cytotoxicity has been reported (Hann et al., 1993; Takei et al., 1984). After therapy with psoralen and ultraviolet A (PUVA), decreased expression of vitiligo-associated melanocyte antigens was noted, leading to a blocking of antibody-dependent cell-mediated cytotoxicity against melanocytes (Kao and Yu, 1992; Viac et al., 1997). The presence or levels of antimelanocyte antibodies have not yet been effectively developed as diagnostic tools or markers of disease activity.

## Concluding Remarks—Future Prospects

Vitiligo has been observed and treated since antiquity, but it still remains an enigmatic disorder in which combined genetic and nongenetic factors can cause the autoimmune-mediated destruction of melanocytes from epidermis, but often sparing HF melanocytes. The treatment in vitiligo must consider two distinct aspects: (1) limitation of the immune process which halts the progression of depigmentation and (2) stimulation of repigmentation of vitiligo lesions by mobilizing the stem-cell populations to proliferate, migrate, and differentiate to regenerate the interfollicular epidermal melanocytes. The effective treatment of vitiligo involves topical medications and phototherapy to both suppress the immune response and to activate melanocyte regeneration from HF reservoirs of pluripotent stem cells (Birlea et al., 2012). New research initiatives are focusing on the

repopulation of affected interfollicular epidermis with melanocyte precursors from the bulge region of the HF. This process is a classic example of regenerative medicine, based on stem-cell activation. The key to improving therapeutic approaches for vitiligo is targeted stimulation of the principal repigmentation genes/proteins or designing new compounds which are potent and selective inducers of melanocyte activation, migration, and differentiation.

## PSORIASIS

### Clinical, Pathologic, and Epidemiologic Features

Psoriasis is a common, chronic, immune-mediated inflammatory skin disease with polygenic inheritance, characterized by erythematous scaly plaques that can range from a few scattered lesions to the involvement of the entire body surface. Psoriasis may progressively worsen with age or wax and wane in severity (Stern et al., 2004; Gelfand et al., 2005; Kurd and Gelfand, 2009; Parisi et al., 2013). The disease prevalence is 2%–4% of the population in Western countries (Parisi et al., 2013), ranging from 0.91% (United States) (Robinson et al., 2006) to 8.5% (Norway) (Bø et al., 2008). Psoriasis can present at any age (see Table 61.4); type I psoriasis presents in younger patients and has a poor prognosis, while type II psoriasis presents in elderly patients and is easier to control. When psoriasis has extensive distribution, especially involving the groin and hands or feet, it produces

**TABLE 61.4** Classification of Psoriasis

Types and subtypes of disease	Features
1. Plaque psoriasis/vulgaris type	Sharply circumscribed, round–oval, or nummular (coin-sized) plaques Plaques occur on elbows, knee, trunk, back Most common type, occurring in 85%–90% of patients
2. Guttate psoriasis	Small, 2–10 mm diameter; acute onset, centripetal distribution Lesions occur shortly after an acute streptococcal infection of the pharynx or tonsils Common in children; occasionally in adults
3. Flexural (inverse) psoriasis	Affects the flexures (inframammary, perineal, and axillary) Lesions devoid of scale appear as red, shiny, well-demarcated plaques Differential diagnosis: candidal intertrigo, dermatophyte infections
4. Erythroderma	Total or subtotal involvement of the body skin
a. Chronic plaque psoriasis	May impair the thermoregulatory capacity of the skin, leading to hypothermia, high output cardiac failure, and metabolic changes
b. Unstable psoriasis	a. Lesions gradually progress as plaques and become confluent and extensive b. Precipitated by infection, tar, drugs, withdrawal of corticosteroids; becomes rapidly extensive
5. Generalized pustular psoriasis (von Zumbusch)	Monomorphic, sterile pustules, which may coalesce to form sheets Active, unstable disease; sometimes requires hospital admission Precipitated by withdrawal of systemic or potent topical corticosteroids and by infections
6. Palmoplantar pustulosis	Sterile, yellow pustules on erythematous-squamous background Frequently with nail involvement Prevalent in women, in the fourth to sixth decade, and in smokers
7. Psoriatic nail disease	Small pits, onycholysis, “oil spots” thickening, dystrophy, discoloration, subungual hyperkeratosis

**FIGURE 61.3** Typical plaque of psoriasis.

significant morbidity and a decrease in the quality of life (Nestle et al., 2009). The prototypic lesion is plaque psoriasis, characterized by raised, well-demarcated, erythematous, oval plaques with adherent silvery-white, dry scales (Fig. 61.3). The histopathology of psoriasis characteristically shows a thickened epidermis with an expanded proliferative compartment, premature maturation of keratinocytes, and incomplete cornification with retention of nuclei in the stratum corneum (parakeratosis) (Nestle et al., 2009). The dermal inflammatory infiltrate consists mainly of dendritic cells, macrophages, and Tcs, while the epidermis contains neutrophils and some Tcs. Erythema in lesions is due to the increased numbers of tortuous capillaries in the rete ridges, covered by a very thin epidermis (Nestle et al., 2009). Psoriasis may be triggered by trauma or injury (Koebner's phenomenon), infections (Leung et al., 1995, 1998), xerosis, and reactions to various drugs (Gudjonsson and Elder, 2008). Psoriatic arthritis presents as distal interphalangeal disease, axial arthritis, or symmetrical arthritis (Winchester, 2008). Nail involvement may be present, particularly associated with arthritis. The various types and presentations of psoriasis are outlined in Table 61.4 (Langley et al., 2005), and guttate and pustular psoriasis are presented in Figs. 61.4 and 61.5.

## Autoimmune Features

It is now generally accepted that psoriatic lesions are caused by abnormal reactivity of specific Tcs in the skin. It is also accepted that alterations in the epidermal barrier, in innate immune defenses, and in processing of inflammatory signals may all contribute to the triggering of nonspecific innate immune mechanisms. The effector mechanisms in the epidermis include the increased production of IL-23 and Th1- and Th17-type cytokines (Gudjonsson and Johnston, 2009).

The concept of an autoimmune basis for psoriasis notwithstanding the presence of a dysregulated immune system (Nestle et al., 2009) is supported by the following:

1. Increased numbers of immune cells (mainly dendritic and Tcs) within the lesions, and the appearance of oligoclonal Tcs in lesions overtime.
2. Oligoclonal Tc activation in psoriatic lesions (Lin et al., 2001).
3. Efficacy of Tc-targeted treatments (cyclosporine, efalizumab, alefacept) (Lowes et al., 2007), drugs that inhibit Th1 and Th17 cells and their cytokines (ustekinumab), or therapies that are thought to target the adaptive immune system rather than modify keratinocyte function (corticosteroids, ultraviolet B (UVB)) (Schwarz, 2008; Bergboer et al., 2012).
4. Genetic associations that are largely immunologic (discussed next).
5. Xenograft animal models (Bergboer et al., 2012) that have focused on the functional role of Tcs and cytokines (Nestle et al., 2009).
6. The observation that bone marrow transplantation into psoriasis patients may cure the disease and that psoriasis can be transferred from a psoriatic transplant donor to the recipient (Nestle et al., 2009).

**FIGURE 61.4** Guttate psoriasis of the trunk.

**FIGURE 61.5** Pustular psoriasis of the neck and upper chest.

However, as yet there is no convincing evidence identifying the specificity of autoreactive Tc clones in psoriasis. Although it has been proposed that CD4 Tc activation initiates psoriasis and CD8 intraepidermal Tcs cause lesion persistence, there is no evidence that these cells are activated by self-antigens (Lin et al., 2001). Many of the triggers for psoriasis are not antigen specific (Leung et al., 1993, 1998), and several of the most effective treatments such as antitumor necrosis factor (TNF) biologics may affect both innate and acquired immunity as well as inflammation in general. It has been proposed that psoriasis is a hybrid of autoimmune and autoinflammatory diseases (Liang et al., 2017).

## Genetic Features

The importance of a hereditary component in the pathogenesis of psoriasis has been established through the population-based studies (Gudjonsson and Elder, 2008). They indicate that the incidence of psoriasis is greater among first-degree and second-degree relatives of patients than among the general population (Nestle et al., 2009). Twin studies showed a concordance rate of 35%–72% in monozygotic twins and 12%–23% in dizygotic twins (Bowcock and Krueger, 2005). About 71% of the patients with childhood psoriasis report a positive family history (Morris et al., 2001). In the past decades, several linkage studies and genome-wide association studies (Bergboer et al., 2012) identified susceptibility loci for psoriasis. Genome-wide linkage analysis has identified at least nine chromosomal loci with statistically significant linkage to psoriasis (called PSORS1–PSORS9) (Nestle et al., 2009). Genomic signatures in psoriatic lesions point to dendritic cells as a key cell type, and IFN- $\gamma$  and TNF- $\alpha$  as key cytokines; this reinforces the concept that cells and mediators of the immune system have essential roles in susceptibility to and maintenance of psoriasis (Nestle et al., 2009). The psoriasis genome-wide association signals confirmed (Bergboer et al., 2012) are listed in Table 61.5.

## In Vivo and In Vitro Models

### ***In Vivo Models***

#### **SPONTANEOUS MOUSE MODELS**

A number of spontaneous mouse mutations give rise to psoriasiform inflammatory and scaly phenotypes (Sundberg and King, 1996; Raychaudhuri et al., 2001), which usually represent only a limited set of psoriatic features (Gudjonsson et al., 2007; Nestle et al., 2009).

