# Autoimmune Disease: Reflections and Projections

Noel R. Rose

Department of Pathology, Brigham and Women's Hospital/Harvard Medical School,  
Boston, MA, United States

## OUTLINE

Foreword	3	Genetics and Exposures	6
Personal Introduction	3	Epidemiology and Prediction	7
Autoimmunity and Autoimmune Disease	4	Acknowledgment	8
Clonal Balance and Regulation	5		

## FOREWORD

The overriding message of this book is that autoimmunity is a common phenomenon in normal individuals, but that it may be a signal of disease, and play a primary or secondary role in the disease process. Autoimmune diseases are diverse because they occur in differing anatomical sites, but they share many key pathogenetic features. In human medicine, they represent a category of disease and benefit from considering them as a family, sharing a genetic pool and experiencing many similar exposures. Most of this book, therefore, is devoted to descriptions of the human diseases that are most firmly established to be the consequence of an autoimmune response. Other chapters of the book detail the common features, their genetic, molecular, and pathologic significance, and their application to diagnoses and treatments.

## PERSONAL INTRODUCTION

I began my career in immunology when I was a student at the University of Pennsylvania School of Medicine in the years 1948–51. I was fortunate to receive a fellowship at the University's Center for the Study of Venereal Diseases. Syphilis and other sexually transmitted diseases had undergone the expected increase during World War II and remained a major public health problem in the immediate postwar years. Most of my time was devoted to my basic research on *Treponema pallidum*. My sole clinical responsibility at the center was to assist in a study of the efficacy of the newly available drug, penicillin, in patients with primary syphilis. We were provided with samples of chancre fluid on admission to the clinic. Following penicillin therapy, samples were taken daily until all the spirochetes were inactive. My job was to enumerate the proportion of viable *T. pallidum* under the darkfield microscope. With a little practice, it was quite easy to recognize the living *T. pallidum* by its well-named “queenly motion,” a dignified profile worthy of royalty. Other dermal spirochetes showed jerky movements suggestive of plebeians.

At this time, the field of syphilis serology was undergoing a major resolution, occasioned by the introduction of the treponemal immobilization test (TPI) by Robert Nelson and Manfred Mayer at the Johns Hopkins University. As the name suggested, the assay was based on the loss of motion of viable *T. pallidum* produced by antibodies (and complement) from patients. This test represented the first diagnostic procedure for demonstrating antibodies specific for the pathogen rather than the standard "Wassermann test" used in various formats in the diagnosis of syphilis. Intrigued by the fact that the TPI depended upon a loss of motility, I wondered if the antibody reacted with flagella of the organism. It was not known whether *T. pallidum* had flagella or moved by its spiral motion. My first publication was an electron microscope study of spirochetes showing that they do have flagella-like structures. I never had an opportunity to go on with the hunch that syphilitic patients produce antibodies to flagellar antigen.

## AUTOIMMUNITY AND AUTOIMMUNE DISEASE

The Wassermann test mentioned above was devised by Wassermann et al. at the Robert Koch Institute in Berlin in the early 1900s (Chapter 2, Autoimmunity: A History of the Early Struggle for Recognition). In its many modifications, it quickly became the standard serologic test to assist in diagnosis and in following the treatment of patients with syphilis (Chapter 69). The antigen to which the Wassermann antibody is directed was later characterized by Pangborn at the New York State Health Department as a phospholipid and named cardiolipin because of its relative abundance in heart tissues. Cardiolipin, a component of cell wall, is found in differing amounts in virtually any organ of the body and in any vertebrate. Despite a great deal of speculation over the years, cardiolipin has never been shown to play a pathogenic role in syphilis even though its specific antibody is still of great value in recognizing and following the infection. It represents the first autoantibody widely used as a diagnostic reagent in the clinical laboratory. One might speculate that had *T. pallidum* not already been identified as the cause of syphilis, cardiolipin, or a replica might have been considered the causative agent of an "autoimmune" disease, syphilis.

The gradual acceptance of autoimmunity as a frequent consequence of a normal immune response and of disease as an occasional consequence of autoimmunity is described in Chapter 2. Briefly, studies of human immunology began near the end of the 19th century with experiments on infection by Roux and Yersin at the Pasteur Institute showing that several major human diseases such as tetanus and diphtheria are attributable to production by the respective pathogen of a specific toxin. Behring and Kitasato produced a disease-specific antibody to the toxin could treat or even prevent the disease. Even in other human diseases in which there is no special toxin, an immune response could provide protection.

Soon afterwards, Jules Bordet showed that an immune response was generated by parenteral injection of even harmless substances, such as red blood cells from another species. Thus immunology became the physiological science not only of infection but of recognition of substances foreign to the host.

A natural follow-on question raised at the time is whether the immune response can be generated by injection of molecules of the host itself. Early experiments clearly showed that antibodies could be induced quite regularly to isolated sites such as the eye or the testis. Production of these antibodies were sometimes associated with disease (Chapter 2).

Paul Ehrlich found that he could produce antibodies to red blood cells of most other goats but never to the immunized donor goat itself. He suggested that there were natural barriers to such autoimmune responses, because they could result in harm. These experiments were widely interpreted by most immunologists to suggest that immune responses to the host itself were not possible. Reports that autoantibodies could be the agents of disease were greeted with the greatest skepticism. A change in thinking followed research on inflammation as a consequence of immunization.

The concept of inflammation as the body's response infection or other cell injury goes back to the earliest days of medicine. Metchnikoff pointed out that, although normally a method of protection, inflammation that exceeds its normal boundaries can itself cause disease. In contrast to immunity, inflammation is nonspecific; that is, it does not target to the specific inducing molecule. The major cells initiating the inflammatory process such as polymorphonuclear and mononuclear cells broadly respond to nonself or altered-self substances. They are not capable of distinguishing fine differences among molecules as can the specialized lymphocytes of the immune system (Chapters 4, 10 and 11).

By the 1950s, immunology crossed the line and recognized that uncontrolled inflammation induced by an autoimmune response can cause disease in the host. This dramatic change in thinking can be related to the introduction of a number of new technical advances in immunology that opened previously impossible opportunities. They included novel methods for separating mixtures of antibodies or antigens in gels, localizing antibodies in tissues by labeling them and providing more sensitive procedures for identifying and quantitating circulating antibodies. These methods showed that antibodies capable of reacting with antigens of the host are commonly found normal animals and in healthy individuals. When present in heightened amounts, beyond a population-based "normal" range autoantibodies were often associated with, and predictive of, disease (Chapters 69 and 70). On occasion autoantibodies can be acknowledged directly as a causative agent of pathology based on accidental or deliberate transfer of the autoantibodies between human subjects. Most of the advancement in the field, however, has depended on investigating genetically defined animals in which cellular manipulation and transfer can prove that autoantibodies or selected lymphocytes, even in the absence of antibody, can cause of similar disease. Animal experiments were particularly convincing in instances where the human disease involves inflammation in a specific organ site such as the brain or the thyroid gland [Chapters 40 and 51]. Other diseases more often systemic can be modeled in animals by selection or by genetic manipulation [Chapters 30 and 31]. By the early 1980s, the list of diseases reputed to be caused or significantly aggravated by autoimmunity, based on firm experimental evidence, increased several folds.

Concurrently, the immune response itself was dissected with greater precision. The clones of B cells as the source of specific autoantibodies (Chapters 8 and 9) provide the basis for clonal-based therapies (Chapters 71 and 72). Clonal definition of T cells based on antigen specificity is a bit more difficult because additional limitations are placed on T-cell recognition. It requires help from cells bearing the corresponding major transplantation markers which serve as antigen-presenting cells, to be discussed later. Despite their clear association with autoimmune-induced inflammatory diseases, autoantigen-specific T cells are more often more conveniently identified and measured through cell surface markers or by the cytokine products generated by living, activated cells rather than by direct antigen binding (Chapters 5 and 6).

The realization that self-reactive B cells and T cells are plentiful in normal individuals raised the question that Ehrlich had considered: Will they do harm? Disease due to autoimmunity is relatively uncommon compared to the frequency of autoimmune lymphocytes because evolution has provided the host with devices to tolerate them. Much of the knowledge of tolerance came from studies on transplantation which proceeded in tandem with research on autoimmune disease in the 1950s and 60s.

## CLONAL BALANCE AND REGULATION

The experimental basis of specific immune tolerance was established by Medawar et al. Their first experiments were inspired by the original observation of Ray Owen. He reported that cattle exposed in utero to nonidentical blood cells can tolerate these cells without the expected immune response. Medawar supported these observations by transferring spleen cells into genetically different new-born mice. He found that the recipient mouse tolerated skin grafts from donor mice.

MacFarlane Burnet realized that these experiments provided an alternative to the then-prevalent instructive theories of antibody production. Those earlier theories suggested that the broad, almost infinite, recognition capacity of the cells of the immune system was achieved by instructions given by the antigen itself. Burnet proposed that the role of antigen may be to select its counterpart "immunocyte" (lymphocyte) from a large repertoire of T cells and B cells. The selected ones then multiplied and produced a clone of identical antigen-specific lymphocytes. Burnet further envisioned that an antigen-driven negative selective process takes place during the embryonic development of immunologically active lymphocytes. In that way the immune repertoire encompasses the universe of nonself-antigens but eliminates reaction to self-antigens.

The antigen-selection model became the prevalent explanation for self-tolerance but left open the question of how autoimmunity could ever occur. Burnet's first suggestion was that autoimmunity may represent a chance mutation, resulting in production of a "forbidden clone." Experimental evidence supporting this view, however, has been meager because autoimmune responses are rarely mono- or pauciclonal. More commonly negative selection is incomplete, so that a small population, mainly of low affinity T cells or B cells, escapes complete elimination. Small numbers of self-reactive lymphocytes are not uncommon in the blood. Based on their low frequency and low affinity, they may never inflict pathologic effects. They do, however, represent a potential risk for pathogenic autoimmunity.

If the self-antigen is presented in a particularly potent manner even low affinity T cells and B cells can be stimulated into action. These conditions prevail when an antigen is given with a powerful adjuvant to potentiate the response. In inducing experimental models of autoimmune disease, the appropriate antigen is commonly administered with complete Freund adjuvant containing both a mycobacterial peptide and selected mineral oil. This method is used in producing models of organ-specific autoimmune disease in experimental animals. Autoimmune diseases have often been associated with a prior infection that provides an adjuvant effect (Chapters 21 and 70). In other instances the stimulus from a viral infection or environmental agent may serve as an adjuvant (Chapters 20 and 64).

Good health of the immune system depends upon maintaining homeostasis through a proper balance between the signals that may stimulate clones of self-reactive lymphocytes and those that tend to suppress them. I suggested several years ago that the term “clonal balance” is more appropriate than clonal selection for describing a healthy immune system. It is likely that multiple mechanisms are in place in most individuals most of the time that maintain favorable clonal balance. Some of these regulatory agents may be found within the immune system itself such as suppressor B cells, T cells, and monocytes. Additional signals come from other regulatory systems such as the endocrine system. The sex bias, usually favoring females, and age-related susceptibilities represent the close interaction between endocrine and immune systems (Chapter 24). Recent studies of neurologic and psychological disorders and autoimmune disease exemplify comparable interactions, particularly through the generation of mediators that affect both immunologic and neurologic responses. The availability of multiple, overlapping regulatory mechanisms is the most effective mechanism for assuring a well-balanced immune system.

Strong evidence supporting the importance of clonal balance in human subjects has come from recent investigations on immunologic approaches on cancer therapy. The oncologist may administer drugs designed to inhibit critical steps (checkpoints) that regulate self-directed immune responses, including antigens on cancer cells. Checkpoint inhibitors are drugs that facilitate the development of a cancer-specific immune response. In some instances, however, they can also trigger an immune response to normal self-antigens and cause autoimmune disease. Two diseases that were considered rare are relatively frequent outcomes of efforts to alter the normal immune homeostasis. Well-studied examples are hypophysitis (Chapter 43) and myocarditis (Chapter 64).

Why does the body nurture and maintain self-reactive immune cells? One possibility is based on the well-described phenomenon of molecular mimicry; that is, antigenic determinants (epitopes) found in other organisms, even in plants, may closely resemble epitopes present in the body of the host. In some instances, the mimicry may be involved in inducing a pathogenic autoimmune response (Chapter 21). The complete elimination of these cross-reacting lymphocytes could significantly deplete the extensive immunologic repertoire that is the basis of clonal selection theory.

## GENETICS AND EXPOSURES

The next theme for research on autoimmune disease reached prominence in the 1970s based on understanding that immune system function follows the principles of Darwinian selection. The growing acceptance of autoimmune diseases as a family of related diseases reflected itself in a growing number of clinical reports of clustering of different autoimmune disorders. A patient with one autoimmune disease tends to have a greater likelihood of a second or even third autoimmune disease suggesting shared heredity and/or environment. Some of the reported cooccurrences were quite striking; for example, an individual with autoimmune thyroid disease a heightened risk of autoimmune diabetes due to shared genes or common exposures (Chapters 40 and 70).

A concurrent pathway of research supporting a genetic component of autoimmune disease came from long-standing investigations of genetically defined rodents, especially rats and mice. These investigations, dating back to the 1930s by Peter Gorer in London and George Snell at the Jackson Laboratory, recognized that transplantation of tumors between experimental animals depended mainly upon the genetic constitution of the animals rather than on tumor-specific antigens. The studies led to development of inbred strains of rodents in which histocompatibility genes were defined. By the 1960s, it was recognized that there is a cluster of genes that are pre-eminent in controlling acceptance of tumor and tissue transplants. The major histocompatibility complex (MHC) dominated acceptance of allografts in all of the animals investigated, including humans (Chapters 23 and 26). Hugh McDevitt and Michael Sela, taking advantage of these genetically defined animals, showed that the MHC regulated the immune response to simple synthetic or small natural peptides.

Investigations on autoimmune disease began in the late 1960s when Vladutiu and I were able to induce experimental autoimmune thyroiditis in inbred mice, taking advantage of the many defined strains provided by the Jackson Laboratory. We were able to discern that the autoimmune response to a large protein molecule, thyroglobulin, was determined genetically by the mouse MHC. Later we were able to report that a similar MHC-related predominance was present in spontaneously developing thyroiditis in partially inbred chickens. Parallel studies of other autoimmune diseases including both experimentally induced models and in spontaneous examples rapidly followed and genetic studies in humans became the focus of extensive investigation.

In addition to the MHC as the dominant inherited determinant of resistance to autoimmune disease in experimental animals and humans, many other genes make small but significant contributions. Frequently these genes turn out to be the controlling factors already known to be important in regulating the normal immune response as well as controls of cancer immunity.

These genes, acting collectively, contribute to the broad susceptibility to autoimmune diseases. Yet a few examples have been described in which a single gene locus dictates susceptibility to a group of autoimmune diseases. This turned out to be particularly striking in the polyendocrine syndromes where autoimmune regulatory genes predominate by preventing expression in the thymus of certain organ-specific antigens the endocrines during negative selection (Chapter 39).

Despite the importance of genetic regulation, susceptibility to autoimmune disease is not attributable mainly to heredity. Among even highly inbred rodents and identical human twins, there are still differences in the occurrences of autoimmune disease. Monozygotic twins may show a statistically significant cooccurrence but rarely develop the same autoimmune disease at the same time. These differences may be attributable to the well-known postgermline changes. There is already solid evidence that epigenetics plays an important role in determining autoimmune susceptibility (Chapter 25). Genetically identical animals differing only in the sex-related genes can be dramatically different in susceptibility (Chapter 24). Although in most instances, the bias favors females, few autoimmune diseases are more prevalent and sometimes more severe in males.

In addition to their own genome, humans carry a second population with its own genetic constitution, the microbiome (Chapter 19). The interaction between a human host and its bacterial inhabitants calls attention to the importance of nutrition in immune response. The microbial population, once established during infancy, tends to be quite stable in health but can change remarkably with illness. Working out the cause-and-effect relationship remains an intriguing problem for research.

One of the great voids in research on autoimmune diseases is the lack of firm knowledge of when and how noninfectious agents in the environment may instigate a pathogenic autoimmune response (Chapter 2). Studies of experimental animals have made it clear that exposure to nonviable agents such as mercury have vastly different effects on autoimmune responses. Studies on humans have been difficult because it is rare that a single environmental agent can be identified and studied in isolation. Generally, large populations must be investigated over long periods of time to minimize the effects of background confounders. Other than governmental agencies, few institutions are able to provide the infrastructure for such large-scale, long-term studies. Yet it is likely that such exposures represent the reason that many of the autoimmune diseases appear to be increasing in prevalence, particularly in the more industrialized societies.

One example of reductionist experiments carried out on human subjects is the administration of vaccines (Chapter 22). Because of their importance in maintaining a high standard of public health, vaccine safety remains a matter of great concern. Despite the hundreds of millions of vaccinations administered around the world, rarely is there a statistically valid increase in a well-recognized disease. A small cohort of individuals receiving seasonal influenza vaccine in 1967 developed Guillain–Barré syndrome. The basic biologic for this unique event has not been elucidated. Ongoing studies of narcolepsy may provide a second example of influenza vaccine–related autoimmune disease. Here the potential antigen must be better defined.

Vaccination is immunology's greatest success. Vigilance must be maintained for public health purposes but also for opportunities to identify critical early steps in the induction of pathogenic autoimmune responses in humans.

## EPIDEMIOLOGY AND PREDICTION

As indicated previously, remarkable progress has been made in detailed genetic studies of susceptibility to autoimmune disease in experimental animals. In contrast, epidemiologic investigations in humans have too often been indecisive. Large populations must be studied over time to track all but the most prominent genes.

Future volumes of "The Autoimmune Diseases" will certainly need to provide a greater understanding of the epidemiology of autoimmune disease. Only in that way can we determine who is most likely to develop one of these diseases, what the outcome may be, and what methods could be instituted to treat or prevent them. Such epidemiologic study is emerging through technologic advances in handling large amounts of information. They permit us for the first time to study enough individuals over long periods of time to look for correlations and associations with environmental and dietary exposures.

At the same time, the availability of clinical data collected over the life-span allows us to focus with more precision on individuals and permit a rational definition on a personal basis of normality and departure from normality. The clinical laboratory will not have to depend upon population-based normal ranges but may also look more precisely at departures from personal norms, representing an individual's established homeostasis.

At this time, the best predictor of autoimmune disease remains the antibody. It is well established that in many autoimmune disease elevated levels of autoantibodies appear well before clinical evidence. Combined with family history or genetic analysis, they open the possibility to earlier intervention.

The most advanced studies have been carried out with autoimmune diabetes (Chapter 70). A combination of genetic data obtained either from family history or actual genome studies have been coupled with appearance or rise of multiple relevant autoantibodies. These early warning signs convey with a high degree of probability that a child will develop diabetes. The next goal will be the design of benign interventions; that is, procedures that could be instituted in a clinically well child that will prevent the occurrence of a disease without itself producing injury.

New, more targeted treatments appear almost daily and promising opportunities for the specific inhibitors of key steps of pathogenesis are on the horizon (Chapters 70 and 72). The future management of the autoimmune diseases will certainly be intervention before irreversible damage has occurred. Ian Mackay and I hope that this book will help to achieve that goal.

## Acknowledgment

I thank Arthur Silverstein and Jorge Kalil for their corrections, suggestions, and wise advice.