#### **CONSTRUCTED MOUSE MODELS**

Over the last four decades, more than 40 unique mouse models for psoriasis have been described or constructed. These models can be categorized into three major types: acute (inducible), genetically engineered (transgenic), and xenograft (humanized) (Hawkes et al., 2018a,b).

#### **ACUTE MODELS**

Since the initial description of the imiquimod (IMQ)-induced psoriasiform dermatitis model (van der Fits et al., 2009), acute or inducible mouse models have rapidly emerged as one of the most widely used systems for studying human psoriasis, in spite of serious reservations about how valid a facsimile the IMQ model really is.

#### **GENETICALLY ENGINEERED MOUSE MODELS**

Transgenic mice have been generated that overexpress adhesion molecules, cytokines, transcription factors, and inflammatory mediators in both keratinocytes and immunocytes to define the important cell types in psoriasis disease initiation. Epidermal overexpression of molecules under the control of promoters in the epidermis (e.g., keratin (K)5, K14, and K10 or involucrin) induces the development of a psoriasis-like disease in several mouse models. The K5-STAT3C mouse develops a psoriasis-like disease, with keratinocyte hyperplasia, loss of stratum granulosum, and parakeratosis.

Knockout or hypomorphic mice, in which a specific genetic element has been removed or attenuated, have also been used to study a given mediator in psoriasis. Mice develop a condition that resembles psoriatic skin disease after *ITGB2*, *ITGAE*, *IL1RN*, and *IRF2* genes are knocked out (Wagner et al., 2010).

**TABLE 61.5** Top Psoriasis Signals With Immune Function

Putative biological pathway	Gene/locus

## XENOGRAFT MODELS (Nestle et al., 2009; Gudjonsson et al., 2007)

Psoriasis-like findings were observed in *Prkdc<sup>scid</sup>* mice receiving CD4<sup>+</sup>-CD45-RBhi Tcs from donors who were MHC matched but mismatched for minor histocompatibility antigens (Schön et al., 1997). Humanized xenotransplantation models most closely resemble psoriasis. Their advantage is that both human skin and immune cell infiltrate are transplanted and can be studied directly.

### In Vitro Models

Because of the complex nature of psoriasis, in vivo models are the preferred platform for investigation of most aspects of disease. However, in vitro studies have been useful in isolating infiltrating lymphocytes from lesional areas, in studying selected functions in psoriatic keratinocytes, and showing the effects of deepidermized psoriatic dermis on the disease process.

### Pathogenic Mechanism

The mechanism of evolution of a psoriatic lesion from initiation to persistence of disease has been thoroughly studied (Nestle et al., 2009, Hawkes et al., 2018a,b).

1. Molecular control of inflammation in psoriasis centers on the IL-23/IL-17 pathway, and the most effective modern therapies for psoriasis target some specific component of this pathway (Hawkes et al., 2018a,b).
2. Initial triggers (e.g., physical trauma or bacterial products) start a cascade of events that include the formation of DNA-LL-37 complexes, activation of plasmacytoid dendritic cells, and secretion of the cytokine IFN- $\alpha$  (both found increased in early psoriatic lesions). Clinical observation points to an important role of IFN- $\alpha$  as an inducer of psoriasis (Funk et al., 1991).
3. Psoriatic keratinocytes are a rich source of antimicrobial peptides, including LL-37,  $\beta$ -defensins, and psoriasin. In addition, keratinocytes are responsive to key dendritic cell-derived and Tc-derived cytokines, including IFNs, TNF, IL-17, and IL-20, and in turn will produce.
4. Proinflammatory cytokines including IL-1, IL-6, and TNF- $\alpha$ .
5. Myeloid dermal dendritic cells are increased in psoriatic lesions and induce proliferation of Tcs and production of Th1 cytokines. The activated myeloid dendritic cells migrate into draining lymph nodes and stimulate differentiation of naïve Tcs into effector cells, Th17 or type 17 cytotoxic Tcs17, Th1, or Tc1 (Nestle et al., 1994). They have proinflammatory effects, producing TNF- $\alpha$  and nitric oxide synthase (NOS) (Lowes et al., 2005).
6. Effector cells recirculate and slow down in skin capillaries in the presence of selectin- and integrin-guided receptor-ligand interactions. Immune cells expressing the chemokine receptors CCR6, CCR4, and CXCR3 emigrate into skin tissue along these chemokine gradients. The key processes during disease maintenance are the presentation of putative autoantigens to Tcs and the release of IL-23 by dermal dendritic cells, the production of proinflammatory mediators such as TNF- $\alpha$  and nitric oxide (NO) by TNF- $\alpha$  and inducible NOS-producing dendritic cells, and the production of IL-17 and IL-22 by Th17 and Tc17 cells, and of IFN- $\gamma$  and TNF- $\alpha$  by Th1 and Tc1 cells. These mediators act on keratinocytes, leading to the activation, proliferation, and production of antimicrobial peptides (e.g., LL-37, cathelicidin, and  $\beta$ -defensins), chemokines (e.g., CXCL1, CXCL9–CXCL11, and CCL20), and S100 proteins by keratinocytes. Dendritic and Tcs form perivascular clusters in the presence of CCL19 produced by macrophages. An essential event is the migration of Tcs from the dermis into the epidermis, controlled through the interaction of  $\alpha 1\beta 1$  integrin (very late antigen 1) on Tcs with collagen IV at the basement membrane.
7. NK Tcs contribute to the disease process.
8. Feedback loops involving keratinocytes, fibroblasts, and endothelial cells contribute to tissue reorganization with endothelial cell activation and proliferation and deposition of extracellular matrix. Neutrophils in the epidermis are attracted by chemokines, including CXCL8 and CXCL1.
9. Studies have indicated a defect in the overall suppressive activity of Tregs (Sugiyama et al., 2005), with decreased contraregulation of the proinflammatory state (Nestle et al., 2009).

### Autoantibodies as Potential Immunologic Markers

Autoantibodies to keratin-associated intermediate filaments (Shigenobu et al., 1989), to U1 and U2 small nuclear ribonucleoproteins (Reeves et al., 1986), to calpastatin (Matsushita et al., 2005), and to other epidermal proteins have been described in psoriasis, but none has proven reliable as a biomarker of disease activity or has been accepted as a participant in disease pathogenesis.

## Concluding Remarks—Future Prospects

Psoriasis is a common inflammatory skin disease of undetermined etiology in which an autoimmune basis is suspected but is far from established. There is no cure, although multiple treatments can produce worthwhile disease remissions (UV light phototherapy, methotrexate, biologics, and small molecules); all of the treatments that induce remissions decrease the population of activated Tcs within the lesions. This heterogeneous, cutaneous, inflammatory disorder is histopathologically characterized by prominent epidermal hyperplasia and a distinct inflammatory infiltrate. Cross talk between immunocytes and keratinocytes, which results in the production of cytokines, chemokines, and growth factors, is thought to mediate the disease. Given that psoriasis is only observed in humans, numerous genetic approaches to model psoriasis in mice have been undertaken (Wagner et al., 2010). Existing and new mouse models are needed in order to dissect this complex disease and to provide novel insights into the molecular mechanisms and pathways that incite the disease initiating events, and also those which are responsible for recurrences following the successful treatment. An impressive array of modern biological therapies and small molecules are already providing remarkable clinical responses. However, the high cost of these treatments, the loss of effectiveness with time, and uncommon but dangerous side effects compel us to seek better treatments. It is also important to seek alternative treatments that can maintain disease remissions achieved by modern biology therapies combination treatments intended to reduce the immune activation and angiogenesis in psoriasis and to restore differentiation of keratinocytes in a disease stage-dependent manner will be beneficial.

## CHRONIC URTICARIA

### Clinical, Pathologic, and Epidemiologic Features

Chronic urticaria (CU) is a relatively common type of urticaria, defined as hives lasting longer than 6 weeks (Kaplan, 2004). It affects around 0.1% of the population including both adults and children (Schocket, 2006), with a higher predilection in women than in men (2:1), and with significant adverse effects on quality of life (Schocket, 2006). CU is currently divided into three subcategories (Greaves and Tan, 2007): (1) urticarial vasculitis (leukocytoclastic vasculitis of the small vessels with hives duration of more than 24 hours which can accompany autoimmune rheumatic diseases, inflammatory bowel disease, viral hepatitis, and paraproteinemia); (2) physical urticarias with several subtypes, for example, solar, cold, aquagenic, delayed pressure, vibratory, cholinergic, and dermographism (these are commonly referred to as chronic inducible urticaria—CindU); and (3) chronic autoimmune urticaria (which is caused by anti-high-affinity receptor for the Fc region of immunoglobulin E (Fc $\epsilon$ RI) antibodies, and less often by anti-IgE antibodies).

Chronic spontaneous urticaria (with more than 6 weeks' duration of symptoms) is a subtype of urticaria in which there is no identifiable cause (Zuberbier, 2012). Spontaneous urticaria is about three times as frequent as CindU.

The characteristic clinical lesion of both acute urticaria and CU is the hive; hives present as pruritic, erythematous, blanching, circumscribed macular, or raised lesions, involving the superficial layers of the skin (Joint Task Force on Practice, 2000). Up to 40% of the CU patients have associated angioedema (swelling of the deeper structures) (Kaplan, 2004). Generally, an individual CU lesion does not persist in the same location for greater than 24 hours (Joint Task Force on Practice, 2000). The untreated CU should virtually always be associated with pruritus. In the absence of pruritus the clinician should consider alternative diagnoses. A thorough history is critical to identifying known causes of urticaria.