# Autoimmunity: A History of the Early Struggle for Recognition

1955-1965 [was] the decade marked by the question, Does autoimmunity exist? [Rose and Mackay \(1985\)](#)

It is one of the curious situations in science that certain well-demonstrated facts are refused entry into the body of accepted knowledge and may become so effaced from the collective memory that they must be rediscovered many years later in order to gain acceptance. Such was the case in immunology, with [Ehrlich's \(1897, 1900\)](#) suggestion that an immune response is initiated by the antigen activating an antibody receptor on the surface of a cell, or with [Clemens von Pirquet's \(1910\)](#) explanation of serum sickness as an immune complex disease. More pertinent to the present discussion, the same was also true of [Donath and Landsteiner's \(1904\)](#) demonstration that paroxysmal cold hemoglobinuria (PKH) is an autoimmune disease.

The cause of this selective amnesia may merely be an earlier contradictory pronouncement by a respected leader in the field; sometimes it lies in an inability to fit the new finding into the working paradigm that guides thought in the field, as the historian of science [Kuhn \(1970\)](#) has suggested. In the end, it may be that [Fleck \(1979\)](#) was right when he proposed that the acceptance of a fact in science depends less upon its truth than upon its acknowledgment by the leaders in the discipline (whom Fleck called the Denkkollektiv). Ultimately, the truth in science will emerge, although sometimes it takes a very long time.

The earliest discoveries in immunology were made in the context of the battle to ward off infectious diseases. These included [Pasteur's \(1880\)](#) preventive vaccines, [Metchnikoff's \(1884\)](#) bacteria-eating phagocytes, and [Behring and Kitasato's \(1890\)](#) curative antidiphtheria and antitetanus sera. It seemed evident that these efficient mechanisms for the protection of the body were Darwinian adaptations designed to prevent or control infectious disease, a widespread view in the 1890s even after it was demonstrated that specific antibodies might be formed against such innocuous antigens as egg albumin, bovine serum proteins, and sheep red cells. It seemed unthinkable at the time that a grand mechanism designed to prevent disease might turn the tables and cause disease. So well established did this concept of a benign immune system become that demonstrations that antibodies

might cause disease were either disregarded entirely or else ascribed to “aberrant” antibodies acting under the influence of a “misdirected” immunity (Silverstein, 2009). This was how the early discoveries of serum sickness, hay fever, asthma, and a variety of other immunopathological phenomena were treated by mainstream immunology during the first half of the 20th century.

It is beyond the scope of this chapter to discuss the entire history of the unwillingness to accept that the immune response might lead to a variety of harmful outcomes (which we now describe under the rubric “immunopathology”). We shall limit the present discussion to the way in which a subset of the whole, autoimmune diseases was regarded (or rather disregarded) during the first half of the 20th century. This sample should provide a quite adequate representation of the way that early immunologists dealt with the paradox presented by the almost oxymoronic term immunopathology.

## THE SEARCH FOR AUTOANTIBODIES

### Horror Autotoxicus

A new mechanism that functions to mediate immunity—the destruction of bacteria by humoral antibodies—was discovered by Pfeiffer (1894). Then Bordet (1899) showed that not only were bacteria lysed by thermostable antibody and a thermolabile substance that he called alexine (soon termed *Komplement* by Paul Ehrlich), but that mammalian erythrocytes could be hemolyzed specifically by two analogous agents. Here was a technique that would see a broad application in many areas of immunology (Silverstein, 1994), not least in connection with the question of whether an individual could form antibodies against its own self. Two consequences of Bordet’s report were immediately apparent. Landsteiner (1900) became interested in red cells and discovered blood groups in humans (for which he received the Nobel Prize in 1930). Then Ehrlich and Morgenroth (1900, 1901) launched a series of studies of immune hemolysis in order to develop additional support for Ehrlich’s (1897, 1900) side-chain theory of how antibodies are produced and how they function. It was Ehrlich’s interpretation of his hemolysis experiments that would play a major role in the early history of autoimmunity. These hemolysis experiments are described and analyzed in detail by Silverstein (2002).

During the course of these experiments, Ehrlich and Morgenroth immunized many different species with the red cells of other species. They also immunized animals with the red cells of other members of their own species and even tried to immunize animals with their own red cells. In every case, they were able to demonstrate the production of xenoantibodies and isohemolysins, but autohemolysins were never observed. This led inexorably and logically to the conclusion that animals could not make autotoxic antibodies to any self-antigens, a postulate that Ehrlich named *horror autotoxicus*. Indeed, he concluded, “It would be dysteleological in the highest degree, if under these circumstances self-poisons of the parenchyma—autotoxins—were formed” (Ehrlich, 1902). But Ehrlich was not the only one who responded to Bordet’s publication on immune hemolysis. If red cells could stimulate an immune response, why not other tissues and organs? In no time, attempts were undertaken to immunize animals with all types of cells and tissue extracts, especially at the Pasteur Institute in Paris where Bordet had worked. As expected, cytotoxic xenoantibodies against a variety of tissues were reported; indeed, a volume 14 of the Annales de l’Institut Pasteur was largely devoted to these studies, including a review of antisubstance antibodies by Metchnikoff (1900). Most surprising was a report by Metalnikoff (1900) that some animals were able to form antibodies against their own spermatozoa. But while these autoantibodies could destroy the sperm in vitro, they seemed to have no effect in vivo on the viable sperm in the immunized animal.

Ehrlich was not impressed! These are not “autocytotoxins within our meaning,” said he, since they do not cause disease (Ehrlich and Morgenroth, 1901). Here was the true meaning of *horror autotoxicus*: not that autoantibodies cannot be formed, but that they are prevented “by certain contrivances” from exerting any destructive action (Goltz, 1980). Due in part to Ehrlich’s worldwide prestige and to the fact that an autoantibody seemed so obviously counter-intuitive, *horror autotoxicus* found broad acceptance as a guiding principle. Indeed, so firm was the conviction that autoimmune disease was impossible that everyone soon forgot Ehrlich’s suggestion that an autoantibody might exist without causing disease. It would be some 80 years before the important distinction would be made between autoimmunity and autoimmune disease (Rose and Mackay, 1985). The modern finding of normally circulating autoantibodies and of “antiself” immunocytes, perhaps best exemplified by Cohen’s (2000) concept of “the immunological homunculus,” has shifted much of current immunological research in the direction of immunoregulation (the present term for Ehrlich’s “contrivances”).

## The Nature of Ehrlich's "Contrivances"

Paul Ehrlich was nothing if not logical. He proposed one of his typical thought-experiments to examine the possible outcomes (Ehrlich and Morgenroth, 1900). Suppose the existence of a self-antigen x. Then, since antibody formation results from the interaction of antigen with preformed cell receptors according to the side-chain theory (the first selection theory!), the following two possibilities are seen:

1. The host possesses no anti-x cell receptors. Therefore no autoantibody response and thus no disease can occur. [Here is, in embryo, the later clonal deletion (central tolerance) idea! If the cell possessed all other receptors, what could have happened to the anti-x?]
2. The host does possess anti-x cell receptors on its cells. Therefore autoanti-x formation is possible. But the host also possesses (by definition) the self-antigen x on its cells, with which the anti-x may react to stimulate the formation of anti-anti-x. (Remember, Ehrlich knew nothing about lymphocytes and conceived that all cells possess the full repertoire of receptors and thus may be specifically stimulated to form all different antibodies.) But the specific site on the anti-antibody should be identical with that on the original antigen, since they both are able to react specifically with the antibody combining site! Ehrlich, therefore, concluded that a self-regulating equilibrium would be established between autoantibody and antigen (or anti-antibody) to suppress the development of autoimmune disease. (Here was a regulatory network theory 70 years before Jerne's (1974) idiotype/antiidiotype theory!)

## CHALLENGES TO THE EHRLICH THESIS

### Lens Autoantibodies

The initial flurry of interest in antitissue antibodies quickly subsided as the implications of *horror autotoxicus* gained broad acceptance. But Uhlenhuth (1903) demonstrated the existence of organ-specific antigens by showing that the proteins of the lens are unique to that tissue; they are found nowhere else in the body. Moreover, these antigens are shared by the lenses of different species. Ophthalmologists seized upon this finding to suggest that an immune response to one's own lens might be responsible for the development of senile cataract (Römer, 1905). They showed further that an intraocular inflammation may be induced by the experimental rupture of the lens in the eye of a lens-immunized animal (Krusius, 1910).

Here were observations that would fascinate both ophthalmic clinicians and a later generation of immunopathologists interested in the possible workings of autoimmune disease. First, there was this early preview of what would later be called the "sequestered antigen" concept. Since "self" antigens by definition cannot elicit an immune response, then such antigens as do must be "foreign"—in this case isolated from the immunologic apparatus of the host, such as sperm and lens. Second, Römer and Gebb (1912) concluded that if indeed disease does result from the formation of autoantibodies, this would represent a most unusual occurrence and must be considered as an aberration due to a malfunction of Ehrlich's "contrivances." Here they showed that unlike a future generation, they understood Ehrlich's "law of immunity research" completely.

Interest in the possibility that autoimmunity to lens might lead to disease did not disappear in the years that followed. But whereas the initial studies had been done in the context of the new immunology and were known to all workers in the field, further work was restricted to ophthalmologists and eye departments. Thus a broad clinical study led Verhoeff and Lemoine (1922) to identify numerous cases of lens-induced inflammatory disease, to which they gave the name phacoanaphylaxis, a process which would later be accepted as a true autoimmune disease. Thenceforth, the description would appear routinely in textbooks of ophthalmic pathology, and clinical diagnoses would be made.

### Paroxysmal Cold Hemoglobinuria

Fast on the heels of the lens antigen demonstration came an even more convincing case involving erythrocyte antigens. PKH was a rare disease presenting with signs of intravascular red cell lysis and a resulting hemoglobinuria, following exposure of the patient to the cold. Donath and Landsteiner (1904, 1906) published reports that reproduced in vitro all features of the disease. They demonstrated beyond question that it was due to a peculiar autoantibody in the patient's serum that affixes to his own red cells only in the cold, and mediates hemolysis with complement when the sensitized cells are rewarmed. It was clear from the outset that Landsteiner understood fully

the implications of this discovery and its meaning for Ehrlich's *horror autotoxicus*. Indeed, even Ehrlich's student Hans Sachs gave a somewhat grudging acceptance of the phenomenon and its interpretation ([Sachs, 1909](#)). But again, the implication seemed to be that this was a most unusual exception to the regular scheme, and the implications of PKH as the prototypical autoimmune disease soon vanished almost completely from view.

### Sympathetic Ophthalmia

It had always seemed odd to clinicians that after traumatic injury to one eye, the second eye might spontaneously develop a blinding inflammatory disease even years later. Soon after the discovery of cytotoxic antibodies, the proposal was advanced that sympathetic ophthalmia might be caused by the formation of "autocytotoxins" ([Santucci, 1906](#)). The concept was picked up and given broad currency by one of the foremost ophthalmologists of the day ([Elschnig, 1910a,b](#)). As with autoimmunity to lens, work on the immunology of sympathetic ophthalmia continued, but only in ophthalmology departments. [Woods \(1921, 1933\)](#) reported the presence of antiuveal antibodies in patients with perforating injuries of the globe, and uveal pigment was implicated as the causative antigen ([Woods, 1925; Friedenwald, 1934](#)).

### The Wassermann Antibody

The discovery of the role of complement in immune hemolysis was soon followed by the finding that any antigen–antibody interaction would fix complement nonspecifically ([Bordet and Gengou, 1901](#)). The ability to measure this uptake using a hemolytic assay meant that the antibody could be titrated if specific antigen were available. With the recent identification of *Treponema pallidum* as the cause of syphilis, a serological test for this disease was sought. But since the organism could not be grown in culture, [Von Wassermann and colleagues \(1906\)](#) and, independently, [Detré \(1906\)](#) used extracts of tissues from syphilitic patients as the antigen, and a valuable diagnostic test was born.

Most perplexing, however, was the report from many laboratories that positive tests for syphilis might be obtained as well, using extracts of normal tissues as antigen. This ran counter to the prevailing view that only specific antigen can interact with antibody to fix complement. It appeared necessary to conclude, therefore, that the "Wassermann antigen," being native, must be measuring an autoantibody rather than an antitreponemal antibody. This suggestion was made, in fact, by [Weil and Braun \(1909\)](#) who speculated that the Wassermann antibody is an autoantibody specific for the tissue breakdown products generated in the syphilitic lesions. They suggested further that these autoantibodies exacerbate the disease, and that the brain lesions in tertiary syphilis (paresis) may represent an autoimmune disease directed against neural antigens. (Half a century later, the antigen involved in the Wassermann reaction was identified as a phospholipid named cardiolipin, but why these antibodies are formed is still a mystery, as is their role in the disease process!)

## THE SHIFT TO IMMUNOCHEMISTRY

Despite all these hints that autoimmune diseases might exist, interest in the question waned in mainstream immunology—indeed almost disappeared—for some 40 years, from just before the First World War to the mid-to-late 1950s. This was due in part to the continuing sway of Ehrlich's *horror autotoxicus*. But there was another factor at play, the change in the overall direction of the field of immunology. During the quarter-century prior to the First World War, immunology had been concerned chiefly with medical problems and disease and was pursued almost exclusively by biologists and physician-researchers. It had achieved notable successes in the prevention of some infectious diseases (vaccine development), their cure (serotherapy), and their diagnosis (serology). It had even begun to define several immunogenic diseases (anaphylaxis, serum sickness, hay fever, and asthma). But most of the easy problems had been solved, and further successes in these areas became disappointingly rare. Vaccines were sought, generally unsuccessfully, for the remaining great scourges of mankind: syphilis, tuberculosis, typhus, and the many serious tropical diseases. Few diseases were caused by exotoxins such as diphtheria and tetanus, and thus new serotherapeutic approaches were rare.

Yet other forces were at work. The Wassermann test and its offshoots became so widespread for the diagnosis of disease that it moved from the immunological research laboratory to the clinic. A new discipline, serology, arose that soon became almost independent of the mother discipline, immunology. In the same way,

experimental anaphylaxis and its human disease relations had fever and asthma stimulated the interest of clinicians, who soon took over work in this field and called their new discipline “allergy.” When in a science one research direction reaches the point of severely diminishing returns, its practitioners will usually move to more productive pursuits. So it was with immunology, beginning shortly after the end of the First World War. Karl Landsteiner started working with haptens and soon devoted himself almost entirely to a chemically oriented study of the structural basis of immunological specificity and crossreactions (Landsteiner, 1962). Then Michael Heidelberger studied the immunochemistry of pneumococcal polysaccharides (Heidelberger and Avery, 1923) and introduced a variety of quantitative methods for the estimation of antigens and antibodies, best typified by the popular text written by his students, “Quantitative Immunochemistry” (Kabat and Mayer, 1949).

For more than three decades, the field was devoted largely to studies of structure, specificity, and the thermodynamics of antigen–antibody interactions. The texts and monographs were primarily chemically oriented, and the practitioners were either chemically trained or at least chemically oriented. Even the theories of antibody formation that guided the field, Breinl and Haurowitz’s (1930) and Pauling’s (1940) antigen-instruction concept, were chemical (i.e., nonbiological and non-Darwinian) in spirit. It was easy to assume that a protein might be synthesized according to external instruction; for the chemist, molecules have no evolutionary history.

Given the continuing influence of Ehrlich’s dictum, and the generally nonmedical orientation of the most prominent immunological investigators, it is not surprising that autoantibodies and autoimmune diseases were not among the most popular topics in the research laboratory. This is not to say, however, that there was absolutely no work along these lines. As we have seen, ophthalmologists reported findings in lens-induced disease and in sympathetic ophthalmia, but these were published in specialty ophthalmic journals. In the early 1930s, Rivers et al. (1933) and Rivers and Schwentker (1935) published a series of papers on the production of an experimental encephalomyelitis that only later would be shown to represent an autoimmune process. While these studies are viewed today as important milestones in autoimmunity research, they attracted little attention at the time among immunologists.

The contemporary view of autoimmunity during the 1940s and early 1950s is perhaps best exemplified by the position of Ernest Witebsky, trained in immunology by Ehrlich’s student Hans Sachs and himself a disease-oriented physician. He could say as late as 1954 at the celebration of the centenary of the birth of Ehrlich, “The validity of the law (sic!) of *horror autotoxicus* certainly should be evident to anyone interested in blood transfusion and blood disease. Autoantibodies—namely, antibodies directed against receptors of the same individual—are not formed” (Witebsky, 1954). This from the individual who, only 2 years later with his student Noel Rose, would help refocus interest on autoimmunity with the demonstration of the production of experimental autoimmune thyroiditis! (Rose and Witebsky, 1956; Witebsky et al., 1957).

## THE RETURN OF IMMUNOBIOLOGY

During the late 1930s and 1940s, a series of observations began to question the assumptions that had guided recent thought and experiment in immunology. How could one explain in chemical terms the enhanced booster antibody response or the change with time in the specificity and affinity of the antibodies formed? How to explain the persistence of antibody formation in the apparent absence of antigen? Even more troubling was the lack of relationship between immunity to certain viral diseases and the titer of antiviral antibodies, or the absence of a correlation between antibodies and “delayed” hypersensitivity skin tests like the tuberculin test. Here were basic biological questions that demanded answers—questions with which current theory was unable to cope, and for which it could not even provide experimental approaches. But even more difficult questions arising from biology and medicine would pose further challenges.

Medawar’s (1945) experiments showed that the rejection of tissue grafts was somehow mediated by immunological mechanisms. Then Owen (1945) described the paradoxical situation in which dizygotic twin cattle might share one another’s red cells without being able to mount an immune response to these foreign antigens. Macfarlane Burnet, biologist par excellence, called attention to all of these inexplicable phenomena and hypothesized the existence of a fundamental biological mechanism to explain Owen’s finding—an embryonic process that would suppress the ability to respond to one’s own native antigens (Burnet and Fenner, 1949). This was soon confirmed by Medawar’s group (Billingham et al., 1953) and would be termed immunological tolerance. Yet other observations would emphasize the awakening biomedical movement in immunology—the description of a group of immune deficiency diseases. Taken together, these new questions and phenomena foretold a radical change of direction—what I have termed elsewhere the “immunobiological revolution” (Silverstein, 1991).

**TABLE 2.1** The “Dark Ages” of Autoimmunity

Disease/Organ	Last “classical” contribution	First “modern” contribution
Hemolytic disease	1909	Coombs et al. (1945)
Sperm and testicular	1900	Voisin et al. (1951)
Encephalomyelitis	1905	Kabat et al. (1947)
Sympathetic ophthalmia	1912	Collins (1949)
Phacoanaphylaxis	1911	Halbert et al. (1957)
Thyroid	1910	Rose and Witebsky (1956) and Roitt et al. (1956)
Wassermann antibody	1909	—
Platelet disease	—	Ackroyd (1949)

Adapted from Silverstein, A.M., 2009. *Allergy and immunopathology: the price of immunity*. In: *A History of Immunology*, second ed. Elsevier, New York, pp. 177–209.

Not only did these questions challenge the accepted dogma but they also served to stimulate the entry into the field of a new generation of investigators. These were basic scientists from such fields as genetics and physiology, and clinicians from a variety of medical disciplines. They were unfettered by any allegiance to earlier ideas and techniques and thus could entertain iconoclastic ideas and design novel experiments.

Perhaps the best illustration we may provide of the long period during which immunologists showed little interest in disease may be seen in Table 2.1. Here we list for each organ or disease entity the interval between the last significant study during the “classical” period and the first significant contribution of the “modern” era.

The average hiatus, for those for which both ending and restarting dates can be identified, is about 44 years! This is an extremely long interlude for a field that was only some 70 years old in 1950. In the context of a growing interest in the more biomedical aspects of the immune response, work on autoimmunity thus became respectable. This was due also to the increasing use of Freund’s adjuvant, which made animal models of the various autoimmune diseases more readily available and more reproducible. Advances came rapidly. Coombs et al. (1945) showed with the antiglobulin test that many cases of acquired hemolytic anemia were due to “incomplete” (nonagglutinating) antibodies. Kabat et al. (1947) refocused attention on the immunopathogenesis of “allergic” encephalomyelitis. Collins (1949) introduced a reproducible animal model of sympathetic ophthalmia against retinal antigens. Voisin et al. (1951) showed how to produce an experimental allergic orchitis. Finally, Rose and Witebsky (1956) demonstrated in experimental animals and Roitt et al. (1956) in human Hashimoto’s disease that some forms of thyroid disease might be based upon autoimmune processes. In addition, an understanding of the pathogenesis of some of these diseases was made easier by the increasing appreciation of the fact that not all were mediated by circulating antibodies; some involved the action of subclasses of lymphocytes that originate in the thymus. Some of these—“T cells”—may mediate disease directly, while others cooperate in the process of antibody production.

These new findings not only opened wide the floodgates of autoimmunity studies but stimulated further interest in the more general field of immunopathology as well. This new movement was provided with a theoretical base with Talmage’s (1957) suggestion and Burnet’s Clonal Selection Theory (Burnet, 1959), which emphasized for the first time the biologically important role of cell dynamics in the antibody response. It is no accident that the late 1950s saw the first international conferences on immunopathology (Miescher and Vorlaender, 1958; Grabar and Miescher, 1959) and on the fundamentals of hypersensitivity (Lawrence, 1959; Shaffer et al., 1959). For the first time, in 1963, there appeared a textbook aimed at medical students (Humphrey and White, 1963), and then two comprehensive descriptions of immunological diseases aimed at clinicians (Gell and Coombs, 1963; Samter et al., 1965). It was in the spirit of the new immunology that Mackay and Burnet (1963) could summarize contemporary knowledge in the increasingly active field of the autoimmune diseases. It would also stimulate great interest in the workings of immunological tolerance and other forms of immunoregulation, so critical for an understanding of why autoimmune disease might or might not develop.

The present summary of the early history of autoimmune diseases has been written with almost a sociological approach, emphasizing the importance of major reorientations in the parent discipline for how autoimmunity was viewed. The reader might also be interested in an alternative approach, presented in “Intolerant Bodies: A Short History of Autoimmunity” (Anderson and Mackay, 2014). This is more clinically oriented and includes a more philosophical approach, with emphasis on the important conceptual role of “the immune self.”

## CONCLUDING REMARKS

This, then, is the story of the early stirrings of interest in the possibility that disease might result from an immune response to one's own autochthonous antigens. Perhaps the initial reports were too premature to be incorporated into the received wisdom of the young field of immunology, just as the discovery of the several allergic diseases could not at first be integrated into this system clearly designed to protect us. Certainly Paul Ehrlich's dictum of *horror autotoxicus* contributed to an unwillingness to recognize the full significance of the initial findings of a response to spermatozoa, erythrocytes, and retina. But the mounting challenges to the dogma would eventually prove irresistible, and with the entry into the field of other biological disciplines, autoimmunity (and the broader field of immunopathology) would finally flourish. The more modern history of autoimmunity, resulting from the remarkable modern advances in our understanding of the cellular, molecular, and genetic contributions to the field, will be found in the accompanying chapters in this volume.

Triggers of Autoimmunity	25		

A host of diseases are characterized by the activation of the immune system in the absence of an external threat to the organism. In these diseases, inflammation and tissue damage occur in the absence of trauma, infection, toxin exposure, or tumor growth (Rose and Bona, 1993). These diseases can be characterized as those that display the activation of the innate immune system and an excess of inflammatory mediators, but no evidence of an antigen-specific immune response; familial Mediterranean fever and other inflammasome diseases, Behçet disease, even atherosclerosis, can be considered to fall within this category. Alternatively, there are diseases characterized by an activation of the adaptive immune response with T and B lymphocytes responding to self-antigens in the absence of any detectable microbial assault or tumor invasion. These diseases constitute the vast majority of diseases considered to be autoimmune in origin. There are over 80 defined autoimmune diseases in composite affecting 5%–7% of the population. Moreover, their incidence is increasing (Lerner et al., 2015; Patterson et al., 2009).

## INNATE IMMUNE ACTIVATION

The activation of the innate immune response is a feature of many, perhaps all, autoimmune diseases (Mills, 2011). This activation may be the primary event involved in triggering the disease process. One example is the activation of the innate immune system in systemic lupus due to complement deficiencies that permit an excess accumulation of proinflammatory apoptotic debris (Elkon and Santer, 2012; Macedo and Isaac, 2016; Manderson et al., 2004). Increased production of type 1 interferon is present in first degree relatives of some lupus patients suggesting that this enhanced innate immune activation may be a triggering immune abnormality in these patients (Niewold, 2011). Likewise, inflammatory bowel disease (IBD) is associated with genetic alterations in multiple innate pathways including bacterial sensing, autophagy, and endoplasmic reticulum (ER) stress, leading to an increased inflammatory response to intestinal flora (de Souza and Fiocchi, 2016; Stange and Wehkamp, 2016). The innate immune system also provides critical defense at epithelial barriers; loss of the mucin layer and the antimicrobial peptides that it contains allows access of bacteria to epithelial cells and the activation of myeloid cells that help to initiate disease (Exley et al., 2016; Shikhagaie et al., 2017; Stange and Wehkamp, 2016; Wenink et al., 2017). It is also apparent that the innate immune system can be activated secondarily in autoimmune disease. Immune complexes containing endogenous Toll-like receptor (TLR) ligands, such as DNA, RNA, or citrullinated proteins, can activate dendritic cells (DCs) and other myeloid cells to amplify inflammatory pathways (Green and Marshak-Rothstein, 2011; Sokolove et al., 2011). Tissue injury also leads to the activation of innate immune cell networks (Kawai and Akira, 2010; Miyake and Yamasaki, 2012); thus once autoimmune-triggered tissue injury is ongoing, the innate, as well as the adaptive, immune system is always engaged.

A low threshold for the activation of myeloid cells and differentiation of monocytes to DCs predisposes to autoimmune disease in animal models, and blockade of pathways of the innate immune system can ameliorate many autoimmune diseases. In particular, TLR signaling, both in myeloid cells and lymphocytes, seems to be a critical feature of many autoimmune diseases as deletion of MyD88, a common component of the signaling cascade for several TLRs, and neutralization of HMGB1, a cytokine which synergizes with many TLR agonists, can prevent or treat murine models of diabetes, rheumatoid arthritis, systemic lupus, IBD, and more (Andersson and Tracey, 2011; Herlands et al., 2008; Pagni et al., 2010; Rivas et al., 2012). Cytosolic innate receptors also play a role in the initiation of autoimmune responses; for example, cyclic GMP-AMP synthase (cGAS) deficiency protects completely against Systemic Lupus Erythematosus (SLE) induced by an overabundance of intracellular DNA (Gray et al., 2015a). The success of TNF and IL-6 inhibition in rheumatoid arthritis and of TNF and IL-12 inhibition in IBD also attests to the involvement of the innate immune response in autoimmune diseases. However, even when the innate immune system is involved, some diseases respond better to certain cytokine inhibitors than others. IL-6 inhibition for example is effective for the treatment of rheumatoid arthritis and giant cell arteritis but not for ankylosing spondylitis (Koster et al., 2016; Loricera et al., 2015; Schoels et al., 2013), whereas TNF inhibition is effective for both rheumatoid arthritis and ankylosing spondylitis and for Takayasu's arteritis but not for giant cell arteritis; these differences reflect the different functions of these cytokines but their exact relationship to pathogenesis of each of these diseases is still a subject of investigation (Muratore et al., 2017; Schoels et al., 2013).

Other innate immune cells may also contribute to disease pathogenesis. The role of neutrophils has recently been highlighted in lupus which is characterized by the presence of an atypical neutrophil population that is subject to cell death by NETosis and that may release pathogenic oxidized DNA after exposure to TLR containing immune complexes (Caielli et al., 2016; Grayson et al., 2015; Jorch and Kubes, 2017; Kienhofer et al., 2017; Villanueva et al., 2011). Innate immune cells derived from the lymphoid lineage but without T or B-cell receptors (TCR or BCR) have important homeostatic functions, particularly at epithelial barriers, but may become dysregulated in autoimmunity and secrete pathogenic cytokines. An expansion or imbalance of several subsets of these cells has been observed both in the blood and tissues of patients with a variety of autoimmune diseases and in some instances these changes correlate with disease activity, although a causative link remains to be shown (Exley et al., 2016; Shikhagaie et al., 2017; Wenink et al., 2017).

Interestingly, the innate immune response, and, more specifically, monocyte activation, is under the control of the cholinergic antiinflammatory pathway. This pathway is initiated in the central nervous system, is mediated through the vagus nerve (cholinergic) and the splenic nerve (adrenergic), and culminates in the induction of acetylcholine production by splenic T cells that then inhibits the production of inflammatory cytokines by monocytes that express an  $\alpha 7$  cholinergic receptor (Chavan et al., 2017; Rosas-Ballina and Tracey, 2009). The identification of this pathway has provided a potential therapeutic target that regulates multiple cytokines simultaneously, and there are current trials to exploit this pathway in IBD, rheumatoid arthritis (RA), and SLE (Chavan et al., 2017; Koopman et al., 2016).

## CELLS OF THE ADAPTIVE IMMUNE SYSTEM

There is a coordinated interplay among the cells of the adaptive immune system with DCs, T cells, and B cells collaborating to activate this branch of the immune system. DCs activate T and B cells, T cells activate DCs and B cells, and B cells activate only T cells. This cascade leads to an immune response that recognizes a broad spectrum of epitopes of microbial pathogens and enlists multiple effector mechanisms (Blanco et al., 2008; Goodnow et al., 2010; O'Shea and Paul, 2010; Shlomchik, 2008; Steinman, 2007).

DCs are antigen-presenting cells (APCs) that are the intermediary between the innate and the adaptive immune systems. DCs can be tolerogenic in their resting state, but when activated, they are critical in initiating an immune response (Devi and Anandasabapathy, 2017; Kalantari et al., 2011; Morel and Turner, 2011). Similarly, monocytes clear the apoptotic debris generated from the billions of cells that die daily in a tolerogenic fashion but, when exposed to inflammatory mediators, they differentiate into macrophages or DCs (Dominguez and Ardavin, 2010; Horton et al., 2017; Poon et al., 2014; Takenaka and Quintana, 2017). The activation of the innate immune system, therefore, can establish a population of immunogenic DCs for the activation of the adaptive immune system. Like essentially, all cells, monocytes, and DCs display surface expression of class I major histocompatibility complex (MHC) molecules, which permit the presentation of intracellular antigens to T cells. DCs and some macrophage subsets also express class II MHC molecules, which are present on a much more restricted set of cells and permit the presentation of extracellular antigens (Banchereau and Steinman, 1998). Multiple alleles of class I and II molecules exist, and, thus, each individual has a unique set of MHC molecules (Beck and Trowsdale, 2000). DCs also express an array of nonpolymorphic receptors, such as TLRs, and pattern-recognition receptors that bind microbial antigens, products of tissue injury, and nucleic acids (Kawai and Akira, 2010, 2011). Engagement of these receptors causes the DCs to upregulate expression of costimulatory molecules and to deliver an obligatory second signal for activation (Dzopalic et al., 2012; Engels and Wienands, 2011; Vincenti and Luggen, 2007). It is important to note that each DC can recognize and respond to a broad spectrum of microbial antigens.

MHC molecules have innate properties in that they also interact with Killer cell immunoglobulin receptor (KIR) that have inhibitory functions on innate lymphoid cells; these interactions prevent the killing of MHC I expressing cells. Some KIR receptors have an activating function, and these can enhance immune responses to pathogens and may predispose to autoimmunity (Espeli et al., 2010; Rajalingam, 2011).

Each T and B cells express a single receptor for antigen. These antigen receptors are acquired by gene rearrangements that occur in somatic cells (Gellert, 2002); thus there is no inheritance of the T- or B-cell repertoire. T cells mature in the thymus (Stritesky et al., 2012). Each T cell expresses a unique receptor (TCR) that recognizes a molecular complex on the surface of an APC consisting of a class I or class II MHC molecule associated with a small peptide derived from an intra- or extracellular protein antigen, respectively. Signaling through both the TCR and costimulatory molecules is needed to effect activation of mature T cells (Engels and Wienands, 2011; Esensten et al., 2016; Vincenti and Luggen, 2007; Weinstein et al., 2012). B cells also express a single receptor for antigen, but the BCR recognizes native antigen rather than processed antigen. B-cell activation also requires signaling through both the BCR and costimulatory molecules (Crow, 2004). Activated B cells not only secrete antibody but can also function as APCs to engage a greater number of T cells in the immune response. B cells also secrete molecules that are essential for lymphoid organization and for the formation of the germinal center (Qin et al., 2007; Wang et al., 2001) and can secrete a variety of cytokines (Leon et al., 2012; Lipsky, 2001; Marino and Grey, 2012).

A critical feature of both T and B cells is that they proliferate in response to antigenic stimulation to create clonal expansions of cells with a unique antigenic specificity and to develop cells with a memory phenotype (Bishop et al., 2003; Chen et al., 2017; Grossman et al., 2004; McKinstry et al., 2010; Watkin et al., 2017). Memory cells have an accelerated and enhanced response following reexposure to antigen. B cells have the added feature of undergoing class switching of the immunoglobulin heavy chain gene and random somatic mutation of the BCR followed by the selection of those B cells with improved affinity for the eliciting antigen (Lee et al., 2016; Li et al., 2004; Victora and Nussenzweig, 2012). Thus there is a progression from low-affinity IgM antibodies to high-affinity IgG antibodies during the course of an immune response. The memory response is characterized by the activation of high-affinity IgG-producing B cells.

Plasma cells also constitute part of the memory B-cell response as they can be extremely long-lived and may, therefore, secrete pathogenic antibodies for long periods. While some autoimmune diseases appear to involve the generation of short-lived plasma cells and are, therefore, self-limiting, others are characterized by the continued presence of autoantibodies for years, in some cases, regardless of disease activity (Liu et al., 2011).

For the immune system to function effectively there must be a sufficient number of T and B cells that can respond to an enormous diversity of microbial antigens, and a means of regulating those cells that respond to self-antigen.

## DEFINING AUTOIMMUNE DISEASE

An autoimmune disease is a condition in which tissue injury is caused by T-cell or antibody reactivity to self. The immune activation may be initiated by infection but then persists in the absence of any detectable microbial antigen (Davidson and Diamond, 2001; Rose and Bona, 1993). It is important to state that although many diseases considered autoimmune display reactivity to self, evidence may still be lacking that the self-reactivity is, in fact, responsible for tissue damage. It is sometimes possible to determine whether autoantibodies are pathogenic by transferring them to a rodent host; however, T-cell reactivity is not transferable from humans to rodents because T-cell activation and T-cell effector function occur only in the context of self-MHC molecules. Thus demonstrating the pathogenicity of the autoimmune response has not been accomplished in all autoimmune diseases. In some instances, a disease is presumed to be of autoimmune origin only because B- and T cells are present in affected tissue.

Animal models of autoimmune disease have been enormously useful in aiding our understanding of both disease inception and disease pathogenesis (Bar-Or et al., 2011; Billiau and Matthys, 2011; Howell, 2002; King, 2012; Lam-Tse et al., 2002; Mandik-Nayak and Allen, 2005; Peutz-Kootstra et al., 2001; Wooley, 2004). Some autoimmune diseases can be triggered in animals by immunization with self-antigen or adjuvants and some develop spontaneously. While animal models have been very important in informing our understanding of autoimmunity, it is important to recognize that we do not know how closely they reflect human disease (Bodaghi and Rao, 2008; Kollias et al., 2011). Some may be more similar to human disease in the effector mechanisms of tissue injury than in the mechanisms of induction of autoreactivity. Indeed, autoantibody-mediated tissue damage is probably most alike in human disease and animal models (Monach et al., 2004). It is also important to consider that there may be extensive heterogeneity in human disease and that the animal models we study intensively may reflect only a subset of individuals with a given disease. A challenge that confronts us is to understand which animal models are most similar to human disease and can teach us most about the genetic predisposition to disease, external triggers of disease, disease pathogenesis, and effective therapy. The opportunity to generate new models based on the functionality of autoimmune risk haplotypes arises from an increasing understanding of genetic risk and may provide better insights into patient stratification and precision therapeutics. As more data are generated from human subjects, mouse models will also be needed to explore the functions of genes relevant to the progression of autoimmune disease.

## PREVALENCE OF AUTOIMMUNITY

It is striking that while each autoimmune disease individually affects only a small number of people, the prevalence of all autoimmune diseases is approximately 5%–7% (Cooper et al., 2009; Hayter and Cook, 2012; Jacobson et al., 1997; Wang et al., 2015). Patients with one autoimmune disease also have an increased risk of a second autoimmune disease (Cooper et al., 2009; Jacobson et al., 1997; Marrie et al., 2015). Two critical facts about autoimmune disease are important in understanding the high frequency of these diseases. First, autoreactivity is an aspect of every normal immune system. In fact, the repertoire of immunocompetent lymphocytes that provides protective immunity is selected based on autoreactivity (Gu et al., 1991; Nobrega et al., 2002; Vallejo et al., 2004). T cells need to recognize self-antigen within the antigen binding cleft of MHC in order to survive the initial steps of T cell selection, whereas circulating B cells receive survival signals as a result of weak interactions with autoantigens (Gu et al., 1991; Nobrega et al., 2002; Vallejo et al., 2004). Second, autoreactivity is a crucial component of immune homeostasis. The regulation of physiologic autoreactivity helps to shape the immune system so that it does not become the pathogenic autoreactivity associated with tissue damage; this is an active process that requires constant vigilance. The immune system maintains a precarious balance between the two: too little response leads to potential neglect of danger, while an overexuberant response can potentially lead to autoreactivity. How this balance is maintained is discussed next. Second, there is a genetic predisposition to autoimmunity, and aspects of this predisposition may be similar for many different autoimmune diseases (Cho and Gregersen, 2011; Gutierrez-Arcelus et al., 2016), perhaps because these genetic traits have been selected for their

capacity to protect against infectious diseases (Liao et al., 1995; Liu et al., 2009). Furthermore, some of the studies of the genetic basis of autoimmunity show that the genetic factors governing autoreactivity are distinct from those governing specific organ vulnerability (Liao et al., 1995; Liu et al., 2009) or severity of tissue damage (Martini et al., 2014). Thus individuals may share pathways promoting autoreactivity, yet present with different autoimmune diseases (Cho and Gregersen, 2011; Cotsapas et al., 2011).