CU is diagnosed clinically. The patient history is critical in making the diagnosis, identifying a potential trigger, and ruling out other diseases. For both acute and CU, important specific points of history include physical triggers, recent changes in medications, recent travel, infections (including parasitic), history of atopy, and a complete review of systems. Additional dermatologic conditions should be considered in the differential diagnosis: erythema annulare centrifugum, erythema chronicum migrans, and erythema multiforme.

The principal histologic finding in CU is dermal edema. There is variable cellular infiltrate around vessels, with the predominance of neutrophils and eosinophils in early lesions and of lymphocytes accompanied by neutrophils and eosinophils in advanced lesions (Lee et al., 2002).

## Autoimmune Features

The presence of autoimmunity in a significant proportion of CU patients was initially suggested by the demonstration of skin reactivity to the injection of the patient's own serum, the so-called autologous serum skin test (ASST) (Grattan et al., 1986, 1990). Later, it was shown that the serum and purified IgG of a subset of patients with chronic idiopathic urticaria release histamine from basophils and dermal mast cells when incubated with leukocytes prepared from peripheral blood from the two healthy human donors. This release could be inhibited by preincubation with the recombinant Fc $\epsilon$ R1 $\alpha$ , the  $\alpha$ -chain of the high-affinity IgE receptor. In a small proportion of patients (5%) the histamine-releasing factor was inhibited not by the  $\alpha$ -chain of Fc $\epsilon$ R1 but by IgE itself (Hide et al., 1993; Niimi et al., 1996).

CU has been shown to be associated with an autoimmune mechanism in 30%–50% of idiopathic urticaria cases. In addition, other concomitant autoimmune disorders including autoimmune thyroid disorders, rheumatoid arthritis, type 1 diabetes mellitus, celiac disease, Sjögren's syndrome, and systemic lupus erythematosus were significantly more prevalent in patients with CU when compared to the general population (Confino-Cohen et al., 2012). Moreover, in the same population, CU patients showed a higher prevalence of other serologic markers of autoimmunity, notably rheumatoid factor and antinuclear antibodies, as compared with the non-CU controls (Confino-Cohen et al., 2012). The association of CU with thyroid autoimmunity was described earlier (Leznoff et al., 1983), followed by the observation that suppression of thyroid activity results in CU remission (Schocket, 2006).

The presence of an inflammatory perivascular infiltrate in many CU patients also supports the immune basis of this disease. This infiltrate is predominantly composed of T lymphocytes, specifically CD4+, T helper cells, and a small number of CD8+ cytotoxic Tcs (Mekori et al., 1983).

## Genetic Features

Autoimmune CU is a complex multifactorial disease with probably genetic and environmental components. CU clusters in families, being more frequent among the first-degree relatives of the affected individuals than in the general population (Asero, 2002). There is a paucity of literature on the proposed genetic susceptibilities, mainly consisting of small candidate genes studies, of which results are still unconfirmed. These studies targeted protein tyrosine phosphatase-22 (Brzoza et al., 2012), formyl peptide receptor-like 1 (Yang et al., 2010), HLA-DRB1, and HLA-DQB1 (Chen et al., 2005).

## In Vivo and In Vitro Models

While it is understood that autoimmune mechanisms are responsible for a subset of CU, no single test is diagnostic, and therefore all require clinical correlation. Biopsy and histologic evaluation are only valuable to confirm features consistent with urticaria when the diagnosis is in doubt, or when alternative diagnoses are being strongly considered. While there is evidence suggesting the presence of immunoglobulin G (IgG) directed against both the IgE receptor  $\alpha$  subunit and the Fc region of IgE (Sabroe and Greaves, 2006), there remains significant debate as to the clinical utility of the available testing modalities. One of the earliest tests performed on patients with CU is the ASST. This involves intradermal injection of autologous serum on the volar surface of an unaffected arm along with positive and negative controls (typically saline and histamine).

The test is read 30 minutes later and is considered positive if the wheal at the serum site is 1.5 mm greater than that of the wheal at the negative control. The sensitivity was calculated at 65%–81% and specificity 71%–78% (Sabroe et al., 1999). Other authors have shown unacceptably high false-positive reactions in healthy controls with the ASST as high as 56% (Taskapan et al., 2008).

The other testing modalities including basophil activation and commercial assays for detecting anti-Fc $\epsilon$ R1 $\alpha$  antibodies (sometimes referred to as the CU index) are available, although there remains much debate regarding their clinical utility. More recently, an assay focusing on a unique connective tissue mast cell line has been proposed (Posthumus et al., 2012).

Animal models for contact urticaria were previously described; however, a suitable model for CU has not been reported so far.

## Pathologic Effector Mechanisms

Histamine-releasing IgG autoantibodies directed against both the IgE receptor  $\alpha$  subunit and the Fc region of IgE remain the basis of the autoimmune subset within CU (Hide et al., 1993; Niimi et al., 1996; Kaplan 2004; Mlynek et al., 2008). It was also suggested that the sera from patients with CU containing Fc $\epsilon$ RI $\alpha$  antibody release mediators and TNF- $\alpha$  by activating human foreskin mast cells (Lee et al., 2002). The mast cells are considered to be the primary effector cells in CU, by releasing a variety of inflammatory mediators such as leukotrienes, tryptase, prostaglandins, histamine, IL-1, IL-6, IL-8, and TNF- $\alpha$  (Lee et al., 2002), which regulate the emigration of leukocytes; these mediators induce a sequential upregulation of endothelial adhesion molecules (P-selectin, E-selectin, intercellular adhesion molecules 1) and vascular cell adhesion molecule-1 (Lee et al., 2002), which facilitate the binding of the activated leukocytes to endothelial cells and then transmigrate into tissues. Recent literature has suggested alternative mast cell–activating factors relate to the coagulation cascade. The activation of the classical complement pathway and formation of C5a are important for dermal mast-cell activation and for neutrophil and eosinophil chemoattraction (Greaves and Tan, 2007). Autologous sera from some patients with CU retain the ability to induce a wheal-and-flare reaction when injected intracutaneously even after depletion of IgG (Mlynek et al., 2008). Other studies have demonstrated that thrombin causes edema development by both direct endothelial and indirect inflammatory mediator mechanisms (Asero et al., 2006, 2007a,b). This effect is reduced by antihistamines and completely absent if mast-cell granules are eliminated. One recent study showed high serum levels of the Th17 cell profile of cytokines including IL-17, IL-23, and TNF- $\alpha$  among the chronic spontaneous urticaria patients (Atwa et al., 2013). Other recent works have focused on a possible hormonal component given that CU is twice as prevalent in women. To date, there is no evidence to suggest a hormonal mechanism.

## Autoantibodies as Potential Immunologic Markers

Numerous attempts to develop immunoassays that measure serum levels of IgG and anti-Fc $\epsilon$ R1 or anti-immunglobulin E (IgE) antibodies in urticaria, although successful, have shown low specificity and poor correlation with in vitro serum histamine release and disease activity (Greaves and Tan, 2007).

However, specificity of IgE in spontaneous CU is producing important results. IL-24 is a common and specific autoantigen of IgE in patients with chronic spontaneous urticaria (Schmetzler et al., 2018). In chronic spontaneous urticaria, IgE against staphylococcal enterotoxins is common and functional (Altrichter et al., 2018).

## Concluding Remarks—Future Prospects

Regardless of the mechanism, the first-line treatment for CU remains H1 antihistamines. The second-line treatments include addition of an H2 antihistamine, or of a leukotriene modifier (Tilles, 2005). Using oral glucocorticoids is a common practice for refractory symptoms. In light of the likely adverse effects with long-term use, most clinicians recommend using them for short periods (usually 3–7 days) at the minimally effective dose to control symptoms. The third-line treatments include immunomodulators, but the evidence for efficacy with these agents is largely based on the clinical experience and small-scale studies. Management guidelines also recommend dapsone as the next line of therapy. In patients with anemia, sulfasalazine is used as an alternative. In patients with only modest impairment in quality of life, the use of hydroxychloroquine was suggested given its slow onset of action (Reeves et al., 2004). Alternative immunomodulators used for refractory cases include other calcineurin inhibitors (Trojan and Khan, 2012), mycophenolate mofetil (Zimmerman et al., 2012), immunoglobulin (Asero, 2000), TNF inhibitors, colchicine (Pho et al., 2011), methotrexate (Gach et al., 2001; Perez et al., 2010; Sagi et al., 2011), and cyclophosphamide (Bernstein et al., 2002; Asero, 2005). Phototherapy has also been shown to be effective and is a treatment option for patients desiring to avoid systemic medications (Berroeta et al., 2004; Engin et al., 2008; Aydogan et al., 2012). More recently, omalizumab, a human monoclonal antibody against the high-affinity IgE receptor Fc $\epsilon$ RI, has been shown to be effective, although cost remains a limiting factor (Maurer et al., 2013).

More recent studies have shown that omalizumab has substantial benefits in various CIndUs; the evidence is strongest for symptomatic dermatographism, cold urticaria, and solar urticarial (Maurer et al., 2013).

Although CU is a relatively common condition, identifying the precise trigger in individual patients is usually not possible. Better testing for antigen specificities is a high priority to correct this important issue and is essential

for the best treatment outcomes. Blocking mast-cell degranulation or blocking the effects of released mast-cell mediators is often an inadequate approach to treatment.

The addition of immunosuppressive drugs and specific anti-IgE biologics has enhanced the effectiveness of treatment for recalcitrant CU patients. Nevertheless, better tools for immunologic characterization of the autoimmune mechanism in individual patients, better drugs for mast-cell stabilization, and better drugs to block the autoimmune mechanisms of CU are all important to enhance the effectiveness of treating these patients.

## INTRODUCTION

Experimental studies predict a frequent occurrence of human gonadal autoimmunity. In spontaneous multiorgan models of autoimmune diseases, the testis and ovary are frequent targets. Although progress in clinical research has been slow, in part explained by the success of assisted reproduction techniques, experimental studies have yielded exceptional information on the fundamental mechanisms of tolerance and autoimmunity. They include the discovery and functional analysis of the CD4+ CD25+ Foxp3+ regulatory T cells (Tregs) as a major tolerance mechanism, the sequel of autoimmune regulator (AIRE) gene deficiency, molecular mimicry as a basis of autoreactive T-cell response, the epitope spreading phenomenon in autoantibody production, and neonatal propensity in autoimmunity development. In addition, they provide guidelines for translational research into human disease and better understanding of chronic inflammatory conditions of the gonads associated with subfertility and infertility. Finally, knowledge of the local immune regulation in testis as an immune privileged site, and the recently discovered systemic tolerance mechanism, have contributed to a more complete understanding of the immunological control against gonadal autoantigens, as well as to the numerous human cancer antigens that they share with normal germ-cell antigens in testes and ovaries (cancer/testis antigens). In this chapter, we will present the experimental autoimmune models, followed by a description of existing data supporting an autoimmune basis in human testicular and ovarian diseases.

## AUTOIMMUNE DISEASE OF THE TESTIS

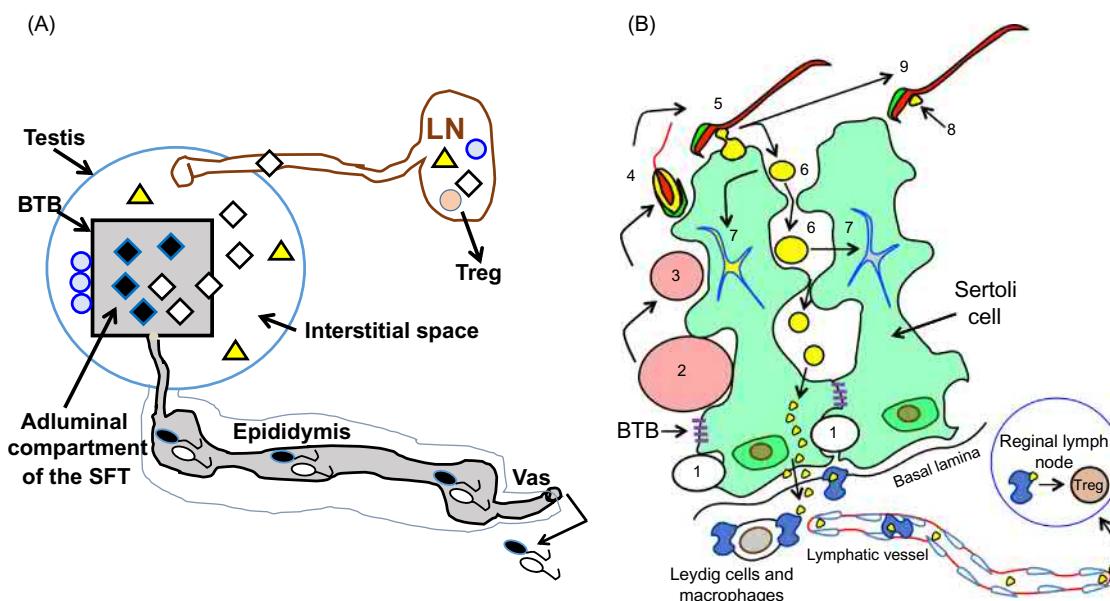

### Tolerance Mechanism for Testis Autoantigens

Peripheral systemic tolerance requires continuous exposure of the immune system to tissue antigens (Samy et al., 2005; Setiady et al., 2006; Wheeler et al., 2009). Therefore it is important to examine their location in the testis relative to the strong blood–testis barrier (BTB).

### The Landscape of Testicular Autoantigen Expression

The BTB is a basal tight junction between adjacent Sertoli cells completely encircling the adluminal compartment of the seminiferous tubules that are lined by the basement membrane and peritubular cells. The adluminal compartment is occupied by all the developing meiotic germ cells. External to this compartment reside the stem cells and premeiotic germ cells (spermatogonia and the preleptotene spermatocytes), Leydig cells, and macrophages (interstitial space) (Fig. 62.1A and B). Blood vessels and afferent lymphatics traverse the interstitial space, providing full access of the interstitial testis antigens to the immune system. They also allow circulating antibodies and activated leukocytes to enter the interstitial space. The interstitial space contains two classes of resident macrophages with essential nonimmune functions (Hutson, 1998; Smith et al., 2015): the yolk sac–derived macrophages in close proximity to the Leydig cells (Mossadegh-Keller et al., 2017) and the postnatal bone marrow–derived macrophages close to the spermatogonia (DeFalco et al., 2015). Macrophages are also the major antigen-presenting cells in the murine testis (Winnall and Hedger, 2013).

In contrast, all the autoantigens expressed by sperm and other meiotic germ cells in the adluminal compartment have been considered to be totally sequestered in a closed environment, invisible to the immune system (Mital et al., 2011; Hedger, 2002; Fijak and Meinhardt, 2006; Li et al., 2012), and would not be protected

**FIGURE 62.1** (A) A landscape of cellular antigens in testicular compartments, epididymis and regional lymph node. The blood–testis barrier (BTB) divides the normal testis into the seminiferous tubule compartment and the interstitial compartment. Antigenic resident cells in interstitial space are: spermatogonia and preleptotene spermatocytes (circle) and Leydig cells (triangle). Seminiferous tubule contains all meiotic germ cells (diamonds). Some meiotic germ cell antigens (white diamond) continuously egress into interstitial space to reach the regional lymph node while other antigens are sequestered (filled diamond). (B) A cartoon showing the location and fate of male germ cell development adjacent to two Sertoli cells (in green). Spermatogonia (1) transverses the BTB to become spermatocytes (2 and 3) and early spermatid (4) that develops acrosome (in green), cytoplasm (in yellow) and tail (in red). Spermiation occurs when late spermatid (5) becomes sperm (9). Some meiotic germ cell cytoplasm becomes the residual body (6) and others become cytoplasmic droplet on sperm (6 in 9). Most residual bodies are engulfed and destroyed by Sertoli cell (7). However, some residual bodies stay outside Sertoli cells until reaching their base, and enter interstitial space. The testis autoantigens protected by the Treg-dependent tolerance mechanism include those in: 1) Leydig cell, 2) spermatogonia and preleptotene spermatocytes, 3) meiotic germ cell antigens in residual body (example: LDH3). The sequestered meiotic germ cell antigens (example: zonadhesin in sperm acrosome) are not protected by systemic tolerance. (Fig 1B is reproduced from Tung et al., 2017, with permission from the Publisher.)

by systemic tolerance. However, recent studies have challenged and shifted this complete testis antigen sequestration paradigm.

First, a cohort of meiotic germ-cell antigens, located inside the seminiferous tubule behind the BTB, is continuously “exported” into the interstitial space despite an intact BTB (Fig. 62.1A and B). Importantly, these exposed autoantigens are protected by systemic tolerance conferred by the CD4+ CD25+ Foxp3+ Treg (Tung et al., 2017). Second, the testis autoantigens in the interstitial compartments are also relevant to testicular autoimmunity: (1) Leydig cell steroidogenic enzymes commonly targeted by autoantibodies in the autoimmune polyendocrine syndromes (APS) (Sotsiou et al., 1980; Elder et al., 1981); (2) antigens expressed in the spermatogonia, expressed in many human cancers as cancer/testis antigens, are currently utilized in human cancer vaccines (Simpson et al., 2005); and (3) autoimmunogenic antigens are known to exist in preleptotene spermatocytes (Yule et al., 1988).

Testis antigens with capacity to induce experimental autoimmune orchitis (EOA) are localized in meiotic germ cells including the spermatozoa. When strictly defined as antigens capable of inducing EAO at the low µg range, only very few orchitogenic antigens have so far been identified (reviewed by Frayne and Hall, 1999). They included the meiotic germ cell–specific guinea pig PH20 (Tung et al., 1997) and the murine zonadhesin (ZAN) (Wheeler et al., 2011). However, mice with EAO also produce autoantibodies that target somatic antigens but their orchitogenicity has not been analyzed (Terayama et al., 2016).

### **Systemic Tolerance to the Exposed Meiotic Germ-Cell Antigens**

Discovery of systemic tolerance to the exposed meiotic germ-cell antigens involves a study on the cytoplasmic lactate dehydrogenase 3 (LDH3) (Hintz and Goldberg, 1977), the acrosomal membrane antigen ZAN (Hardy and Garbers, 1994), and transgenic ovalbumin (OVA)—a surrogate cytoplasmic meiotic germ-cell antigen, based on the following findings (Tung et al., 2017). First, ZAN, normally hidden and not tolerogenic, elicits a strong orchitogenic response only when exposed in the epididymal interstitium after vasectomy (Wheeler et al., 2011). Second, tolerogenicity of LDH3 is documented in a study on the DEREG mice that express the human diphtheria toxin receptor exclusively on the Foxp3+ Treg (Lahl et al., 2007). Transient Treg depletion by diphtheria toxin leads to spontaneous EAO and production of antibodies that target LDH3 but not ZAN. A similar study also identified the transgenic OVA as an exposed meiotic germ-cell antigen (Fig. 62.2A and B). Third, LDH3 (Fig. 62.2A) and OVA but not ZAN (Fig. 62.2B) are contents in the residual bodies (Fig. 62.1B); these residual bodies stay outside the Sertoli cell and escape degradation (Fig. 62.1B). Fourth, and most directly, LDH3 escape is documented in normal wild-type mice injected intravenously with rabbit LDH3 antibody, which forms immune complexes with LDH3 on the seminiferous tubule boundary outside the BTB (Fig. 62.2C), and this is not observed in mice injected with ZAN antibody (Fig. 62.2D).