## GENETICS AND EPIGENETICS OF AUTOIMMUNITY

### Monogenic Disease

It is clear from epidemiologic studies and studies of animal models of autoimmune disease that there is a genetic component to essentially every autoimmune disease. A few autoimmune diseases appear to be monogenic diseases (Melki and Crow, 2015). The human disease autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, an autoimmune disease of multiple endocrine organs, is a consequence of a deletion in the autoimmune regulator (AIRE) gene that encodes a protein that causes tissue-specific genes to be expressed in medullary epithelial cells in the thymus (Akirav et al., 2011; Anderson and Su, 2011). These cells mediate negative selection of T cells reactive with peptides that derive from tissue-specific proteins. In the absence of AIRE expression, a spectrum of autoreactive T cells fails to be deleted; these cells mature to immunocompetence and mediate an immune attack on various organs. The absence of the AIRE gene appears sufficient for autoimmunity, although the phenotype of the disease that emerges, even within a single family, can be quite variable. Similarly, a defect in the Fas gene can also lead to autoimmunity. The Fas protein is expressed on activated lymphocytes. Engagement of Fas by Fas ligand leads to the death of the Fas-expressing cell, a process critical for downregulating the immune response. Individuals deficient in Fas expression have a disease called autoimmune lymphoproliferative syndrome (ALPS) characterized by an excess of T and B cells and by autoantibody production (Fleisher et al., 2001; Grodzicky and Elkon, 2002; Madkaikar et al., 2011). Of note, not all individuals with deficient Fas expression display ALPS; thus even in this disease, other genes must modulate disease phenotype. Deficiency in certain complement components also results in a high incidence of the autoimmune disease SLE. In this case, the mechanism is thought to be a failure of clearance of immune complexes and apoptotic material resulting in an overload of immunogenic material that can activate the immune system through engagement of TLRs and other innate receptors (Lewis and Botto, 2006; Pettigrew et al., 2009). Deficiency of enzymes that remove DNA to prevent TLR activation can result in SLE (Bodano et al., 2016; Rice et al., 2008; Sisirak et al., 2015; Stetson et al., 2017; Yan, 2006). Deficiency of Foxp3 or of IL2R $\alpha$  that are required for the development of regulatory T cells (Tregs) is both associated with severe autoimmunity affecting the bowel and endocrine organs (Lewis and Botto, 2006; Ochs et al., 2007; Pettigrew et al., 2009; Sakaguchi, 2007).

### Polygenic Disease

For most autoimmune diseases, multiple susceptibility loci contribute to the disease phenotype. Studies from mouse models of autoimmune disease have also revealed the presence of loci that suppress the autoimmune phenotype (Wakeland et al., 2001). Thus an individual's risk of developing an autoimmune disease depends on a summation of susceptibility and resistance loci. A major advance in the last 15 years has been the application of genome-wide association studies (GWAS) that evaluate large numbers of common single nucleotide polymorphisms (SNPs) as genomic markers in well-defined patients and control populations. Studies in multiple autoimmune diseases have definitively linked a number of genetic variants to disease susceptibility (Deng and Tsao, 2010; Flesher et al., 2010; Harley et al., 2008). Most of these variants are in noncoding regions of a gene and control basal expression [expression quantitative trait loci (eQTL)] or expression following stimulation (response eQTLs) (Gutierrez-Arcelus et al., 2016; Wang et al., 2015).

Despite the identification of a large number of autoimmunity associated genes using the GWAS approach, the polymorphic locus most closely linked to autoimmunity in studies of virtually every autoimmune disease is the MHC locus, an association that has long been known (Gutierrez-Arcelus et al., 2016). For example, anti-CCP seropositive rheumatoid arthritis in the Caucasian population is highly associated with the expression of a set of DR4 alleles that have a particular structural motif, called the "shared epitope" (Winchester, 2004). Reactive arthritis occurs in individuals expressing B27 or, less commonly, B7 class I MHC molecules. In type I diabetes both pathogenic and protective DR and DQ alleles have been identified and the heterodimer encoded by DQA1\*0501 and

DQB1\*0302 confers very high risk. In celiac disease, 98%–99% of the affected individuals bear a susceptibility DQ allele; thus DQ testing can be used clinically to exclude disease with a high degree of certainty (Wolters and Wijmenga, 2008). Multiple sclerosis and systemic lupus display particular human leukocyte antigen (HLA) associations, as do many other autoimmune diseases (Fernando et al., 2008; Tomlinson and Bodmer, 1995; Winchester, 2004; Wong and Wen, 2003). The basis for the association of MHC polymorphisms with autoimmune disease is still for the most part unknown but might be due to T-cell recognition of particular pathogenic peptides that can bind within the peptide binding cleft of certain MHC molecules, cross-reactivity of peptides derived from infectious organisms with self-peptides, or alterations in the T-cell repertoire that result in a decrease in Tregs (Cho and Feldman, 2015; Raychaudhuri et al., 2012; Sollid, 2017).

With the exception of the MHC, the other genetic risk loci for autoimmunity that have been identified by GWAS involve a conglomeration of approximately 300 relatively common alleles, each of which confers only a modest risk, with odds ratios <1.5–2 (Gutierrez-Arcelus et al., 2016; Wang et al., 2015). Some, but not all, of these polymorphisms cross major racial groups. In mouse models, there is evidence that genetic susceptibility can be a consequence of combinations of genes within each gene locus and not the consequence of a single gene in each locus. For example, a region on chromosome 1 that is implicated in autoimmunity in systemic lupus erythematosus has several subloci which contribute to various aspects of the disease (Morel, 2010; Morel et al., 2001).

## Shared Risk Alleles

Clinically, it has long been appreciated that autoimmune diseases cluster in families. The biologic basis for this observation is now clear; the same susceptibility genes can influence many different autoimmune diseases. For example, a polymorphism of cytotoxic T-lymphocyte-associated antigen (CTLA4), an inhibitory costimulatory molecule present on activated T cells, conveys risk for insulin-dependent diabetes, autoimmune hemolytic anemia, and Graves' disease (Ueda et al., 2003), while the CARD15 (NOD-2) gene is associated with both IBD and psoriasis (Bene et al., 2011; Rahman et al., 2003; Russell et al., 2004; Zaki et al., 2011). Similarly, polymorphisms in PTPN22, a molecule that regulates lymphocyte receptor signaling, is associated with type 1 diabetes, SLE, RA, and Crohn's disease but not with multiple sclerosis (Burn et al., 2011). The differences in disease phenotype may lie in associated genes, those governing target-organ susceptibility or those that modulate disease severity (Russell et al., 2004) or in different environmental exposures. Indeed, the genetic association of HLA and PTPN22 with cyclic citrullinated peptide (CCP)-positive rheumatoid arthritis is considerably magnified in smokers, leading to a postulated pathogenic mechanism whereby damage to the lung by cigarette smoke induces autoimmunity to citrullinated proteins in genetically susceptible individuals (Mahdi et al., 2009).

One of the most striking advances made as a result of GWAS has been the identification of immune pathways associated with autoimmune tendencies, some of which are shared across diseases. A metaanalysis of the autoimmunity associated genes identified thus far suggests that individual diseases can be clustered in groups that share pathogenic mechanisms. For example, using this type of methodology, disease associations with polymorphisms in IL-2 can be distinguished from those associated with IL-21 that is within the same genetic locus (Cotsapas et al., 2011). The genetic studies in sum suggest that autoimmunity can result from a defect in almost any pathway of immune homeostasis as they affect thresholds for innate immune cell activation and for negative and positive selection of lymphocytes prior to immunocompetence and the activation of autoreactive lymphocytes (Gutierrez-Arcelus et al., 2016; Marson et al., 2015).

Applying this new information to individual patients represents a major challenge since attribution of a SNP identified by GWAS to a single gene often requires extensive resequencing of large regions of DNA from many patients. Furthermore, since the GWAS approach identifies only common polymorphisms with frequencies within the population of >1%–5%, the risk variants identified by this method account for only a small proportion of the overall heritability of the disease (Deng and Tsao, 2010; Gutierrez-Arcelus et al., 2016). New methodologies to identify rare variants or copy number variations are being developed, but these variations will only be seen in a small fraction of those who are affected. Finally, establishing a link between genetic variations, gene function, and disease pathogenesis has not been easy. Many of the risk alleles identified by GWAS are common variants with subtle effects that are compatible with normal immunological function; in most cases, the variation is not within the gene coding region but governs gene expression (Rieck et al., 2007; Zhang et al., 2011). Combinations of genes are starting to be identified in longitudinal cohorts that predict the risk of disease (Achenbach et al., 2013; Langefeld et al., 2017; Laufer et al., 2017; Lempainen et al., 2015). More studies will be

required to understand how the disease-associated variants affect immune responses and interact with each other to contribute to the risk of a particular disease. One approach is to knock-in the disease-associated variants into mouse models of autoimmunity. For example, mice with a knock-in of a variant of the RNA sensor IFIH1 that confers a high risk for type 1 diabetes have a higher basal level of type I interferons and an increased propensity to develop diabetes compared with their wild-type littermates that is dependent on the RNA sensing function of IFIH1 and is further increased by the introduction of the diabetes associated PTPN22 variant (Gorman et al., 2017). As the function of all the autoimmune-associated variants is similarly clarified and potentially pathogenic pathways are identified, personalized interventions may become possible.

## Contribution of Epigenetic Modifications and Transcriptional Regulation

Despite the advances in understanding the genetics of autoimmunity, concordance in monozygotic twins remains below 50% for most diseases, indicating a contribution from random and/or environmental factors. Epigenetic alterations that change the access of DNA regions to the transcriptional machinery through DNA methylation or histone acetylation, or alterations that silence transcription through inhibitor miRNAs, or alter protein longevity or processing within the cell through ubiquitination or citrullination, may all influence the immune system function (Long et al., 2016; Tost et al., 2017). T-cell differentiation, for example, is influenced by epigenetic mechanisms that reinforce the T-cell cytokine producing phenotype (Nakayamada et al., 2012; Pereira et al., 2017; Qiu et al., 2017). While it is clear that epigenetic alterations may profoundly influence cell phenotype, the application of this concept to autoimmunity remains in its early phases. Abnormalities of methylation or acetylation or expression of particular miRNAs has been demonstrated among peripheral blood cells of patients with several autoimmune diseases (Ceribelli et al., 2011a, 2011b; Ghosh et al., 2012) and there are several examples of deficiencies of particular enzymes or miRNA species causing spontaneous autoimmune disease in mice (Glasmacher et al., 2010; Namjou et al., 2011). The inactivation of the X chromosome that contains several genes involved in immune responses is not always complete, perhaps contributing to the increased risk of autoimmunity in women (Wang et al., 2016). A study of discordance in monozygotic twins for disease demonstrates a similar epigenome despite lack of disease concordance, suggesting that epigenetic profiling might be useful in assessing risk for disease (Generali et al., 2017). Another study of patients with rheumatoid arthritis suggests that epigenetic profile correlates with response to therapy (Tost et al., 2017). Since epigenetic modifications are not immutable, they must be analyzed in all relevant tissues and cell types in order to find those that associate with disease risk, severity or response to therapy. As these are identified, the impact of drugs that modify the relevant epigenetic profiles will be of great interest.

## HORMONES AND AUTOIMMUNITY

Since many autoimmune diseases occur more commonly in women than in men, there have been several investigations of the role of sex hormones in autoimmune disease. Animal studies have shown multiple effects of sex steroids on the immune system (Rubtsova et al., 2015); studies of mice lacking an estrogen receptor have clearly attributed estrogen effects to signaling through the estrogen receptor  $\alpha$ . However, it has been difficult to extrapolate the conclusions from these studies to autoimmunity. Not all autoimmune diseases are more common in women. Some, such as ankylosing spondylitis, have a higher incidence in men. Furthermore, the predisposition to autoimmunity can be sex determined or hormonally modulated; thus the higher incidence of disease in women may not always reflect the influence of female hormones on the immune system. The X chromosome, in fact, harbors many genes of immunologic interest. In gonad matched mice the presence of XX confers a greater susceptibility to pristane-induced lupus than does XY (Smith-Bouvier et al., 2008). Similarly, in humans, the XYY phenotype is associated with an increased prevalence of SLE. Nevertheless, the genetic components of the XX chromosome that are associated with lupus risk are not yet clear. The evidence also shows that the effects of sex hormones differ in different diseases. While there is significant evidence that estrogen can exacerbate systemic lupus, estrogen seems to protect against rheumatoid arthritis. In addition, estrogen or other sex hormones might affect target-organ antigen display, target-organ susceptibility to immune-mediated damage or even the composition of the gut microbiota. Thus there is no simple paradigm to explain the relationship between sex and autoimmunity (Grimaldi et al., 2005).

## AUTOIMMUNITY AND CENTRAL TOLERANCE

The hallmark of the autoimmune disease is the activation of self-reactive T and B lymphocytes. A major mechanism of self-tolerance is the elimination of self-reactive immature lymphocytes by antigen ligation of the TCR or BCR at critical stages of development. For autoimmunity to develop there must be a lack of stringency in the elimination of autoreactive cells. Because TCRs and BCRs are generated by random gene rearrangements that occur within the nucleus of the cell and are not determined by knowledge of the world of self or foreign antigen, autoreactive T and B cells arise routinely. To eliminate autoreactive cells and maintain self-tolerance, T and B cells routinely undergo a selection process during their maturation in primary lymphoid organs, the thymus and bone marrow, respectively (Alexandropoulos and Danzl, 2012; Goodnow et al., 2010; Rajewsky, 1996; Vallejo et al., 2004; von Boehmer and Melchers, 2010). B cells again undergo a second process of selection after somatic mutation of immunoglobulin genes, as somatic mutation routinely generates autoreactivity (Brink, 2014; DeFranco, 2016; Goodnow et al., 2010; Liu and Davidson, 2011; Shlomchik, 2008).

T cells that mature in the thymus and enter peripheral lymphoid organs must display TCRs with some affinity for self-peptide–self-MHC complexes in order to receive the necessary signals for survival, which is termed positive selection. T cells arising in the thymus that express TCRs lacking any affinity for the self-peptide–self-MHC complexes fail to undergo positive selection and die. T cells that are strongly reactive to self-peptide–self-MHC complexes are eliminated in a process termed negative selection (Kondo et al., 2017). The threshold for both positive and negative selection represents a continuum. As the peptide–MHC complexes present in the thymus differ in each individual and the threshold for negative selection varies from individual to individual, each individual releases a different repertoire of antimicrobial and self-reactive T cells to the periphery, each reflecting a different spectrum of foreign and self-peptide specificities (Bommhardt et al., 2004; Vallejo et al., 2004; Werlen et al., 2003). It is also probable that certain stimuli can rescue T cells.

B cells similarly undergo a process of negative selection prior to achieving immunocompetence. This process occurs in the bone marrow and continues in the spleen where B cells migrate as transitional cells after exiting the bone marrow. Whether B cells require positive selection on self-antigen for survival and need to display some degree of autoreactivity remains an area of active investigation. It is clear, however, that highly autoreactive B cells are negatively selected on self-antigens encountered during early maturation, and again, the threshold for deletion is different for each individual (Monroe et al., 2003; Nemazee, 2017). The deletion occurs with the highest extent of BCR cross-linking; anergy occurs with less cross-linking. Thus the degree of autoreactivity in the B-cell repertoire is also variable. The selection of B cell is influenced not only by the strength of the signal received through the BCR but also by the availability of the TNF-like cytokine BAFF. In late transitional B cells, the interaction of BAFF with BAFF-R cooperates with signals received through the BCR to promote B cell survival and metabolic fitness. Since the availability of BAFF depends to a large extent on the number of B cells, B-cell depletion can result in high levels of BAFF leading to relaxation in the stringency of selection and the escape of autoreactive B cells to the periphery (Liu and Davidson, 2011; Mackay and Schneider, 2009). Anergic autoreactive B cells may also be rescued in a proinflammatory setting by engagement of costimulatory molecules on the B-cell membrane or by signaling through TLRs (Monroe and Keir, 2008). Thus the repertoire of naïve B cells will vary over time within an individual, with higher affinity autoreactive B cells present during times of infection, inflammation or lymphopenia, and fewer, lower-affinity autoreactive cells present during times of immunologic quiescence (Goodnow et al., 2010; Shlomchik, 2008).

This paradigm must be understood in the context of our knowledge that autoimmunity is often accompanied by some degree of immunodeficiency. A failure of proper selection may lead to a repertoire that includes too many self-reactive T or B cells. The presence of autoreactivity in individuals who are immunosuppressed is more straightforward. For example, the increased levels of BAFF that result from B-cell lymphopenia will lead to a failure to appropriately select the B-cell repertoire. Some defects that affect T-cell activation also impair expansion of regulatory cells or T-cell apoptosis and may, therefore, impair both responses to pathogens and self-tolerance. In the presence of T-cell lymphopenia, homeostatic expansion of self-reactive cells can occur.

## AUTOIMMUNITY AND PERIPHERAL TOLERANCE

Negative selection of T and B cells occurs in the periphery as well as in primary lymphoid organs, permitting the removal of autoreactive cells that do not encounter autoantigen in the thymus or bone marrow. This process

of negative selection is termed peripheral tolerance. Like central tolerance, it is mediated by engagement of the TCR or BCR in a noninflammatory setting (Devi and Anandasabapathy, 2017; Goodnow et al., 2010; Nemazee, 2017; Tsubata, 2017). Although it has been traditional to debate whether autoimmunity results from a defect in central tolerance in the thymus or bone marrow, or in peripheral tolerance in secondary lymphoid organs, current knowledge of tolerance induction suggests that this may be an artificial distinction. Engagement of the antigen receptor is critical to both central and peripheral tolerance, although there are some differences in antigen receptor signaling pathways, expression of coreceptors, and costimulatory molecules that exist between immature T or B cells and their mature counterparts. Mouse models of autoimmunity suggest that defects in negative selection can be limited to central or peripheral tolerance (Anderson and Su, 2011; Linterman et al., 2009; Vinuesa et al., 2005), whereas others may paradoxically impair central tolerance and enhance peripheral activation (Seo et al., 2003). Thus some autoimmune-prone individuals might exhibit a general lack of stringency in B or T-cell tolerance, while others might have a defect that is stage specific. This distinction has important therapeutic implications; learning to subset patients based on their tolerance impairment mechanism might permit a better pairing of a patient with the therapy, in short, more personalized medicine.

In summary, the thresholds for survival and deletion need to be set within appropriate limits at multiple times in the maturation and the activation of a lymphoid cell (Goodnow et al., 2010; Liu and Davidson, 2011; von Boehmer and Melchers, 2010). Too little deletion at any stage and autoreactivity ensues; too much deletion and the protective repertoire may be compromised. Any genetic or nongenetic change that reduces deletion or enhances activation may be a risk factor for autoimmunity.