### **Local Regulation in the Testis (Immune Privilege)**

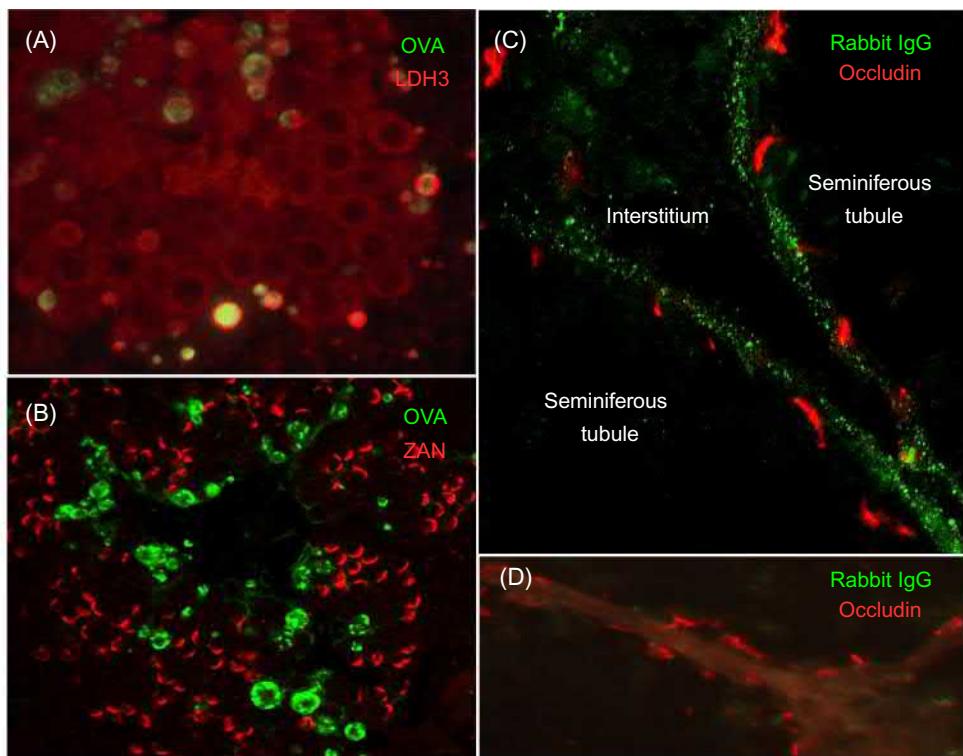

Systemic tolerance and local immune privilege are partners for the complete immune protection of sperm autoantigens. Local regulation of antigen exposure and tolerogenic presentation by unique antigen-presenting cells ensures successful maintenance of Treg and systemic tolerance. In addition, local regulation per se provides barrier function and controls immune mediators that operate in the efferent arm of autoimmunity, or from any other causes of testis inflammation, including infections.

Head et al. (1983) discovered the prolonged survival of an allogeneic organ grafted in the testicular interstitial space and called attention to the testis as an immunoprivileged organ (reviewed by Fijak et al., 2011; Li et al., 2012). Since then, many soluble and cell-based immunosuppressive factors have been discovered in the testis interstitium, largely based on in vitro studies. We summarize the major cell types and soluble factors involved in testicular immune privilege in Table 62.1.

## **Experimental Autoimmune Disease of the Testis**

### **Classical Experimental Autoimmune Orchitis Induced by Immunization with Testis Antigen in Adjuvant**

EOA in guinea pigs was first described by Voisin et al. (1951) and by Freund et al. (1953). Attempts to transfer disease by serum antibody to normal guinea pig failed but the study clarified regional differences in the barrier properties in different spermatogenic compartments (Tung et al., 1971a, 1987b; Johnson, 1973). Lymphocytes retrieved directly from immunized guinea pig transferred EAO only by subcapsular injection but not by intravenous injection (Tung et al., 1971b). This suggested T cells need to express tissue homing receptor to enter

**FIGURE 62.2** LDH3 (A) but not ZAN (B) is co-localized with ovalbumin (OVA) in the residual bodies of mice expressing a transgenic OVA. OVA, a surrogate meiotic germ cell antigen expressed under the protamine 1 promoter, serves as residual body marker (Tung et al., 2017). (C and D) Normal wild type mice, injected intravenously with rabbit antibody to LDH3 (C), but not antibody to ZAN (D), develop immune complexes as punctate rabbit IgG surrounding the seminiferous tubule, outside the occludin-positive BTB. Therefore, mouse LDH3 but not ZAN egresses normal seminiferous tubule. (Confocal microscopy  $\times 1600$ .)

the testis. Further progress come from mouse and rat EAO models. In general, EAO induction requires the injection of testis antigen in complete Freund's adjuvant (CFA) and/or pertussis toxin (Kohno et al., 1983; Doncel et al., 1989); however, murine EAO can also be induced by subcutaneous injections of viable testicular cells without adjuvant (Sakamoto et al., 1985; Itoh et al., 1991, 2005). A detailed description of the protocols for testicular autoimmune disease was described.

EAO induced by active immunization is initiated in subcapsular seminiferous tubules, adjacent to the major lymphatic vessels (Hirai et al., 2012). In contrast, when orchitogenic T cells are adoptively transferred to normal recipients, they initially target the straight tubules and the ductus efferentes that are not lined by Sertoli cells; subsequently, they spread to the seminiferous tubules (Tung et al., 1987b; Itoh et al., 2005). After migration into the testis interstitium, the macrophages, dendritic cells (DCs), and T cells form multiple cell clusters around the seminiferous tubule. In many species, with the exception of rat EAO, these cells invade the BTB and enter seminiferous tubules. It is important to understand how T cells enter the testis, damage the BTB, and induce sloughing and apoptosis of germ cells.

EAO mechanisms have been elucidated by investigations on rat with active EAO induction. First, chemokines and cytokines upregulate adhesion molecules on the endothelial cell (EC) and support T-cell attachment to EC and extravasation into the interstitial space. Also required is contact between the activated form of CD44 on lymphocytes and its major ligand hyaluronic acid expressed on EC (Guazzone et al., 2005). Second, chemokines (which include CCL2/MCP1, CCL3/MIP1 $\alpha$ , and CCL4/MIP1 $\beta$ ) expressed by testicular cells convert the leukocyte rolling into cell arrest. In addition, the higher percentage of leukocytes expressing CD49d integrin and the increased expression of CD106/VCAM ligand in EC mediate the step of firm adhesion. Third, inflammatory cell transmigration occurs via the interaction of CD106 and CD31/PECAM-1 (Guazzone et al., 2009, 2012). Finally, germ-cell apoptosis involves several mechanisms, including TNF $\alpha$ /TNFR1, IL-6/IL6R, and FasL/Fas (Suescum et al., 2003; Theas et al., 2003, 2008; Rival et al., 2006b), as well as the death receptor and mitochondrial apoptotic pathways (Theas et al., 2006).

**TABLE 62.1** Immune and Somatic Cells Involved in Testis Immune Privilege

Cells	Functions
Foxp3 Tregs	Treg maintain systemic tolerance to nonsequestered meiotic germ-cell antigens in normal mice (Tung et al., 2017) <sup>a</sup>
Dendritic cells	DCs in rat testis are functionally tolerogenic: do not stimulate T-cell proliferation (Rival et al., 2007)
Macrophages	Resident macrophages, highly represented in testis (Rival et al., 2008), have an impaired capacity to act as costimulators for T cell–activation responses (Winnall et al., 2011) but are able to expand Tregs (Wang et al., 2017)
Sertoli cells	As implant in ectopic site, prevent allograft rejection and suppress diabetes (Selawry and Cameron, 1993; Mital et al., 2010) <sup>a</sup> Express/secrete immunoregulatory molecules <ul style="list-style-type: none"> <li>• TGF<math>\beta</math> expression by murine prepuberal Sertoli cells was associated with protection of islet allografts from autoimmune destruction, with generation of Treg (Suarez-Pinzon et al., 2000; Campese et al., 2014)</li> <li>• Inhibition of IDO expression abrogates the ability of porcine prepuberal Sertoli cells to protect allografts in mice (Fallarino et al. 2009). IDO is downregulated in rats with autoimmune orchitis (Guazzone VA, <i>personal communication</i>)</li> <li>• Prepuberal murine Sertoli cells expressing Galectin1 promote the in vitro differentiation of tolerogenic dendritic cells (Gao et al., 2016). Adult mice Sertoli cells also express galectin1. However, mice genetically deficient in Galectin1 present a decreased incidence and severity of orchitis versus wild-type mice (Pérez et al., 2015)<sup>a</sup></li> <li>• Prepuberal murine Sertoli cells expressing PD-L1 reduce CD8<math>^{+}</math> T-cell proliferation (Dal Secco et al., 2008)</li> </ul> <i>BTBS</i> ertoli cell tight junction proteins play a key role in structure and function of BTB that blocks antibodies and lymphoid cells entering seminiferous tubules (Mruk and Cheng, 2015) <sup>a</sup> Negative regulator of innate system TAM receptor tyrosine kinase subfamily is a negative regulator of innate immune system (Lu et al 1999; Lemke and Rothlin, 2008; Zhang et al. 2013; Li et al., 2015). Also enhance Sertoli cell and macrophage phagocytosis of apoptotic germ cells and reduce accessible testis autoantigens (Xiong et al., 2008)
Leydig cells	Secret TT regulates BTB permeability by modulation of claudin 3 expression (Meng et al, 2005) <sup>a</sup> T stimulates the differentiation of Treg (Fijak et al., 2015)
Germ cells	PD-L1 expression in spermatocytes and spermatids constitutively. Its inhibition abrogates long-term survival of intratesticular islets allografts (Cheng et al., 2009) <sup>a</sup>

<sup>a</sup>In vivo studies.

IDO, Indolamine 2,3-dioxygenase; PD-L1, programmed death-ligand 1; BTB, blood–testis barrier; TAM, tyro 3-Axl-Mer; T, testosterone.

Interstitial macrophages and DCs are critical participants in EAO; in vivo depletion of these cells in rat EAO by clodronate-containing liposomes significantly reduces EAO incidence and severity (Rival et al., 2006a, 2007, 2008). The interstitial macrophages express high levels of MHC class II, CD80, and CD86; their numbers are increased (Rival et al., 2008); and they produce proinflammatory cytokines, mainly TNF $\alpha$ , IL6, IFN $\gamma$  (Suescum et al., 2003; Rival et al., 2006b), and nitric oxide (Jarazo-Dietrich et al., 2012, 2015). The mediators also alter the integrity and function of Sertoli adherens and tight junctions facilitating germ-cell sloughing (Lee and Cheng, 2003; Pérez et al., 2011, 2012, 2014). The DCs from testicular draining lymph nodes (LNs) are mature and express more IL-12p35 mRNA than do DCs from nondraining LN (Guazzone et al., 2011). Excessive male germ-cell antigens released into the interstitium during EAO further stimulate T-cell response in the testis draining LN.

CD4 $^{+}$  but not CD8 T cells are pivotal. Polyclonal or monoclonal murine CD4 $^{+}$  T cells adoptively transfer severe EAO (Tung et al., 1987b; Yule and Tung, 1993). In rat EAO, detection of an increase in the testicular IL17 and IL23 suggests the involvement of Th17 subsets (Jacobo et al., 2011a). At the chronic stage, variable number and cytokine profile (Th1 and Th17) of CD8 $^{+}$  T cells are also identified (Jacobo et al., 2009, 2011a). In mouse EAO, Th subset requirement is strictly strain dependent, with IL17 being necessary and sufficient for C57BL/6 mice, but requiring both IL17 and IFNg in BALB/c mice (Rival and Tung, unpublished data).

The changes in Treg have been investigated in rats and mice with EAO. They are distributed as clusters in the subcapsular seminiferous tubules of rats with classical EAO (Jacobo et al., 2009). In a transgenic mouse EAO model (Paul and Tung, unpublished data), these clusters were found to include antigen-specific Treg. In rat EAO, the Tregs isolated from regional LN are more potent suppressors of polyclonal T-cell response than the Treg from other LN in vitro (Jacobo et al., 2015). However, Treg fails to effectively suppress ongoing inflammation in vivo. This may be caused by effector T-cell resistance to suppression or to the reduction of the

Treg-suppressive function (Jacobo et al., 2011b). In a study on transgenic mouse EAO, Tregs in LN and testis with EAO were found to lose Foxp3 expression, produce specific proinflammatory cytokines that match the cytokines produced by the host antigen-specific effector T cells in the inflamed testis (Paul and Tung, unpublished data).

Although antibody per se does not transfer EAO to normal recipients, it participates as immune complex formation in the tubular basement membrane. In murine EAO, spontaneous EAO, and vasectomized rabbits, immune complexes are characterized by granular deposition of IgG and complement C3. In addition to complement activation, the antibody can also synergize with effector T cells to induce severe EAO (Wheeler et al., 2011; Paul and Tung, unpublished data).

### **Autoimmune Orchitis in the Dark Mink**

Inbreeding of mink for a dark fur has coselected male infertility in this seasonal breeder (Tung et al., 1981) but also in mink with other fur colors (Pelletier, 1986). There are two histopathologic patterns: one with massive granulomatous inflammation and the other extensive germ cell loss with little inflammation. In the latter, antibodies to sperm acrosome form a massive immune complex, with IgG and complement C3 depositing in the basement membrane outside the BTB. Interestingly, an association of autoimmune orchitis with abnormal hypothalamic–pituitary–testicular function is suggested by the finding that EAO is inhibited by exogenous gonadotropins (Tung et al., 1984). Pelletier et al. (2009) have critically analyzed the spermatogenic cycle in this seasonal breeder and provided evidence for defects in the apoptotic cell clearance, a mechanism that may cause breakdown of self-tolerance in mink leading to spontaneous autoimmune orchitis.

### **Autoimmune Orchitis in Rats Expressing Transgenic Human HLA B27 and Human $\beta$ 2 Microglobulin**

Lewis rats with transgenic human HLA B27/ $\beta$ 2m spontaneously develop spondyloarthritis and rheumatoid arthritis that mimic the human diseases (Taurog, 2009). Unexpectedly, severe autoimmune orchitis was discovered in the transgenic rats several months before the onset of joint disease (Taurog et al., 2012). Inflammation first appears in the ductus efferentes when the first wave of apoptotic testicular germ cells transits this region to reach the epididymis. Three months later, severe inflammation shifts to the testis and ultimately eliminates sperm production. Interestingly, bilateral excision of the orchitic testes prevents arthritis development and establishes a causal link between two organ-specific autoimmune diseases (Taurog et al., 2012). Although autoimmune orchitis has not been reported in men with spondyloarthritis, sperm abnormalities are reported in these patients (Villiger et al., 2010).

### **Testis Antigen-Specific Tolerance Occurs in Vasectomized Mice and Concomitant Treg Depletion is Required for Postvasectomy EAO Induction**

Vasectomy is a major global contraceptive method adopted by over 0.5 million men in the United States alone. Autoimmune orchitis with immune complex deposition occurs in vasectomized rabbits, guinea pigs, monkeys, and others (Bigazzi, 1981), and they develop sperm antibody, generally of late onset. A recent study in unilaterally vasectomized mice focused on the immunological events over the first 10 weeks. It revealed that the release of sequestered sperm cell antigens rapidly induced a Treg response that prevents subsequent active EAO induction. Tregs are testis antigen specific; they do not prevent EAE induction (Wheeler et al., 2011). Indeed, postvasectomy orchitis and sperm antibody response within the first 10 weeks do not occur unless the Tregs are partially (60%) depleted. Depletion had to occur at the time of vasectomy, but not at 1 week after vasectomy. Importantly, the antibodies targeted the sequestered Zan but not the exposed LDH3 (Wheeler et al., 2011; Tung et al., 2017). Therefore even the sequestered sperm antigens, when released into the epididymis microenvironment, can rapidly initiate Treg-dependent tolerance. However, after 3–4 months, mice with vasectomy alone begin to show detectable serum sperm antibody that fluctuates over time; this is likely dependent on the balance of effector Treg and effector T-cell actions (Rival et al., 2013).

### **Autoimmune Orchitis Associated With Bacterial and Viral Infections**

Autoimmune orchitis may be relevant to the development and the sequel of infectious orchitis. Microbial antigens may cross-react with testis antigen via molecular mimicry at the T- or B-cell level. Alternatively, autoimmune response and orchitis may result from severe infection. In mice with *Listeria monocytogenes* infection only in one testis, the contralateral testis develops orchitis without detectable microorganisms, suggesting an

autoimmune component in an infectious orchitis (Mukasa et al., 1995). Indeed, CD4+ T cells from the infected donors transfer orchitis to uninfected recipients. In this study,  $\gamma\delta$  T cells in both testis are found to regulate  $\alpha\beta$  pathogenic T cells by cytokines, notably involving IL10 and TGF $\beta$  (Mukasa et al., 1997, 1998). The injection of uropathogenic *Escherichia coli* (UPEC) into the vas deferens of rats results in a severe epididymo-orchitis. This experimental model mimics one of the most frequent acute epididymo-orchitis in men. The UPEC elicited differential responses in testicular and peritoneal macrophages, with findings that suggest bifunctional testicular macrophages: one that can initiate immune responses to bacteria, while maintaining testicular immune privilege (Bhushan et al., 2011).

Viruses have been shown to directly infect somatic cells or germ cells and modify their functions, leading to "autoimmune" tissue damage. Orchitis develops in rabbits infected with myxoma virus (Fountain et al., 1997) and Sendai virus (Melaine et al., 2003). More recently, in vitro experiments showed that mumps virus triggers innate immune responses in mouse Sertoli and Leydig cells through TLR2 and retinoic acid-inducible gene-I signaling, which results in the production of proinflammatory cytokines and chemokines (Wu et al., 2016). Herpes simplex virus infection is also evaluated in an experimental model of ascending infection in mice resulting in orchitis, irreversible atrophy of the germinal epithelium, and infertility (Malolina et al., 2014). Mice infected with a mouse-adapted Zika virus (ZIKV) develop testicular and epididymal damage that can progress to reduce key sex hormones, destroy germ, and somatic cells in the testis, inducing loss of mature sperm and infertility. It was suggested that the spermatogonia and other germ cells as well as the Sertoli cells are key targets for ZIKV in the testis (Govero et al., 2016).