## TRIGGERS OF AUTOIMMUNITY

Environmental factors are important triggers for expression of autoimmunity. Autoimmunity may develop following sterile tissue damage. Smoking, drug exposure, diet, chemical exposure, and sunlight have all been implicated as risk factors for particular diseases (D'Cruz, 2000; Debandt et al., 2003; Knip and Akerblom, 1999; Moriyama and Eisenbarth, 2002; Price and Venables, 1995; Steen, 1999; Vaarala, 2012). Molecular pathways for some of these have been established. Smoking and periodontal disease lead to the generation of citrullinated proteins; these are a target of autoantibodies in rheumatoid arthritis (Klareskog et al., 2011; Routsias et al., 2011). Notably, PADI4, the gene encoding peptidyl arginine deiminase involved in the citrullination of proteins, contains a susceptibility allele for rheumatoid arthritis (Bang et al., 2010; Kochi et al., 2011); inhibitors of PAD4 are effective in mouse models of rheumatoid arthritis (Willis et al., 2017). UV light causes apoptosis of keratinocytes, liberating cellular debris which is then bound by SLE-associated autoantibodies initiating an inflammatory response in the skin (Bijl and Kallenberg, 2006; Kuhn and Beissert, 2005); this can be mimicked by overexpression of inflammatory cytokines in the skin (Seery et al., 1997). It is now appreciated that pattern-recognition receptors for microbial pathogen-associated molecular patterns also bind to endogenous ligands, DAMPs or damage-associated molecular patterns. The release of DAMPs in damaged tissue can establish a proinflammatory milieu leading to the immunogenic presentation of self-antigens, including intracellular antigens that are normally sequestered from the immune system (Zhang et al., 2010). Once these become targets of an immune response, ongoing inflammation may be sustained. For example, the ongoing inflammation in some diseases, such as autoimmune myositis, targets regenerating tissue in which the disease-specific autoantigens are most abundantly expressed; this prevents tissue repair and resolution of inflammation (Mammen et al., 2011; Suber et al., 2008).

Clearly, infection can also precipitate autoimmune disease. It has even been suggested that most autoimmune diseases represent the late sequelae of an infectious process (Christen et al., 2012; James and Robertson, 2012). Proving this hypothesis has, however, been difficult. For some diseases, such as rheumatic fever or Guillain–Barré disease, the causal connection between microbial infection, the antimicrobial response, and autoimmune disease is clearly established (Cunningham, 2003; Guilherme and Kalil, 2004). Persistent reactive arthritis may follow a variety of bacterial and viral infections (Schmitt, 2017). For other diseases, there is suggestive epidemiologic evidence in humans or evidence from animal models that autoimmunity can follow microbial infection, or T cell or antibody cross-reactivity with both microbial and self-antigen has been identified (James and Robertson, 2012; Kuon and Sieper, 2003; Strassburg et al., 2003). In general, researchers have sought to implicate particular infections in the pathogenesis of particular autoimmune diseases, but it is possible that for some autoimmune diseases there is more than one possible microbial trigger. Importantly, the interaction of the TCR with a peptide–MHC complex must be of higher affinity to activate a naïve T cell than a memory T cell. Thus a microbial peptide may initiate a response that can then be sustained by self-peptide. Moreover, once a response to

self-antigen is initiated, epitope spreading to other epitopes on the same protein or on associated proteins occurs, often through B cell–mediated antigen presentation (Shlomchik et al., 2001). Autoantibodies may also amplify disease, especially those that form immune complexes containing endosomal TLR ligands.

Recent studies have provided remarkable information on the progression of autoimmunity, demonstrating that the autoantibodies characteristics of a given autoimmune disease are present as early as 10 years before the onset of clinical disease (Arbuckle et al., 2003). Moreover, cytokine abnormalities can also be observed before the onset of clinical symptomatology (Arbuckle et al., 2003; Deane et al., 2010) and early transcriptional signatures of preclinical disease are now starting to be identified (Chang et al., 2016; Kallionpaa et al., 2014). These observations suggest that there may be an opportunity to abort or retard the progression to disease in predisposed individuals.

Finally, the adipocyte has joined the ranks of immunomodulatory cells. It can secrete a variety of cytokines that are either protective (Kamata et al., 2015) or that promote a proinflammatory, proimmunogenic milieu (de Heredia et al., 2012). Thus increasing obesity may be one contributor to the increasing incidence of autoimmune disease.

## ACTIVATION OF THE IMMUNE SYSTEM

The activation of both T and B cells in the periphery requires that the cells receive two signals: the first one is generated by ligation of the antigen receptor and the second by engagement of a costimulatory receptor. In general, when an antigen enters the system, there is an activation of DCs, the critical APC in a primary immune response. This occurs because microbes express molecules that bind to pattern-recognition receptors or TLRs on the DC. The consequence of this binding is upregulation of the costimulatory molecules CD80 (B7.1) and CD86 (B7.2) on DCs, and transformation of the DC from resting, or tolerogenic to activated, or immunogenic. T cells recognizing a microbial peptide in either class I or class II MHC molecules on the immunogenic DC will be activated. It is a feature of memory T cells that they can be activated by a lower-affinity interaction with the TCR than is required to activate primary T cells; this is due to epigenetic changes and alterations in the structure of lipid rafts in the membrane that facilitate rapid receptor cross-linking and less requirement for costimulatory signals (Weng et al., 2012). Thus a T cell that is not activated by a self-peptide–self-MHC complex while still a naïve cell, may be activated by self-antigen once it becomes a memory T cell. There are many examples in the literature of a T cell that is derived from an individual with autoimmune disease, which recognizes both a microbial peptide and a self-peptide. This cross-reactivity is termed molecular mimicry and represents a mechanism by which autoimmunity can be triggered by infection (Cusick et al., 2012). The hypothesis that molecular mimicry predisposes to autoimmunity clearly has validity in rodent models of autoimmune disease and suggests that laxity in the selection of the naïve T-cell repertoire can be a major contributor to autoimmunity. Those individuals with less stringent negative selection will have multiple T cells that can be activated by foreign antigen and will also display pathogenic autoreactivity. In addition, the signaling cascades within activated lymphocytes may differ in autoimmune versus healthy individuals. For example, T cells from SLE patients have altered signaling and a faster T cell calcium flux than those of healthy individuals due to the replacement of the principal signaling molecule of the TCR complex, CD3 $\zeta$ , by the FcR $\gamma$  chain (Moulton and Tsokos, 2011). This results in use of the adaptor molecule Syk rather than ZAP70 and the activation of the downstream kinase calcium/calmodulin-dependent protein kinase type IV (CaMK4) that enhances the production of IL-17 and blocks the production of IL-2 (Koga et al., 2014, 2016).

The activated T cell provides T-cell help or costimulatory signals to B cells that are encountering microbial antigen. B cells that bind both microbial antigen and self-antigen will ingest, process, and present epitopes of self-antigen, which can then be recognized by T cells. Because B cells often process antigen to different peptides than do DCs, the B cells can present novel epitopes of self-antigen and activate T cells with novel autoreactivities (Bockenstedt et al., 1995; Sercarz et al., 1993; Sinmaz et al., 2016; Yan et al., 2006). These cross-reactive B cells will, therefore, contribute to a cascade of autoreactivity, as they activate an expanded repertoire of T cells. Memory B cells are also potent APCs that can activate naïve T cells. The B-cell repertoire, therefore, critically influences the T-cell repertoire (Whitmire et al., 2009). The fewer autoreactive B cells present, the less presentation of self-antigen to T cells.

There is much complexity in the cytokine expression patterns of activated T cells with at least four subsets of well-described helper T cells (Th1, Th2, Th17, and T<sub>FH</sub>) as well as regulatory cells that help to restrain immune responses. The balance of transcriptional regulators expressed in each T cell will help to determine its phenotype,

whereas epigenetic changes will help to reinforce that phenotype through subsequent rounds of proliferation. Nevertheless, there is emerging evidence that helper T cells have a substantial amount of flexibility with respect to their phenotype. Signals from the innate immune system can be drivers of T-cell reprogramming, suggesting that inflammation or infection may have a profound effect on T-cell function, converting T cells with a protective phenotype to those that amplify inflammation (Nakayamada et al., 2012). More recently, a CD8 T-cell phenotype relevant to infectious disease, cancer, and autoimmunity has been identified characterized by programmed death (PD1) expression and termed “exhausted.” Exhausted T cells recognize antigen but can no longer carry out effector functions. They arise as the immune response progresses from the acute phase characterized by abundant antigen and costimulation from CD4 T cells to the chronic phase in which costimulation wanes and antigen concentration decreases (McKinney and Smith, 2016). Another feature of exhausted T cells is an altered metabolic profile characterized by high persistent mTOR, glucose dependence, and increased mitochondrial depolarization (Bengsch et al., 2016). The presence of these cells in the peripheral blood is clinically relevant as a molecular profile of exhaustion is associated with the inability to clear chronic infections or to mount vaccine responses and with cancer progression but with a better prognosis in a variety of autoimmune diseases (McKinney et al., 2015).

The appearance of a broad spectrum of autoimmune diseases in a substantial number of patients receiving antagonists of key coinhibitory molecules such as CTLA4 and PD1, drugs that activate exhausted cells as part of cancer chemotherapy, illustrates the trade-off between immunocompetence and autoimmunity (Cappelli et al., 2016; Day and Hansen, 2016). These “checkpoint inhibitor” drugs induce a broad spectrum of autoimmune adverse events in 7%–18% of the treated patients, most commonly affecting the skin, the gastrointestinal tract, the endocrine organs, and the respiratory tract. Immune side effects are less frequent and milder in patients in which PD1 has been targeted, compared with patients taking anti-CTLA4 therapy, perhaps related to the antibody-dependent cellular cytotoxicity-mediated depletion of Tregs by anti-CTLA4. Adverse effects are much more frequent and severe in patients taking a combination of CTLA4 and PD1 directed therapies, reflecting the complementary activities of each of these pathways in suppressing T cell–mediated immune responses (Naidoo et al., 2015). Furthermore, approximately 40% of the patients with an underlying autoimmune disease will flare while taking a checkpoint inhibitor. The frequency of adverse autoimmune events associated with checkpoint inhibitor drugs makes it imperative to understand how to reinvigorate the effector function of exhausted tumor-infiltrating T cells that have upregulated their coinhibitory receptors without breaking self-tolerance in distant organs. This might involve the targeting of more tissue-specific coinhibitory molecules, approaches to reverse the abnormal metabolic profile of these cells, and/or the use of synergistic regimens that enhance inflammatory responses only in the tumor (Bengsch et al., 2016; Lucca and Hafler, 2017).

Much is now known about the signaling pathways that are downstream of receptor and costimulatory molecule–mediated stimulation and that are required for B and T-cell activation and cytokine production. Since activated lymphocytes are major mediators of the effector inflammatory response, some of these pathways are targets for immune interventions with small molecules. Both inhibitors of Syk and of Jak3 have been used clinically in autoimmune diseases and other kinase inhibitors are in development (Baker and Isaacs, 2017; Hirahara et al., 2016; Kontzias et al., 2012). There is increasing recognition that immune responses and cellular differentiation pathways are linked to metabolism and that different types of effector and Tregs have different metabolic requirements (Buck et al., 2017; Gerriets and Rathmell, 2012; Morel, 2017; O’Neill et al., 2016). Recent studies have illustrated how genetic risk may be associated with metabolic irregularities in immune cells. A genetic polymorphism associated with lupus involves a gene that regulates T-cell oxidative metabolism and mitochondrial metabolism leading to an increase in T-cell inflammatory cytokines. Based on this finding, it has been shown that either an inhibitor of glucose oxidation or an inhibitor of mitochondrial oxidation can decrease autoimmune activation in mouse lupus models (Yin et al., 2015). How the fuel requirement and metabolic phenotype of each immune cell in either quiescent or activated state regulates autoimmunity requires future study. More work will also be needed to determine how metabolic irregularities in immune cells can be addressed therapeutically without disrupting homeostasis in other tissues.

## ROLE OF ANTIGEN AS A DRIVER OF AUTOIMMUNITY

A major question in autoimmune disease is whether the process is autonomous or driven by antigen, and, if the latter, whether the antigen is a self-antigen or foreign antigen. Animal models of disease definitively show that molecular mimicry following activation by microbial antigen can initiate autoreactivity (Cunningham, 2003; Cusick et al., 2012; Kuwabara, 2004). There are also data suggesting that self-antigen drives the autoimmune

response. First, in animal models of systemic lupus, it appears that an excess of apoptotic cells, a problem in their clearance, or modifications in the antigens they release can result in a lupus-like serology with antichromatin reactivity (Martinez Valle et al., 2008; Mistry and Kaplan, 2016; Peng and Elkon, 2011). Current understanding would suggest that an excess of apoptotic debris and/or altered forms of nucleic acids (such as oxidized forms or biofilms) can activate endosomal TLRs and transform tolerogenic into immunogenic DCs, as well as activate B cells (Caielli et al., 2016; Colonna et al., 2013; Filardy et al., 2010). The role of each endosomal TLR is different. TLR9 is required for the production of autoantibodies to DNA in lupus models but also has a protective role in autoimmunity (Christensen et al., 2005; Nickerson et al., 2008). TLR7 and 8 recognize the same RNA antigens but have different functions because they are expressed on different cell types. Overexpression of TLR7 in B cells is sufficient to cause a lupus-like autoimmune disease (Jackson et al., 2014). The overexpression of TLR8 that is expressed mainly in myeloid cells causes generalized systemic autoimmunity due to its activation of myeloid cells (Guiducci et al., 2013).

Other DNA and RNA sensors together with their associated adaptors and downstream signaling molecules also contribute to the regulation of autoimmune responses to nucleic acids during the course of a protective immune response to viral pathogens. TREX1, DNase1, DNAl3, and cGAS are all enzymes involved in DNA degradation either intra- or extracellularly (Koyama et al., 2016; Martinez Valle et al., 2008; Sisirak et al., 2015). Deficiency of TREX1 results in excess intracellular DNA that activates cGAS to produce the dinucleotide cGAMP which acts through its downstream adapter STING, to induce proinflammatory cytokines (Gao et al., 2015; Gray et al., 2015b). Nevertheless, the multiple functions of some of the adapters and signaling molecules involved in innate immunity can make them difficult to target therapeutically (Pawaria et al., 2017; Sharma et al., 2015).

Extensive tissue damage can lead to the presentation of normally sequestered self-antigen in a proinflammatory setting (Bratton and Henson, 2011; Horwitz et al., 2002; Vezys and Lefrancois, 2002) or posttranslational alteration of self-antigen such that it is now immunogenic (Doyle and Mamula, 2012). The proinflammatory setting may be enhanced by apoptosis of cells following tissue injury. This can clearly lead to an autoimmune response. Whether in some individuals this response is perpetuated because of a lack of appropriate restoration to homeostasis is an important question.

Finally, polymorphisms in autoantigens may also constitute risk factors for autoimmune disease (Pauza et al., 2004; Suzuki et al., 2003). As the genetic susceptibility to autoimmune disease is further explored, the degree to which molecular mimicry, aberrant expression of autoantigens, or exposure to previously sequestered antigen in an immunogenic setting contributes to disease will become more apparent.

A variety of environmental exposures might also nonspecifically accelerate disease by activating the innate immune system resulting in the release of proinflammatory cytokines that initiate autoimmunity. In mice, for example, type I interferons can initiate SLE in susceptible strains (Koutouzov et al., 2006) and may be responsible for the Koebner phenomenon observed in psoriasis (Koutouzov et al., 2006). Tissue damage also results in the release of soluble mediators (DAMPs) such as HMGB1, cathelicidins, defensins, and heat shock proteins that can activate TLRs and other proinflammatory receptors to further amplify immune activation pathways (Gallo and Gallucci, 2013).

## DEFECTIVE DOWNREGULATION OF AN IMMUNE RESPONSE

The induction of an immune response needs to be followed by a downregulation or elimination of most of the cells that have undergone clonal expansion. A major observation of recent studies of autoimmune disease is that a defect in the restoration of immune homeostasis, or in a downregulation of an immune response, can be a risk factor for autoimmunity. Since all reactivity with foreign antigen includes reactivity to self-antigen, responses to self are routinely generated in the process of mounting an immune response to foreign antigen. The potential pathogenicity of the autoimmune response will vary from individual to individual. In general, however, the mechanisms that exist to dampen the immune response also diminish autoreactivity. B and T cells are routinely downregulated as soon as they are activated. For the B cell, this occurs, in part, by cross-linking of the BCR and FcRIIB by antigen–antibody complexes. When FcRIIB is absent or deficient on B cells, as it occurs in many individuals with SLE, autoantibody production is poorly controlled (Bolland and Ravetch, 2000; Fukuyama et al., 2005), whereas FcRIIB on DCs helps to maintain T-cell tolerance (Li et al., 2014). Multiple coinhibitory molecules are expressed on activated T cells. Interaction with their receptors either within lymphoid organs or in the peripheral site of inflammation transduces an inhibitory signal to the T cells, signaling them to downmodulate their response (Schildberg et al., 2016). Mutations in two coinhibitory molecules, PD1 and CTLA4, are associated

with several autoimmune diseases (Chen, 2004; Khoury and Sayegh, 2004) and pharmacologic antagonism of either of these two molecules induces autoimmunity with high frequency (Kostine et al., 2017). Both B and T cells are also susceptible to activation-induced cell death mediated through Fas–Fas ligand interactions (Brunner et al., 2003; Li-Weber and Krammer, 2003). Defects in this process can lead to autoimmunity.

Thus controlling the immune response is critical to normal homeostasis of the immune system and is mediated by multiple inhibitory pathways. A major component of autoimmune disease in some individuals may be a defect in the suppression of immune activation.

## REGULATORY LYMPHOCYTES

Another area of intensive study is the phenotypic characterization and mechanisms of action of regulatory T and B cell subsets. CD4+ Tregs arise either during thymic development and others are induced after antigen exposure in the periphery (Kasper et al., 2016; Panduro et al., 2016; Wing and Sakaguchi, 2010). These cells regulate immune responses in a variety of ways that include secretion of inhibitory cytokines, promotion of apoptosis of effector lymphocytes, depriving effector T cells of cytokines or essential amino acids leading to apoptosis, or inhibition of DC function. The absence of Tregs in mice results in lymphoproliferation and fatal multiorgan autoimmunity demonstrating the need for the ongoing regulation of pathogenic self-reactive cells that escape into the periphery. A population of CD4+/CD25hi ( $\gamma$  chain of the IL-2 receptor) naturally occurring Tregs arises in the thymus in response to TCR encounter with self-antigens with an avidity lower than that required for negative selection; their development depends on both CD28 and IL-2. Tregs can also be generated after antigen exposure in the periphery from naïve T cells in a manner that is dependent on IL-2 and transforming growth factor (TGF)- $\beta$  and may be enhanced by the vitamin A metabolite retinoic acid. Both types of Tregs express the master transcriptional regulator Foxp3 (Pesenacker et al., 2016); its expression is stabilized by epigenetic modifications of DNA that reinforce transcriptional availability of suppressive cytokines while preventing access of transcription factors to DNA-encoding inflammatory cytokines (Hsieh et al., 2012; Josefowicz et al., 2012a).

Cells expressing immunosuppressive cytokines such as TGF- $\beta$  or IL-10 (Tr1 cells) (Pot et al., 2011) arise under particular conditions of antigen exposure and, once activated, mediate suppression through both limiting cytokine secretion and through contact-mediated lysis of effector cells. Tr1 cells are present in large numbers in the gut where they help to protect from colitis and they can also protect against multiple sclerosis in mice. Tr1 cells are Foxp3 negative and can be induced by IL-27 (Meka et al., 2015; Nadya et al., 2017; Wojno and Hunter, 2012) but have been difficult to study due to lack of a clear phenotype. Nevertheless, the transcriptional program of these cells is being unraveled, and recent studies have suggested that both IFN $\gamma$  and galectin 1 induce DCs to produce IL-27, suggesting a way in which Tr1 cells might be induced therapeutically (Ilarregui et al., 2009).

Other studies have identified a population of CD8 suppressor cells that may directly lyse autoreactive cells or may secrete immunosuppressive cytokines (Cortesini et al., 2001; Jiang et al., 2010; Vuddamalay and van Meerwijk, 2017). In lupus models, these cells can be induced by autoantigen or by idioype peptides (Sawla et al., 2012). CD8+ Tregs have recently been described during adaptive immune responses where they serve to regulate humoral responses in the germinal center by lysing B cells (Kim and Cantor, 2011).

The balance between effector and regulatory cells may determine whether an autoreactive response that arises in the course of microbial exposure or an inflammatory response is terminated or perpetuated (Visperas and Vignali, 2016). However, application of this new knowledge to the treatment of autoimmunity is still in its early stages. One approach has been to use inhibitors of the mTOR pathway, important in autophagy and cell metabolism, to induce or stabilize Foxp3 expression in Tregs (Chinen and Rudensky, 2012; Josefowicz et al., 2012b). Another is to use low-dose IL-2 or IL-2 anti-IL-2 complexes to enhance Treg development and function. This strategy has recently been successfully applied to the treatment of graft versus host disease (GVHD) and cryoglobulinemic vasculitis in humans in which an increase in Tregs was associated with a therapeutic response (Oo et al., 2012). In vitro expansion and delivery of a stable population of Tregs or in vivo activation of antigen-specific Tregs by tolerogenic self-peptides are in the development and trial stage. Clinical trials directed at tolerance induction in new onset type I diabetes by manipulation of Tregs have so far failed to cure disease despite an increase in Treg numbers, although several approaches have had partial effects (Gallagher et al., 2011; Skyler, 2013). Clinical trials with low-dose IL-2 to induce Tregs are ongoing, and other approaches that stabilize Treg function are being considered (Visperas and Vignali, 2016).

B cells may also have regulatory functions (Klinker and Lundy, 2012). IgM antibodies that have low-affinity autoreactivity suppress immune responses by promoting opsonization of apoptotic material and promoting

noninflammatory clearance (Chen et al., 2009). A subset of B cells with regulatory functions (Bregs) has been described by multiple investigators, but their importance in autoimmune diseases is not clear. These cells are defined by their ability, upon in vitro activation, to produce IL-10 as well as other regulatory cytokines such as TGF- $\beta$  and IL-35 (Lykken et al., 2015; Mauri and Menon, 2017). Some disagreement has arisen in the literature as to their origins and phenotype since they constitute a small proportion of many different activated B cell subsets including plasmablasts. Bregs function to dampen Th1 and Th17 responses and their absence have been associated with an exacerbated disease phenotype in mouse models of autoimmunity. Decreased numbers of Bregs have been reported in human autoimmune diseases but an understanding of how and where these cells regulate autoimmunity remains to be elucidated, and the findings are currently limited and only associative.

Another way in which B cells can regulate immune responses is by posttranscriptional modification of antibodies. Alterations in galactosylation and sialylation of the Fc region of Ig molecules may have a profound effect on immune responses. Fc receptor binding is affected by changes in glycosylation (Bournazos et al., 2016). A decrease in Ig galactosylation and sialylation is found in multiple autoimmune diseases and may increase the pathogenicity of autoantibodies (Biermann et al., 2016; Le et al., 2016). Sialylated immunoglobulin found in preparations of IVIg suppresses immune responses by binding to DC-SIGN on macrophages and DCs and initiating a program that induces the suppressive Fc receptor FcRIIB on macrophages (Anthony et al., 2011; Chen et al., 2009). Moreover, IgG must be sialylated to bind FcRIIB, the inhibitory receptor. On the other hand, fully deglycosylated Ig is protective since it binds poorly to Fc receptors.

## THE ROLE OF THE GUT MICROBIOTA IN AUTOIMMUNITY

An emerging theme in autoimmunity is the heretofore unrecognized role of the gut microbiota in regulating immune responses (Atarashi and Honda, 2011; Fung et al., 2017; Paun et al., 2017; Rosser and Mauri, 2016). A vast array of bacteria of multiple species is found at epithelial barriers including the skin and the gut and can vary with age, gender, genetic background, and environmental exposures such as antibiotics and diet. Gut bacteria play a crucial role in digestion and also produce essential vitamins and metabolites that can influence distant organs. One of the most important observations in this field is that the induction of Th17 cells in mice requires gut colonization with segmented filamentous bacteria; the absence of these bacteria prevents the induction of experimental forms of arthritis and multiple sclerosis in normal mice and the spontaneous onset of type 1 diabetes in a susceptible mouse strain (Romano-Keeler et al., 2012). The bacteria provide TLR ligands and induce other inflammatory genes that trigger DCs and are also a source of ATP that helps to activate Th17 cells. The precise function of these Th17 cells, either as pathogenic cells or as regulatory cells that also produce IL-10, will depend on other factors in the gut environment.

Disease-inducing bacteria may be found in some types of autoimmunity. For example, transfer of commensal bacteria from diseased to normal mice can transmit IBD, suggesting that the initiating trigger for this disease may be communicable (Garrett et al., 2007). Importantly, susceptibility to colitis may be altered by dietary changes that prevent the emergence of the pathogenic bacteria, suggesting that fecal transplants or probiotics are therapeutic strategies that should be tested. Gut microbiota also appears to be required for the generation of gut Tr1 cells, and this may be mediated by different bacterial species than those that induce Th17 cells. The capsular polysaccharide of *Bacteroides fragilis* has been identified as an inducer of Tregs (Round and Mazmanian, 2010). Conversely, the absence of Tregs can affect the composition of the gut microbiota (Chinen and Rudensky, 2012; Josefowicz et al., 2012b). How the balance of pro and antiinflammatory gut microbiota is maintained and how this might be manipulated for the prevention or treatment of autoimmunity has become an important question (Bogdanos and Sakkas, 2017; de Oliveira et al., 2017). It seems apparent, however, that gut microbiota helps to establish immune cell metabolism and, therefore, sets thresholds for activation and effector function. Metabolites released from gut bacteria may also have nonimmune distant effects; for example, intestinal microbiota control the permeability of the blood–brain barrier and may, therefore, modulate entry of immune cells into the brain (Braniste et al., 2014).

Most studies of gut microbiota in human autoimmune disease have so far been limited to comparisons of fecal colonies between diseased and healthy individuals without the establishment of causality. Several interesting new studies, however, have identified changes in the gut microbiota that correspond to seroconversion and diagnosis of type 1 diabetes (Kostic et al., 2015; Mejia-Leon and Barca, 2015). Similar studies in rheumatoid arthritis have identified gut dysbiosis in active patients that is corrected after effective treatment (Zhang et al., 2015); furthermore, transfer of disease-associated bacteria exacerbates disease in animal models (Maeda et al., 2016).

## FLARES AND REMISSIONS DURING DISEASE

The vast majority of animal models of autoimmune disease develop chronic progressive disease activity. Once the autoimmune disease becomes manifest, it progresses to organ failure or death. Much human autoimmune disease, in contrast, is characterized by periods of disease remission and flare. Little is known in human disease about the cellular events that lead to disease remission. It is also true that little is known regarding the cause of disease flares. In mouse models of multiple sclerosis disease flares can result from epitope spreading with sequential recruitment of T-cell populations that recognize different epitopes of myelin (Mallone et al., 2011; Vanderlugt et al., 1998). Similarly in humans, epitope spreading has been observed among cohorts of lupus patients from whom prediseased serum was available (Arbuckle et al., 2003; Deshmukh et al., 2003). Nevertheless, a major area of ignorance concerns the cell type responsible for disease flares. It is not known for most autoimmune diseases whether flares represent de novo activation of naïve autoreactive cells or a reactivation of quiescent memory cells and whether these flares are due to a new environmental exposure or to a failure of regulation, or both. Our ignorance in this regard is largely derived from the difficulty of sampling a large enough repertoire of autoreactive T or B cells. Often, these cells are poorly represented in peripheral blood (Bischof et al., 2004; Newman et al., 2003; Reddy et al., 2003). The development of MHC class I and class II tetramers containing peptides of known autoantigens is beginning to facilitate the analysis of pathogenic T cells in human autoimmune diseases and animal models in which the autoantigens are known (Mallone et al., 2011; Massilamany et al., 2011). Similarly, the development of single-cell PCR technology and, more recently, high-throughput methods for sampling thousands of cells is allowing the analysis of the frequency and binding specificity of both pathogen-induced and autoreactive B cells from peripheral blood (Jardine et al., 2016; Thornburg et al., 2016; Tipton et al., 2015). These studies have shed light on how autoreactivity is regulated in human B cells during B cell development, with loss of autoreactivity as the cells progress from the bone marrow to the periphery (Meffre and Wardemann, 2008). Abnormalities in this regulation have been demonstrated in individuals with a variety of immune deficiencies and autoimmunity-related genetic polymorphisms (Isnardi et al., 2010; Meffre and Wardemann, 2008; Menard et al., 2011; Schickel et al., 2016; Weller et al., 2012). These studies have also demonstrated clonal expansions of both B and T cells in autoimmune patients with some shared V region use between patients (Tipton et al., 2015; Tong et al., 2016). In patients with lupus, the repertoire of clonally expanded B cells is more diverse than in healthy individuals immunized with tetanus or influenza antigens with some clones arising from naïve cells and some from memory cells (Tipton et al., 2015). As the technology for studying single cells advances (Robinson, 2015; Zheng et al., 2017), more information about the diversity of autoimmune lymphocytes in a variety of autoimmune diseases is expected to gather.

## MECHANISMS OF TISSUE DAMAGE

Studies over the past decade have clearly demonstrated that the mechanisms that incite autoimmune disease may differ substantially from the mechanisms that propagate tissue damage. Autoreactive T and B cells that are activated in secondary lymphoid organs and initiate disease are activated in a different microenvironment and may have a different cytokine profile from the effector cells that migrate into target organs and cause tissue fibrosis (Campbell et al., 2001; Gerriets and Rathmell, 2012; Katzman et al., 2011). Therefore it is more clear that at each stage of autoimmune disease, inductions of autoreactivity and tissue destruction need to be separately explored, and that the previous characterization of certain cytokines, as proinflammatory, and others, as antiinflammatory, may be misleading. While TGF- $\beta$  may dampen the induction of autoreactivity, it may hasten tissue fibrosis (Valluru et al., 2011). Similarly, IL-10 is antiinflammatory during disease initiation through its inhibitory effects on APCs but may lose its antiinflammatory properties (Herrero et al., 2003) and even drive T-cell proliferation, immunoglobulin class switching, and antibody production later in the disease (Mocellin et al., 2004). Even the proinflammatory cytokine interferon- $\gamma$  can have antiinflammatory properties in the early stages of some autoimmune diseases (Billiau, 1996; Grohmann and Puccetti, 2002; Rosloniec et al., 2002), perhaps by antagonizing the differentiation of T cells secreting IL-17. It is, therefore, important, as we move forward in studies of autoimmune disease, to consider the mechanism of both immune activation and tissue destruction and to be aware that cytokines, hormones, or other mediators may exhibit differential effects in each process. Studies of animal models have now clearly shown that it is possible to intervene in disease progression to protect organs from immune-mediated destruction, even while autoreactivity continues unabated (Clynes et al., 1998; Schiffer et al., 2003).

Recent studies emphasize the role of innate immune cells in tissue injury, particularly neutrophils and macrophages that are recruited to lesional sites. Macrophages have a complex program in which they first release proinflammatory mediators to fight pathogens but then initiate programs to help in clearance of dead tissue and tissue repair (Huen and Cantley, 2017). While the latter response is beneficial if short-lived, the continued activation of the repair program may be detrimental (Bethunaickan et al., 2011). A role for organ-intrinsic macrophages is also increasingly being recognized; these may be activated *in situ* and contribute to tissue damage (Stamatiades et al., 2016).

The development of fibrosis is of major concern in autoimmune diseases since it is difficult to reverse and may lead to organ failure. Fibrosis is characterized by the deposition of extracellular matrix and collagen due to the sustained activation of myofibroblasts and failure of the normal resolution of wound healing. Multiple triggers for the wound healing response have been identified including excessive cell death, cytokines and other immune mediators, activation of coagulation pathways, and ER stress (Eming, 2017; Wynn and Ramalingam, 2012). Another major driver of fibroblast differentiation is the conversion of TGF- $\beta$  by either chemical danger signals or mechanical stress from a latent form that is tethered to the cell surface to an activated profibrotic form (Friedman et al., 2013; Hinz, 2009). Several types of stromal cells can transdifferentiate into myofibroblasts and this may vary in different organs. TLR signaling in pericytes has recently been shown to be essential for their TGF- $\beta$ -mediated transformation into fibroblasts (Leaf et al., 2016). Resolution of fibrosis is mediated through the induction of proteases that break down collagen and matrix and deactivation of myofibroblasts. Failed resolution and repair may occur because of local tissue hypoxia, infection, or ongoing tissue damage with an accumulation of toxic metabolites (Wynn and Ramalingam, 2012).

Macrophages are key players both in the early inflammatory process and in tissue regeneration and scar tissue formation, and their depletion has different effects depending on the stage of the inflammatory process. The transformation of inflammatory to proresolving macrophages is associated with changes in their metabolism with a switch from dependence on glycolysis to oxidative phosphorylation. Eosinophils and mast cells can also promulgate fibrosis. Profibrotic cytokines include IL-1, IL-6, IL-13, IL-33, thymic stromal lymphopoietin (TSLP), and TGF- $\beta$ ; fibrosis can follow either Th1/Th17 or Th2 inflammatory responses (Eming, 2017).

## THERAPEUTIC ADVANCES

A major advance in the last decade has been the application of new knowledge about immune system function to the treatment of autoimmune diseases. New therapies target innate immunity, adaptive immunity, and even tissue injury. As these new drugs have entered clinical practice, it has become clear that the pleiomorphic and stage-specific functions of particular molecules can result in both beneficial and adverse therapeutic effects of the drugs that target them. TNF inhibitors, for example, while highly therapeutic in RA and IBD, can induce SLE, multiple sclerosis (MS), and vasculitis (Kollias, 2005). While some therapies are highly effective for some diseases but not for others, it has been difficult to predict efficacy or lack of efficacy based on our current understanding of disease pathogenesis. For example, global B-cell depletion using an antibody to CD20 is therapeutic in RA and MS (Barun and Bar-Or, 2012; Buch et al., 2011), diseases that were initially thought to be T-cell dependent, but has much less, if any, effect in SLE, a prototypic B-cell disease (Merrill et al., 2010). Similarly, IL-17 inhibition has been highly effective for seronegative arthritides such as psoriatic arthritis and spondyloarthritis but is less effective for rheumatoid arthritis (Fragoulis et al., 2016; Kunwar et al., 2016). These differences point to heterogeneity in cytokine involvement in inflammatory responses that are difficult to parse out even at the molecular level. Variability among patients results in response rates that rarely reach more than 70% even for the best of the new therapies. Finding ways to identify responders and nonresponders before initiating an expensive and potentially toxic new therapy is a task that is being actively pursued using large patient databases and genetic and “omics” studies.

New drugs to treat autoimmune disease are constantly in development. A major advance has been the development of small molecule inhibitors directed at key signaling molecules within the immune system, particularly a variety of protein kinases. Because there are more than 500 protein kinases, achieving precise specificity of these drugs for their targets can be difficult, but inhibitors of Jak kinases are already in clinical use and other drugs targeting Syk, Btk, PI3 kinase, and MAP kinases are in development (Croxton et al., 2016; Shao and Cohen, 2014; Stark et al., 2015). These drugs have the advantage that they can be administered orally and have been used both for autoimmunity and for oncology indications.

Many of the current approaches are based on a perceived need to institute immunosuppression and anti-inflammatory therapy at the time of autoimmune tissue destruction. Multiple pathways of immune activation,

including innate TLR and pattern-recognition receptor signaling pathways, costimulatory pathways and T- and B-cell activation and cytokine signaling pathways are being targeted to reduce the activation of the immune system (Rosenblum et al., 2012). Our most updated understanding of autoimmunity would suggest that it might also be appropriate to consider treating disease during times of disease quiescence. The goal of this therapeutic approach would be to alter T- and B-cell repertoire selection or to drive the expansion of regulatory cells and enhance regulation (Daniel and von Boehmer, 2011). Antigen-specific therapies require an understanding of the causative antigen; this remains unknown for most autoimmune diseases. Nevertheless, animal studies suggest that it may be possible to convert a pathogenic T-cell response into a regulatory one, for example, by delivering a strong signal 1 without signal 2 (Crepeau and Ford, 2017), by delivering tolerogenic signals to DCs (Yeste et al., 2016), or by expanding or delivering Tregs (Dawson and Levings, 2017; Dwyer et al., 2016; Song, 2016). Optimizing this type of approach for human use remains a dream for the future (Michels and Eisenbarth, 2011).

Protecting target organs and preventing irreversible tissue damage will require different therapeutic strategies from blocking systemic autoreactivity (Katschke et al., 2007; Sica et al., 2011; Szekanecz et al., 2009). Approaches to treating fibrosis by antagonizing cytokines such as IL-13 and TGF- $\beta$  will need to take into account the fine balance between antiinflammatory functions and promotion of healing by these cytokines and excessive collagen and matrix deposition (Eming, 2017; Friedman et al., 2013). There is an increasing understanding of the events that lead to maladaptive resolution of inflammation and consequent tissue fibrosis, with the identification of small proresolving lipid mediators that can trigger resolution of inflammatory responses (Dalli and Serhan, 2016; Fredman and Tabas, 2017; Friedman et al., 2013; Serhan, 2017). Other efforts are being directed at blocking or sequestering reactive oxygen species and other toxic metabolites (Telorack et al., 2012), inhibiting transcription pathways that lead to myofibroblast transdifferentiation (Huang et al., 2016; Yu-Wai-Man et al., 2017), decreasing collagen cross-linking, and many others (Friedman et al., 2013). These new therapeutic approaches offer the hope of maintaining immunocompetence while eliminating the consequences of pathogenic autoreactivity.

Finally, the observation that autoimmunity and immunodeficiency can be linked (Grimbacher et al., 2016) suggests that effective treatment of autoimmunity will lead to enhanced immunocompetence, and the reversal of developmental defects in lymphoid cells should reduce autoreactivity. This is the metric against which therapeutic interventions should be judged.

## GOALS FOR THE FUTURE

Over the past several years, new technologies have been developed that will substantially increase our understanding of autoimmune disease. High-throughput technologies to examine genetic polymorphisms, epigenetic changes, gene expression, and protein expression and modifications, linked with the collection of well-characterized databases of patients, make it possible to determine the level of expression of a very large number of genes or proteins in defined populations of patients and subpopulations of cells. These data may provide new insights into disease pathogenesis and new ways to phenotype patients with autoimmune disease. These technologies may also provide sets of biomarkers that will help to determine risk for developing a particular disease, characterize the current activity of the disease and disease prognosis, and assess response to therapy at an earlier time point than current clinical endpoints. It is reasonable to predict that patterns of gene and protein expression will reveal differences and similarities among autoimmune diseases.