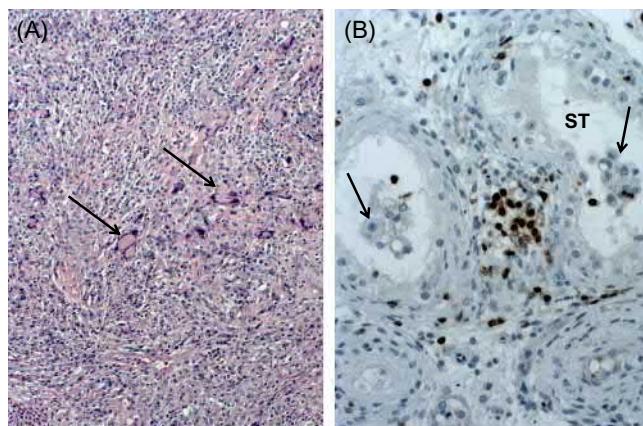

## Clinical Autoimmune Disease of the Testis

### ***Idiopathic Male Infertility***

Antisperm antibodies (ASA) are found in 3%–12% of men with infertility, compared to 0%–2% of the general male population (reviewed by Turek and Lipshultz, 1994). Testicular biopsy indicates that 50% of the patients have focal orchitis (Schuppe et al., 2008). In principle, ASA may cause infertility by interfering with sperm transport and with many steps of fertilization in vitro, such as cervical mucus penetration, acrosome reaction, zona binding, zona penetration, oolemma binding, and pronucleus formation in the fertilized oocyte (reviewed by Tung et al., 2002). The detection by the immunobead assay, of ASA (immunoglobulin A (IgA) and IgG isotypes) in sperm head present in local genital secretions shows a strong collaboration with male infertility (reviewed by Marshburn and Kutteh, 1994), but the nature of the cognate sperm antigens has not been defined (Frayne and Hall, 1999).

Diagnosis of human autoimmune orchitis requires immunopathologic evaluation by testis biopsy which is rarely performed (Schuppe et al., 2008). Most helpful is the detection of orchitis and immune complexes in the testis and sperm or testis autoantibodies in the serum. Immune complexes, detected on frozen section, are found in many types of EAO (Tung, 1978; Tung et al., 1981; Bigazzi, 1981; Lustig et al., 1987, 2000). In human orchitis, light and electron microscope studies showed deposits of electron-dense material in the tubular basement membrane that reacts with antibody to human IgG and complement C3 (Salomon et al., 1982; Lehmann et al., 1987). There are other human orchitides with possible autoimmune basis. One is idiopathic granulomatous orchitis. Clinically, patients present mild scrotal pain or swelling, or a hard scrotal mass. Histologically, the seminiferous tubules are replaced by granulomatous inflammation consisting of T cells, macrophages, and multi-nucleated giant cells (Fig. 62.3A). These findings mimic the changes in rat EAO (Doncel et al., 1989; Taurog et al., 2012). Another and more common type of orchitis contains multiple foci of monocytic inflammation (Suominen and Söderström, 1982; Chan and Schlegel, 2002a,b) and resembles the early lesions in EAO of mice and guinea pig. T-cell and macrophage clusters located at the boundary of seminiferous tubules penetrate the tubule via disrupted BTB (Fig. 62.3B) (Kohno et al., 1983; Schuppe et al., 2008). A recent study detected IL17, IL21, and IL23 among the inflammatory cells and suggests involvement of the proinflammatory Th17 pathway (Duan et al., 2011). Notably, the possible relationship between the infertile patients with circulating sperm antibodies with those whose disease is diagnosed by biopsy-proven orchitis has not been resolved.

Finally, lymphomonocyte infiltration frequently accompanies testis infection and other diseases that damage the testicular parenchyma, including testis cancer, trauma, toxic agents, and cryptorchidism (Jahnukainen et al., 1995; Klein et al., 2016; Nistal et al., 2002). Continuous release of orchitogenic antigens from damaged seminiferous tubules may disrupt tolerance and induce autoimmune orchitis.

**FIGURE 62.3** Human orchitis. (A) Granulomatous orchitis with heavy monocytic inflammation and numerous multinuclear giant cells (arrows); the normal testis histology is effaced. (H and E x200.) (B) Focal “autoimmune orchitis” in testis biopsy of an infertile man. Note CD3+ T cells in a cluster of mononuclear cells that abut the wall of seminiferous tubule (ST). Note macrophage-like cells inside lumen (arrows). These findings phenocopy the histopathology of rodent EAO. (immunoperoxidase x800) (B is photographed from a slide from Dr. H.C. Schuppe and Dr. A. Meinhardt)

### **Infertility and Antisperm Antibodies Coexist With Other Autoimmune Diseases**

The major evidence for an autoimmune basis of human autoimmune orchitis comes from patients with APS. APS-type 1 (APS-1) is a rare autosomal recessive disease caused by AIRE gene mutation (Kisand and Peterson, 2011). About 30% of the male patients develop testis failure with autoantibody to steroidogenic enzymes and other antigens expressed in the Leydig cells (Maclare et al., 2001).

### **Antibody Response in Vasectomy and Cystic Fibrosis**

Patients with vasectomy commonly produce ASA, detectable several months after surgery. Postvasectomy ASA may be a cause of infertility in men with vasovasostomy and adequate sperm count (Lee et al., 2009). Focal orchitis has also been reported in the testes of vasectomized men (McDonald, 1997) and by epidemiological analysis (Goldacre et al., 2007). However, a systematic immunopathologic analysis of the human testes and epididymis in vasectomized subjects is still lacking. Epididymal sperm granuloma commonly occurs in vasectomized mice (>80%) and also occurs in men, but the real incidence in human is unknown in the absence of histopathologic data. Finally, ASA response also occurs in patients with congenital absence of the vas deferens and seminal vesicles associated with cystic fibrosis (D'Cruz et al., 1991).

### **Orchitis Associated With Bacterial and Virus Infections**

Many infectious agents target the testis and cause epididymo-orchitis and infertility. They include bacteria, mainly *E. coli* and *Neisseria gonorrhoea*, and viruses, mainly mumps virus, human immunodeficiency virus (HIV), and ZIKV. The attendant tissue injury may expose germ-cell antigens, which could invoke secondarily an autoimmune response. Indeed, sperm antibodies are detectable in patients with HIV (reviewed by Dejucq and Jégou, 2001; Xia et al., 2009). The immune privilege status of the testis may facilitate the latency of infectious agents (Winnall et al., 2015). HIV and ZIKV, and bacteria that enter Sertoli cells or spermatogonia, would facilitate sexual transmission (Baud et al., 2017; Ma et al., 2017). Finally, idiopathic orchitis such as granulomatous orchitis may have an infectious etiology that has not yet been identified.

## **AUTOIMMUNE OOPHORITIS**

### **Tolerance Mechanism for Ovary Autoantigens**

Suppression of murine ovarian autoimmunity induced by thymectomy on day 3 of life (d3tx), by lymphoid organs implanted from normal donors, eventually led to the discovery of Treg (Nishizuka and Sakakura, 1969). Ovarian antigen-specific Tregs have been shown to accumulate strategically in the ovarian regional LN of normal mice. Whereas 0.5 million Tregs pooled from all LN are required to suppress autoimmune ovarian disease

(AOD), suppression was accomplished with 30,000 Tregs from the ovary-draining LN alone. The enrichment of disease-specific Treg in regional LN applies to the suppression of other autoimmune diseases (Setiady et al., 2006; Samy et al., 2008; Wheeler et al., 2009). Importantly, the regional LN-specific enrichment of organ-specific Treg function is maintained by tissue antigens from the normal target organ. Thus the ablation of prostate antigen led to the loss of prostate LN-specific Treg enrichment, but enrichment is restored upon prostate antigen reexpression (Setiady et al., 2006). The preferential distribution of antigen specific Treg in regional LN is now confirmed at the level of antigen-specific Treg numbers and Treg function (Leventhal et al., 2016; Malchow et al., 2016). In addition, T cell–receptor analysis in individual T cells indicates that the repertoire of Treg is unique for an individual draining LN, but the repertoire for T effectors is shared among all LNs (Hsieh et al., 2012). Therefore the ovarian autoimmune disease is prevented by antigen-specific polyclonal Treg, whose function and/or number are continuously enhanced by interaction with endogenous tissue autoantigens in the strategic location of the regional LN.

## Experimental Autoimmune Ovarian Disease

### ***Spontaneous Autoimmune Ovarian Disease in the AIRE Null Mice***

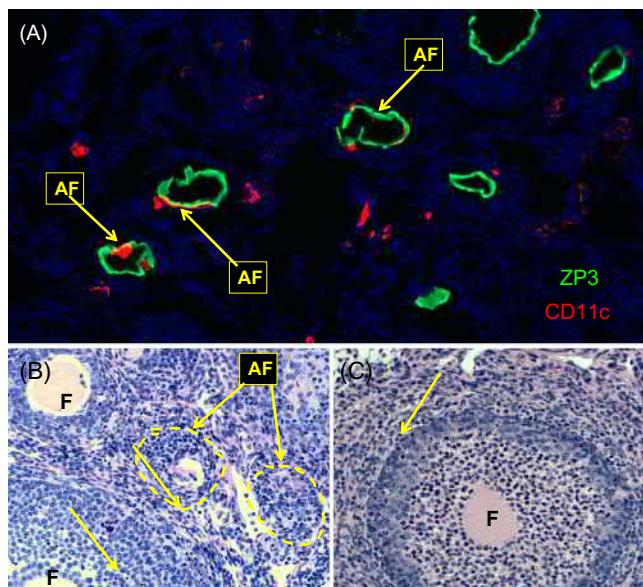

Mice with *AIRE* deficiency resemble humans with the APS-1 syndrome including a high incidence of spontaneous AOD and female infertility (Anderson et al., 2002; Kuroda et al., 2005; Cheng et al., 2007). *AIRE* regulates the transcription of many tissue-specific antigens that are ectopically expressed in thymic medullary epithelial cells. These antigens, presented by unique DC, participate in central tolerance by promoting the development of antigen-specific natural Treg and deleting high-affinity effector T cells (Anderson et al., 2002; Derbinski et al., 2005). In *AIRE* null mice, the absence of thymic ovarian antigen allows the emergence of pathogenic effector T cells against ovarian autoantigen. The major target autoantigen resides in oocyte cytoplasm (Cheng and Nelson, 2011), including NALP5 (or Mater) (Tung, unpublished data). NALP5 antibody is also detected in APS-1 patients.