The development of biomarkers will, undoubtedly, improve the therapy of autoimmune disease. It may be possible to identify early those patients whose disease is likely to be severe and to monitor disease activity without waiting for clinical symptomatology. Furthermore, the recognition, that autoimmunity can be detected before clinical symptomatology and that the likelihood of development of disease in individual patients can be predicted with more certainty, will allow testing of therapies that have the potential to prevent or cure autoimmune disease before tissue damage occurs. Ultimately, it may be possible to customize therapy for each patient, thereby enhancing efficacy and avoiding unnecessary toxicities and expense.

Given that the diagnosis of complex autoimmune diseases may be delayed, preventing and reversing tissue damage once effector cells have arisen is a pressing therapeutic goal for patients with established disease. Approaches to enhance the resolution of inflammation rather than fibrosis in target organs are still mostly in the experimental stage but much progress has been made in understanding this area and two new drugs are now in clinical use (Sathiyamoorthy et al., 2017). Specific targeting of pathogenic lymphocytes is still not possible in humans, although a proof of principle experiment in an animal model with a known autoantigen has recently been successful (Ellebrecht et al., 2016).

## CONCLUDING REMARKS

The past several years have witnessed a change in our understanding of autoimmunity and a clear new direction in our approach to the study of autoimmunity. Multiple genetic polymorphisms contribute to autoimmunity risk and more remain to be identified. The complexity of regulation of gene expression suggests several other mechanisms by which gene expression may be aberrantly regulated in autoimmunity. It is clear that the activation of the innate immune system can act as a trigger for the initiation of autoimmunity in susceptible individuals and can amplify tissue damage in target organs. Autoimmunity can result from either a failure in T- and B-cell repertoire selection or a failure in the regulation of activated T and B cells. Autoimmune B and T cells can be identified years before the emergence of clinical disease, suggesting that multiple triggers act sequentially to precipitate disease. It is also clear that autoimmunity needs to be coupled to target-organ vulnerability to immune attack for autoimmune disease to be present and that inflammatory cascades can be interrupted or regulated in the periphery. This understanding suggests new therapeutic targets and new therapeutic strategies.

Multiple new therapies have been developed and tested in clinical trials in the last two decades leading to major advances in treatment for some but not all autoimmune diseases. However, many knowledge gaps remain to be filled, especially in understanding which pathways to target in each disease and in determining which individuals will respond to each therapy. The focus on new technologies to provide biomarkers of immune function represents an exciting opportunity to treat disease prior to tissue damage and to customize therapy for each patient. Furthermore, studies of gene and protein expression will help to elucidate those mechanisms of immune dysfunction that are shared among multiple autoimmune diseases and those that are unique to a particular disease. Thus there are reasons to be optimistic, but acquiring the necessary new knowledge and translating that knowledge to therapy could take some years.

Soluble Mediators	50	Secondary Lymphoid Tissues	57
<b>Adaptive Immune Responses</b>	<b>51</b>	<b>Resolution of the Immune Response</b>	<b>59</b>
T-Cell Development	51	References	59

The cells of the immune system are derived from self-renewing hematopoietic stem cells (HSCs) which give rise to multipotent progenitors (MPPs) that are no longer able to self-renew (Dharampuriya et al., 2017). Cytokines and other signals lead to the expression of different patterns of transcription factors (Sarrazin and Sieweke, 2011) which drive the MPPs down particular differentiation pathways, ultimately leading to the generation of lymphocytes, natural killer (NK) cells, dendritic cells (DCs), neutrophils, eosinophils, basophils, mast cells, monocytes, macrophages, megakaryocytes, and erythrocytes.

## THE INNATE AND ADAPTIVE RESPONSES

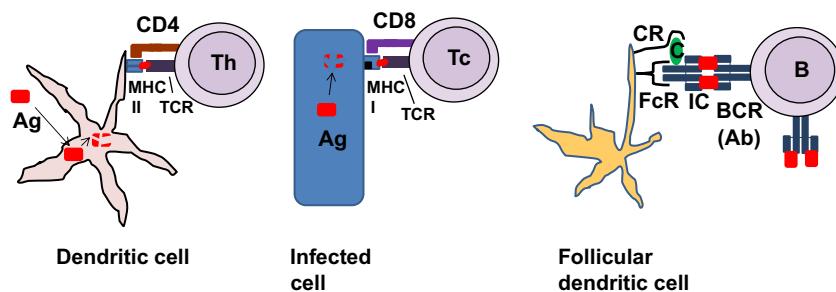

The immune system has traditionally been divided into; innate responses that occur to the same extent however many times the antigen is encountered, and adaptive (acquired) responses that generate immunologic memory leading to quantitatively and qualitatively enhanced responses upon reencounter with the antigen. While this division generally still holds true, it is clear that at least some “innate” cells, for example, NK cells and macrophages, can exhibit a form of immunologic memory referred to as trained or learned immunity (Freud et al., 2017; Kaufmann et al., 2018). Furthermore, there are various subpopulations of innate lymphoid cells, some of which sit at the interface between innate and adaptive responses (Ebbo et al., 2017). Immune responses need to detect a threat using receptors that recognize molecules associated with pathogens (Table 4.1). Innate responses exhibit broad specificity based upon detection of pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) by pattern recognition receptors (PRRs) (Childs and Goodbourn 2017; Broz and Monack, 2013), and the binding to complement receptors and Fc receptors of opsonized antigens coated with complement or antibody. Only the lymphocytes, the dedicated cells of the adaptive response, bear antigen-specific receptors which permit exquisitely refined recognition of individual antigens. Each lymphocyte possesses approximately  $10^5$  antigen receptors of identical specificity. While the B-cell receptor (BCR) recognizes

structures (epitopes) on the surface of native antigen, the epitopes recognized by most T-cell receptors (TCR) are short peptides (Fig. 4.1). The peptides are produced by proteolytic processing of antigen within cells and are presented to T cells by highly polymorphic major histocompatibility complex (MHC) class I and class II cell surface molecules. The main human class I molecules are HLA-A, B, and C and the class II comprises HLA-DP, DQ, and DR. Thus an individual who is heterozygous at each locus will express 12 variants, although cross-pairing of some class II chains can increase this number. MHC class II, which typically presents 15–20 amino acid long peptides to the TCR on CD4<sup>+</sup> helper and regulatory T cells (Tregs), is expressed on DCs, macrophages, B cells, activated human (but not mouse) T cells, and thymic epithelial cells and can be induced on a variety of other cell types. In contrast, MHC class I molecules, which present peptides of 8–10 amino acids in length, are ubiquitously expressed on nearly all nucleated cells in the body and are concerned with alerting CD8<sup>+</sup> cytotoxic T lymphocytes (CTL) to the presence of intracellular infection. Although the peptides presented by MHC class II are longer than those presented by MHC class I, in both cases the TCR recognizes a stretch of about 9 amino acids.

**TABLE 4.1** The Cells of the Immune System Need to Detect a Threat and Do So Using Four Main Groups of Receptors

Receptor	PRR	MHC	TCR	Antibody (BCR)
Location	Cell surface, cytoplasmic, secreted	Cell surface	Cell surface	Cell surface, secreted
Recognition	PAMPs and DAMPs	Each MHC variant can bind many different peptide sequences	Highly antigen specific	Highly antigen specific
Protein diversity in an individual	~100	~12 for classical MHC	Millions	Millions
Genes	Each protein individually encoded. Low polymorphism	Each protein individually encoded. Extremely polymorphic	Genetic recombination creates diversity	Genetic recombination creates diversity

PRR are employed by cells of the innate response (although they are also present on lymphocytes) and collectively are found on cell surfaces, intracellularly or as secreted molecules. They recognize PAMPs, and DAMPs produced by the infected individual in response to infection and/or tissue damage. MHC class I is present on all nucleated cells in the body although MHC class II is highly restricted in its expression. The TCR is present only on T lymphocytes. The transmembrane version of antibody, the BCR, is only present on the surface of B lymphocytes, but antibody is also present throughout the body both as a soluble molecule and held on the surface of cells by Fc receptors. MHC, Major histocompatibility complex; TCR, T-cell receptor; BCR, B-cell receptor; PRR, pattern recognition receptors; PAMPs, pathogen-associated molecular patterns; DAMPs, danger-associated molecular patterns.

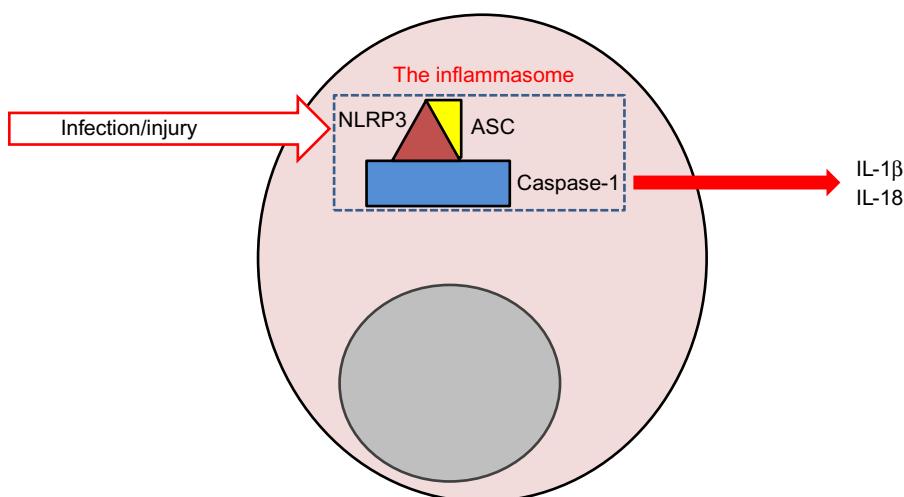

**FIGURE 4.1** Antigen recognition by lymphocytes. Dendritic cells take up external (exogenous) antigen (Ag), process it, and then in the case of protein antigens present it on their cell surface in the form of a peptide fragment bound to MHC class II molecules. This peptide–MHC complex is recognized by the TCR on CD4<sup>+</sup> Th. Antigens lurking inside cells (endogenous antigens, e.g., viruses) can be processed within the cell and then presented on the surface of the infected cell in the form of a peptide fragment bound to MHC class I molecules. This peptide–MHC complex is recognized by the TCR on CD8<sup>+</sup> Tc. Note that some TCR recognize nonprotein antigens such as glycolipids but these are usually presented by the “MHC-like” molecule CD1 rather than by MHC molecules. Cross-presentation can also occur whereby exogenous antigens are presented by MHC class I and endogenous antigens by MHC class II. The BCR is a transmembrane version of the Ab molecule. This directly detects intact antigen, a process which can be assisted by follicular dendritic cells (FDCs) holding immune complexes (IC) of Ab–Ag and complement (C) formed when soluble antibody binds antigen. These complexes become bound to the cell surface Fc receptors (FcR) and complement receptors (CRs) on the FDCs. Note that when the intact antigen is presented by an FDC, the BCR will need to recognize a different epitope on the antigen to that recognized by the antibody in the immune complex.

## INNATE RESPONSES

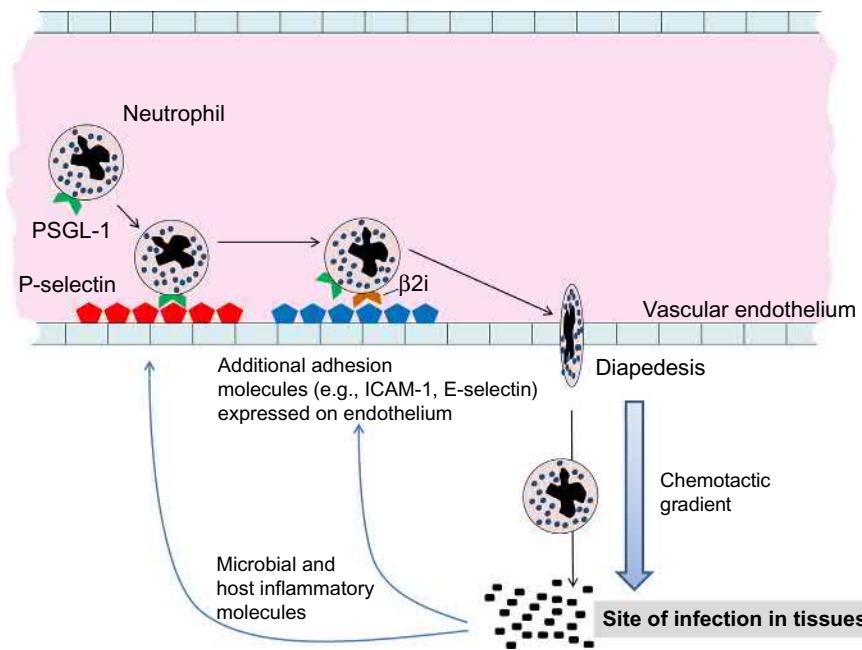

### Cellular Components

Cells of the innate immune response include neutrophils, eosinophils, monocytes, macrophages, and DCs, all of which to varying degrees can act as phagocytic cells, together with the nonphagocytic basophils, mast cells, and NK cells. All of these cell types are capable of producing inflammatory mediators. In myeloid cells, such as macrophages, the detection of infection or tissue injury can result in activation of intracellular molecular complexes referred to as inflammasomes (Fig. 4.2), leading to the secretion of proinflammatory mediators such as the cytokines interleukin (IL)-1 $\beta$  and IL-18 (Malik and Kanneganti, 2017). The immediate consequence of an encounter with an entity that is deemed to pose a threat is the generation of an acute inflammatory response in which cells and molecules of the immune system are rapidly recruited to the site of the stimulus. Inflammatory mediators and microbial products cause the upregulation of adhesion molecules on vascular endothelium, thereby alerting inflammatory cells to the presence of a local infection (Fig. 4.3). Histamine released from mast cells causes smooth muscle contraction and an increase in local vascular permeability, facilitating the passage of neutrophils from the blood to the tissues. Activation of the complement system (Chapter 14: The Roles and Contributions of the Complement System in the Pathophysiology of Autoimmune Diseases) plays a pivotal role in this process, triggering mast cell degranulation and chemotactically attracting the neutrophils (Chapter 13: Granulocytes: Neutrophils, Basophils, Eosinophils). Chemokines (chemotactic cytokines) help guide the neutrophils for antibodies and complement receptors greatly facilitates phagocytosis if the antigen is opsonized with these agents (Freeley et al., 2016; Jacobino et al., 2013). Engulfed microorganisms are killed within the neutrophil by a plethora of toxic molecules including superoxide anions, hydroxyl radicals, hypochlorous acid, nitric oxide, proteases, defensins, and lysozyme. Neutrophil extracellular traps prevent microbial spreading and focus released microbicidal substances onto any nonphagocytosed pathogens in the immediate vicinity of the neutrophil (Lawrence et al., 2018).

Although eosinophils (Chapter 13: Granulocytes: Neutrophils, Basophils, Eosinophils) are able to phagocytose microorganisms, their role in protection against infection is rather more specialized toward the release of granules containing cationic proteins in order to destroy extracellular parasites such as helminths. Eosinophils are also involved in immune regulation, secrete leukotriene C<sub>4</sub>, platelet-activating factor, and an array of cytokines (Robida et al., 2018; Kita, 2011). Blood basophils and tissue mast cells are not phagocytic and share many features. They become sensitized with IgE antibodies bound to their high-affinity Fc $\epsilon$  receptors (Fc $\epsilon$ RI) and,

**FIGURE 4.2** The inflammasome. Inflammasomes comprise multiprotein cytoplasmic complexes that promote inflammation by converting the IL-1 $\beta$  precursor into active IL-1 $\beta$ , and additionally by stimulating the generation of IL-18. The proinflammatory caspase-1, complexed with a receptor such as NLRP3 and with the apoptosis-associated speck-like (ASC) adaptor protein, becomes activated in response to danger signals resulting from infection or tissue damage. There are a variety of inflammasomes which share general characteristics but differ in the receptor they utilize, for example, using other NLR family members, or AIM2 or pyrin. Under certain conditions, inflammasome activation can trigger cell death by pyroptosis or necrosis.

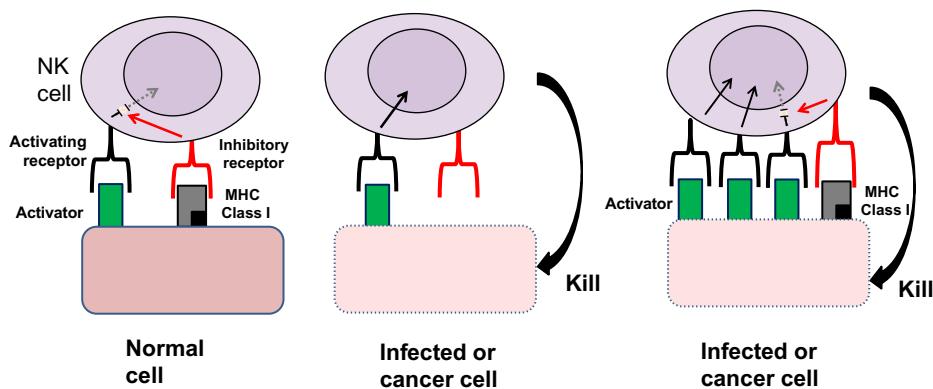

**FIGURE 4.3** Entry of neutrophils into tissue during an inflammatory response. Microbial products, such as LPS, together with inflammatory mediators, such as histamine, thrombin, and the cytokines IL-1 $\beta$ , IL-17, and TNF- $\alpha$ , lead to the increased expression of vascular endothelial adhesion molecules. This alerts neutrophils and other inflammatory cells to the presence of an infection in the underlying tissues. P-selectin becomes expressed on the surface of the endothelium and captures neutrophils due to their possession of P-selectin glycoprotein ligand-1 (PSGL-1). Initially, the neutrophils are slowed down and roll along the blood vessel wall. Signaling through PSGL-1 causes the neutrophils to activate  $\beta_2$  integrins ( $\beta_2i$ ). Additional vascular endothelial adhesion molecules become expressed such as ICAM-1, which binds to the  $\beta_2$  integrins LFA-1 and CR3, and E-selectin which binds to ESL-1, PSGL-1, and CD44 on the neutrophils (Zarbock et al., 2011; Muller, 2011). Eventually, the neutrophils are brought to a halt and squeeze out of the blood vessels, a process known as diapedesis which is greatly facilitated by the deformable nature of the multilobed nucleus in these polymorphonuclear leukocytes.

when antigen cross-links the IgE, release preformed inflammatory mediators including histamine, platelet-activating factor, and many different cytokines. Newly synthesized leukotrienes, prostaglandins, and thromboxanes are also released. Mast cells in humans can predominantly contain tryptase (MC<sub>T</sub>), chymase (MC<sub>C</sub>), or both of these enzymes (MC<sub>TC</sub>), although their phenotype and function are perhaps more strongly linked to their tissue distribution than to the differential expression of these enzymes (Robida et al., 2018).