### ***Autoimmune Ovarian Disease in Day 3 Thymectomized (d3tx) Mice***

Autoimmune disease in d3tx B6AF1 mice commonly targets the ovary, lacrimal gland, prostate, and epididymis (Kojima and Prehn, 1981; Tung et al., 1987a). The depletion of Treg of late ontogeny was initially considered as the mechanism of disease. However, this has been modified by recent studies (Dujardin et al., 2004; Ang et al., 2007; Samy et al., 2008). Tregs with the capacity to suppress autoimmune disease are detectable in normal 3 day-old mice. After d3tx, the mice accumulate more instead of less Treg; in fact, additional Treg depletion from the d3tx mice greatly enhanced disease repertoire, frequency, and severity (Samy et al., 2008). Monteiro et al. (2008) also reported that enhanced effector T cells in a lymphopenic environment are associated with the imbalance in Treg and effectors, and possibly modified thymic T-cell repertoire. Importantly, diseases in the d3tx mice are effectively prevented by CD4+ T cells transferred from normal donors (Sakaguchi et al., 1982; Smith et al., 1991). This key experiment ultimately led to the discovery of the CD25+ Foxp3+ CD4+ Treg (Sakaguchi et al., 1995; Fontenot et al., 2003; Hori et al., 2003). In d3tx mice, effector CD4+ T-cell activation is detected in the regional LN (Alard et al., 2001). This is the same location where the antigen-specific exogenous Tregs accumulate and suppress AOD and effector T-cell and B-cell responses (Samy et al., 2005).

### ***Autoimmune Ovarian Disease in Adult Mice Immunization with Zp3 Peptide (pZP3) with T- and B-Cell Epitopes in Adjuvant***

AOD was first induced in rabbits and dogs by immunization with heterologous zona pellucida (ZP) in CFA (Wood et al., 1981; Mahi-Brown et al., 1982). Since then, significant disease mechanisms have been elucidated by studies in mouse AOD inducible by a novel 13-mer peptide from mouse ZP 3 (pZP3). The pZP3 contains a pathogenic T-cell epitope and a native B-cell epitope (Rhim et al., 1992). First, microbial and other tissue peptides sharing a limited number of critical residues with pZP3 also induced AOD, documenting molecular mimicry at the effector T-cell level (Luo et al., 1993; Garza and Tung, 1995). Second, AOD is inducible by adoptive transfer of pZP3-specific Th1 or Th2 clones. Th1 pathogenic T cells require both CD28 and CD40 costimulatory pathways for activation and disease induction (Griggs et al., 1996). pZP3-specific Th2 cells produce IL4 and IL5 and elicit AOD with dominant eosinophilic inflammation (Lou et al., 2000; Agersborg et al., 2001). A strong murine Th2 autoimmune response to pZP3 is driven by the enteric nematode (the rodent pinworm), a common environmental factor, with neonatal mice being the most susceptible. Neonates injected with pZP3 in water without adjuvant

**FIGURE 62.4** Locations of tissue inflammation and types of inflammatory cells in AOD induced by passive transfer of murine ZP3 specific T-cell clones. (A) T-cell clones alone target the atretic follicles (AF) (arrows with outline) and spare the intact ovarian follicles (no arrow). The zona pellucida that surround oocytes is decorated by a fluorescent Ab to ZP3. (B) Concomitant transfer of T cells and IgG ZP3 antibody results in retargeting of the inflammation into the intact ovarian follicle (C). The transfer of Th1 clones in (B) results in monocytic AOD, whereas transfer of Th2 clones in (C) results in eosinophil-rich AOD. (A: immunofluorescence staining; ZP3 green, CD11c red, x200; B and C: H and E, x200.)

developed severe Th2 AOD and Th2 memory (Agersborg et al., 2001; O’Leary et al., 2008; Lloyd et al., 2010). Notably, monocyte-dominant and eosinophil-dominant ovarian inflammations also exist in human AOD (Lewis, 1993). Research on the pZP3 model also uncovered unique mechanisms of autoantibody induction and its role in disease. Third, mice immunized with a truncated pZP3 T-cell epitope that lacks B-cell epitope rapidly produced antibodies to ZP3 determinants outside the pZP3, including other ZP antigens (Lou et al., 1996; Bagavant et al., 1999). This amplified antibody response is driven by endogenous ovarian antigens and occurs within 7 days. This suggests that autoreactive B cells are not tolerant of the ovarian antigens. The study provided the first definitive evidence for a diversified autoantibody response driven by endogenous antigens (antibody epitope spreading) (Lou and Tung, 1993). Although AOD is not induced in adult mice by ZP antibodies alone, the antibody can strongly influence the distribution of AOD induced by CD4+ T cells. Normal atretic follicles in the ovarian interstitial space, containing the ZP3 antigen and CD11c+ DCs, are major targets of pathogenic CD4+ T cells (Fig. 62.4A). By sparing the mature ovarian follicles, a pure T cell-mediated interstitial oophoritis does not affect mouse fertility (Fig. 62.4B) (Bagavant et al., 1999). However, when ZP3 antibody is bound to the ZP, it redirects the interstitial T-cell inflammation into the mature ovarian follicles (Fig. 62.4C), causing ovarian atrophy and infertility (Lou et al., 2000). Finally, although the antibody does not mediate adult AOD, it induces a unique and severe AOD in the neonatal mice (nAOD).

#### **Neonatal AOD Induction Involves Innate and/or Adaptive Immune Responses Requiring the Neonatal NK Cell with Unique Pathogenic Capacity**

AOD is induced in neonatal mice by antibody injection, or by transplacental transfer of IgG antibody against a ZP3 B-cell epitope (Setiady et al., 2003, 2004; Rival et al., 2014). First, ZP3 nAOD occurs only in neonatal mice that receive the ZP3 antibody between day 1 and day 5 of life. Second, nAOD occurs in both wild-type mice and RAG null mice; the wild-type mice develop a de novo neonatal CD4+ Th1 pathogenic response to ovarian antigens. Third, the neonatal natural killer (NK) cells are absolutely required in AOD that occurs in wild-type or RAG null mice. The NK cells are activated by the ovarian immune complexes via their Fc $\gamma$ RIII. Third, the unique pathogenicity of neonatal NK cells is due to their deficiency of LY49I inhibitory receptor, which is increased after 7–10 days of life. Fourth, the increased susceptibility of newborns to nAOD is unrelated to ontogenetic differences in the ovarian microenvironment (Setiady et al., 2003). And finally, the resistance of nAOD beyond the neonatal time window is caused by Treg suppression, and the window of nAOD susceptibility is extended beyond day 7 after Treg depletion (Setiady et al., 2003, 2004).

### Clinical Autoimmune Disease of the Ovary

Premature ovarian insufficiency (POI) occurs in 1% of women before the age of 40, with amenorrhea, sex steroid deficiency, and elevated levels of gonadotropins (Conway, 2002; Rees and Purdie, 2006; Rebar, 2009; La Marca et al., 2010). POI has known genetic, developmental, and environmental causes, but many are idiopathic. The evidence for an autoimmune basis include circulating autoantibodies against ovarian targets, coexistence with other autoimmune diseases, response to immunosuppressive therapy, and ovarian lymphocytic infiltration (Kim et al., 1995; Hoek et al., 1997).

Human AOD is best documented in POI patients with adrenal autoimmunity; they, in fact, produce antibody to antigens shared by the two organs (Hoek et al., 1997; Bakalov et al., 2005). A percentage of 2–10 POI cases show this association (LaBarbera et al., 1988; Betterle et al., 1993; Kim et al., 1997; Bakalov et al., 2002), which can manifest as part of the APS-1 or type 2. APS-1 patients have mutations in the *AIRE* gene on chromosome 21 (Nagamine et al., 1997; Finnish-German APECED Consortium, 1997). Kriegel et al. (2004) demonstrated that patients with this disease exhibit a defective Treg function. Antibodies against antigenic enzymes common to ovarian theca cells, Leydig cells, and adrenal gland include cytochrome P450 side-chain cleavage enzyme, 17- $\alpha$  hydroxylase, 20-lyase, and 21-hydroxylase (CYP21). Indirect immunofluorescence on frozen adrenal gland sections and CYP21 antibody detection by radioimmunoassays are sensitive diagnostic tests (Falorni et al., 2002a,b; Dal Pra et al., 2003). Female APS-1 patients with infertility and parathyroid disease also develop a high prevalence of autoantibody that targets the oocyte cytoplasmic NALP5 antigen (Alimohammadi et al., 2008). POI also occurs as an independent AOD, which can result in unsuccessful in vitro fertilization (IVF) embryo transfer therapy. Recent studies have identified serum antibodies from POI patients that target ovary-nonspecific antigens including alpha actinin 4, heat shock 70 protein 5, and actin beta (Mande et al., 2011); and mice immunized with their peptides develop loss of ovarian structure and partial fertility reduction (Mande et al., 2012).