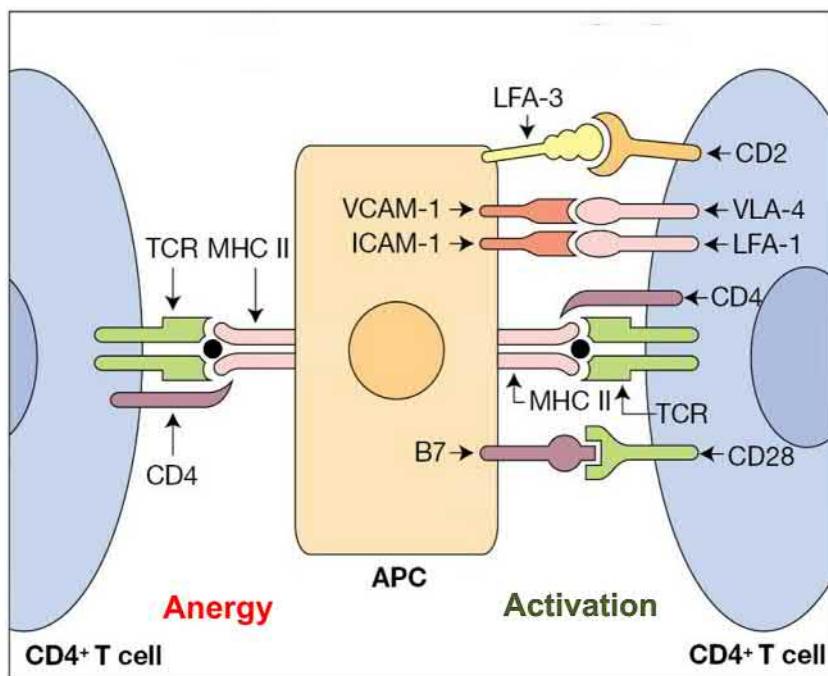

The tissue macrophages (Chapter 10: Role of Macrophages in Autoimmunity) and their circulating precursors, the blood monocytes, possess both Fc receptors and complement receptors and contain similar microbicidal substances to neutrophils. However, they are much longer lived than neutrophils and are able to process antigens for presentation to helper T cells. An additional role of the macrophage is the removal of the body's own dead or dying cells. While tissue damage associated with necrotic cell death triggers inflammation, cells dying due to apoptosis are removed much more quietly. Loss of membrane symmetry is a feature of apoptotic cell death and exposes the molecule phosphatidylserine on the cell surface, marking the cell for phagocytosis by macrophages expressing phosphatidylserine receptors (Arandjelovic and Ravichandran, 2015). Macrophages are key players in inflammatory responses, releasing cytokines such as IL-1 $\beta$  and TNF $\alpha$ , and are particularly characteristic of chronic inflammation.

Sets of activating and inhibitory receptors are expressed on NK cells (Chapter 12: Natural Killer Cells). They enable the NK cells to detect cells that have either lost or altered their expression of self-MHC molecules as a result of infection or oncogenesis. A dominant signal through the activating receptors will lead to the induction of apoptosis in the target cell (Fig. 4.4). NK cells can also mediate antibody-dependent cellular cytotoxicity (ADCC) of antibody-coated target cells and are a rich source of certain cytokines, particularly gamma interferon. This latter activity bestows an important immunoregulatory role upon the NK cell (Wilk and Blish, 2018).

A key interface between innate and adaptive responses is provided by DCs, a heterogeneous population, which include the Langerhans cell in the skin. DCs (Chapter 11: Dendritic Cells in Autoimmune Disease) sample extracellular antigens by endocytosis and become activated to an antigen-presenting mode when their PRRs (Table 4.1), which include Toll-like receptors (TLRs), NOD-like receptors, and various C-type lectin receptors,

**FIGURE 4.4** NK cells possess both activating and inhibitory receptors. The activating receptors recognize a number of different activator ligands constitutively expressed on many cells in the body (e.g., CD112) or expressed in response to factors such as cell stress (e.g., MICA [MHC class I polypeptide-related sequence A]). Activation of killing is usually blocked by engagement of inhibitory receptors that recognize the MHC class I molecules normally expressed on all nucleated cells in the body. Cells lacking MHC class I are not able to engage the inhibitory receptors, are therefore deemed abnormal, and are killed by the NK cells. Even in the presence of MHC class I, if sufficient activating signals are received (because infection, cancer, or other types of cell stress have caused the cell to express higher levels of activators), the inhibitory signal is subdominant and the target cell will be killed.

**FIGURE 4.5** T-cell activation. Interaction of costimulatory molecules leads to activation of resting T lymphocytes by APC on engagement of the TCR with its cognate antigen–MHC complex. Engagement of the TCR without accompanying costimulatory signals leads to anergy (functional inactivation). Note, a cytotoxic rather than a helper T cell would involve coupling of CD8 to MHC class I. Costimulation is delivered to a resting T cell primarily through engagement of CD28 on the T cell by B7.1 (CD80) or B7.2 (CD86) on the APC. Other molecules involved can include ICAM-1, LFA-1/3, VCAM-1, and VLA-4. Source: Modified from Delves, P.J., Martin, S.J., Burton, D.R., Roitt, I.M., 2017. *Roitt's Essential Immunology*, 13th ed. Wiley-Blackwell.

recognize PAMPs such as LPS, terminal mannose, and microbial CpG motifs (unmethylated cytosine–guanine dinucleotide sequence flanked by two 5' purines and two 3' pyrimidines). Endogenous DAMPs such as uric acid and heat shock proteins can also activate these cells (Schaefer, 2014). The activated DCs travel to the local draining lymph node where they present antigen to T cells. During their migration through the afferent lymphatics, they upregulate their cell surface MHC class II molecules and the CD80 (B7.1) and CD86 (B7.2) costimulatory ligands for CD28 on the T cell (Esensten et al., 2016). Such costimulation is required, together with antigen, for T-cell activation (Fig. 4.5). Within the DC, the antigen is processed into short peptides and then expressed on the cell surface together with the MHC class II molecules for presentation to CD4<sup>+</sup> helper T cells and Tregs. DCs are also able to cross-present exogenous antigens by transferring them into the MHC class I processing and presentation pathway for recognition by CD8<sup>+</sup>, mostly cytotoxic, T cells (Cruz et al., 2017). Conversely, cytoplasmic antigens can undergo autophagy and be cross-presented to CD4<sup>+</sup> (mostly helper) T cells following delivery to the MHC class II presentation pathway (Münz, 2016).

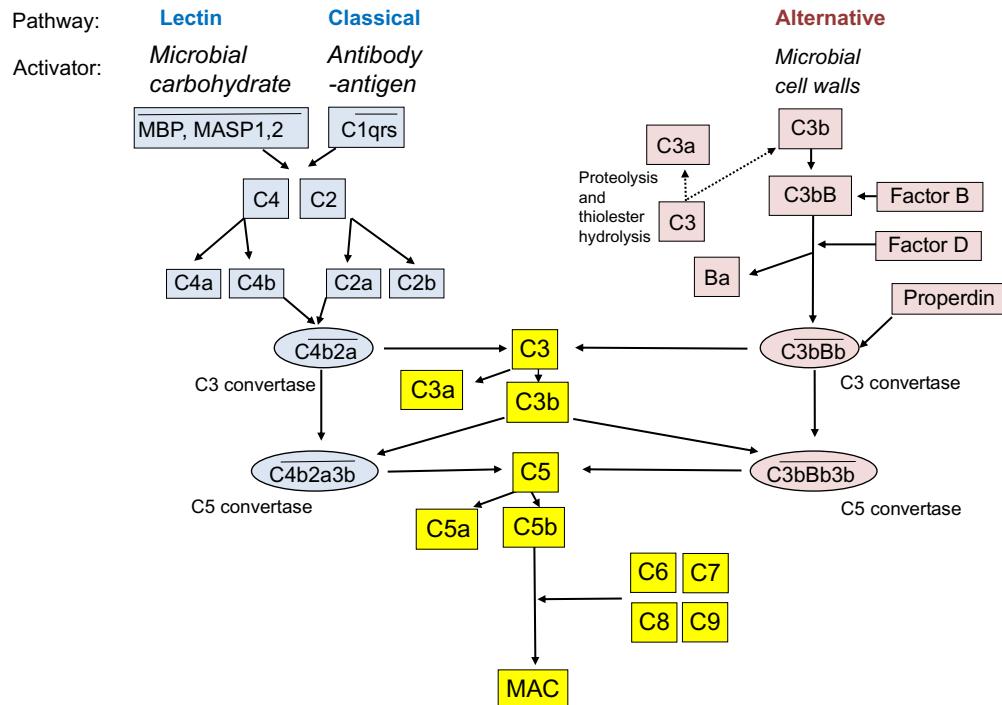

DCs can also act to limit immune responses. T-cell interactions with DCs lacking the expression of the crucial CD80/CD86 costimulatory molecules induce anergy (functional inactivation) in the T cell. Immunosuppression by DCs can be mediated via their production of the tryptophan-depleting enzyme indoleamine 2,3-dioxygenase (tryptophan being required for T-cell proliferation) or by the preferential stimulation of Tregs (Domogalla et al., 2017).

Although B cells are able to recognize antigen without the intervention of any other cell type, recognition is more efficient if multiple copies of the antigen are “presented” to the B cell in the form of immune complexes held on the surface of follicular DCs (FDCs) (Heesters et al., 2014). These are an entirely different cell type to the DCs discussed above. Unlike DCs, they are not phagocytic, and they lack MHC class II molecules. Furthermore, and unlike most cells of the immune response, they are not derived from HSCs but instead are of stromal origin (Heesters et al., 2014). They can present immune complexes to B cells very efficiently by virtue of their Fc $\gamma$ RIIB receptors for IgG and CR1 and CR2 receptors for complement.

The role that erythrocytes perform in immune responses should not be overlooked. Their possession of CR1 complement receptors for C3b, C4b, and iC3b confers on these cells an important role in clearing immune complexes from the circulation, rapidly transporting them to the liver and spleen where they are destroyed by Kupffer cells and splenic macrophages (Birmingham, 1995).

## Soluble Mediators

The complement system (Chapter 14: The Roles and Contributions of the Complement System in the Pathophysiology of Autoimmune Diseases) is based upon an enzymic amplification cascade which can be triggered using one of three pathways; classical, lectin, and alternative (Ehrnthaller et al., 2011). These all lead to the cleavage of complement component C3 into C3a and C3b by a C3 convertase enzyme (Fig. 4.6). The classical pathway is activated by IgG and IgM antibodies when they bind antigen, thereby creating an array of closely associated immunoglobulin Fc regions to which complement component C1q binds, followed by C1r and C1s. This event initiates a series of enzymic reactions leading to the generation of the classical pathway C3 convertase, C4b2a. The lectin pathway, which is essentially an antibody-independent variant of the classical pathway, leads to the generation of the same C3 convertase when microbial carbohydrates interact with mannose-binding

**FIGURE 4.6** The complement system. For simplicity, complement regulatory proteins have been omitted. The classical and lectin pathways (pale blue) are very similar. Like the alternative pathway (pink), these pathways generate C3 and C5 convertases leading to shared post-C3 events (yellow). For details see text.

protein (MBP) which then binds to the two MBP-associated serine proteases MASP-1 and MASP-2. The initially quite separate alternative pathway is activated when complement component C3b becomes stabilized by binding to microbial cell walls. The C3b then combines with factor B which is cleaved by factor D, generating a different C3 convertase, C3bBb. This C3 convertase is further stabilized by properdin. Both proteolysis and thiol-ester hydrolysis of C3 constitutively generate very low levels of C3b. However, in the alternative pathway, it is only when C3bBb is generated that there is a substantial splitting of C3 into C3a and C3b. Subsequently, a C5 convertase, either C4b2a3b (from the classical and lectin pathways) or C3bBb3b (from the alternative pathway), is produced by addition of C3b to the C3 convertase. This splits C5 into C5a and C5b, ultimately leading to the generation of the membrane attack complex (MAC) composed of complement components C5b, C6, C7, C8, and C9. Because complement activation consists of a series of sequential enzyme reactions, there is a tremendous amplification of the initial response, and along the way, a number of complement components with potent immunologic activities are generated.

A major function of C3b (and its cleavage products iC3b and C3d) and of C4b is to enhance the engulfment of antigens by phagocytic cells bearing the complement receptors CR1 and CR3. The C3a, C4a, and C5a components act as anaphylatoxins triggering the release of inflammatory mediators from mast cells and basophils. C5a is also a potent neutrophil chemoattractant. The MAC (C5b6789) generates pores in cell membranes, ultimately leading to the demise of the target cell by apoptosis. Because of these many potent activities, the complement cascades are tightly controlled by a number of complement regulatory proteins including C1 inhibitor (which dissociates the C1qrs complex), factor H and factor I (which cooperate to break down C3b in the alternative pathway), CD46 (membrane cofactor protein) and CD55 (decay accelerating factor) both of which limit the formation and function of the C3 convertases, and CD59 (homologous restriction factor, an inhibitor of MAC formation) (Holders, 2014).

Complement components C3, C9, and factor B are classed as acute phase proteins. This diverse group of mediators, which also include C-reactive protein, serum amyloid A protein, proteinase inhibitors, and coagulation proteins, share an ability to undergo a rapid change in plasma concentration in response to infection, inflammation, and tissue injury. Collectively, the acute phase proteins facilitate host resistance to infection and promote the resolution of tissue damage (Gabay and Kushner, 1999).

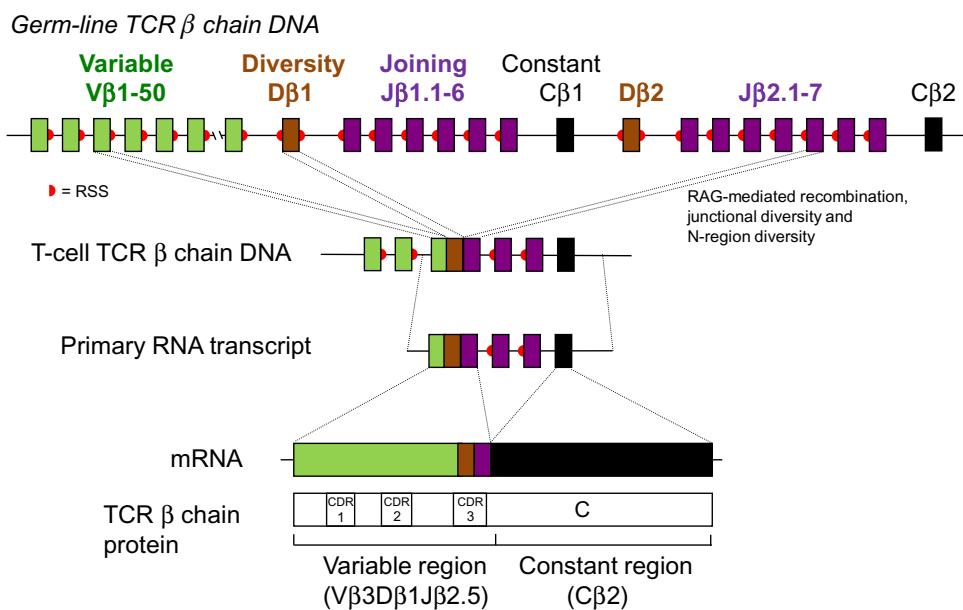

Another group of proteins, which function in both the innate and adaptive response, are the cytokines (Wilson and Barker, 2013) (Chapter 15: Cytokines, Their Receptors and Signals). These soluble mediators facilitate communication both within the immune system and between the immune system and other cells of the body. In order to respond to a given cytokine, a cell must express the relevant cytokine receptor. One subset of cytokines, the chemokines (Chen et al., 2018), is important in ensuring that immune system cells end up in the correct location as already mentioned in the context of an acute inflammatory response. In addition to acting as communication molecules, some cytokines play a more direct role in immune defense. For example, the interferons produced by virally infected cells establish a state of viral-resistance in surrounding noninfected cells, thereby acting as a “firebreak” against the spread of the infection (Fensterl et al., 2015).

## ADAPTIVE IMMUNE RESPONSES

The adaptive responses involve the clonal expansion of antigen-specific B and T lymphocytes. B cells differentiate into plasma cells which secrete the antigen-specific antibodies responsible for the elimination of extracellular antigens. T cells help other cells in the immune response, kill infected cells, or suppress undesirable immune responses.

### T-Cell Development

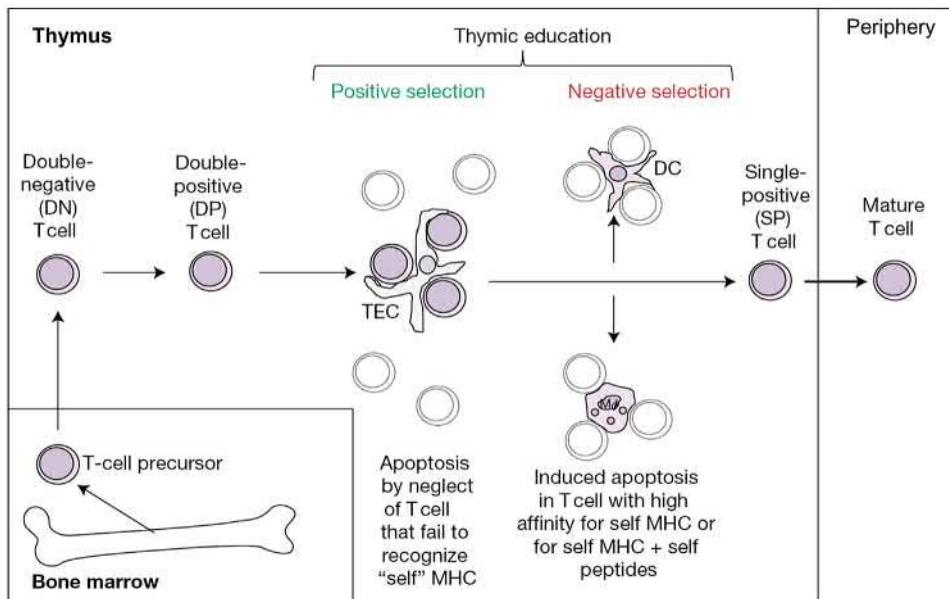

T-cell precursors migrate from the bone marrow to the thymus, an organ essential for their production. T-cell development occurs in the thymus throughout life, despite the fact that it undergoes significant atrophy during aging (Dooley and Liston, 2012). The TCR on T cells comes in two different versions, either an  $\alpha\beta$  or a  $\gamma\delta$  heterodimer; each chain of the dimer having one variable domain and one constant domain. Collectively, T lymphocytes are capable of producing vast numbers of different TCR variable regions by recombining variable (V) and joining (J) gene segments from the pools of  $\alpha$  and  $\gamma$  TCR genes and V, diversity (D) and J gene segments from the pools of  $\beta$  and  $\delta$  TCR genes (Ciofani and Zúñiga-Pflücker, 2010). There are a number of different sequences for each segment and one out of each V(D)J set is utilized in the recombination event (Fig. 4.7).

**FIGURE 4.7** Diversity of antigen receptors. As an example, the recombination of the TCR  $\beta$  chain genes is shown. Early in T-cell development, the recombination-activating genes RAG-1 and RAG-2 are expressed. Random recombination of either the diversity (D)  $\beta$ 2 gene segment next to any one of the 7 joining (J)  $\beta$ 2 gene segments, or of the D $\beta$ 1 gene segment to any one of the 13 J $\beta$ 1 or J $\beta$ 2 gene segments, is followed by recombination of any one out of approximately 50 variable (V) gene segments next to the already rearranged DJ segment. The RAG enzymes recognize RSS found 3' of each V gene segment, both 5' and 3' of each D gene segment, and 5' of each J gene segment. Different T cells will recombine a different segment out of each pool, thereby creating one level of diversity. Additional heterogeneity is brought about by junctional diversity due to splicing inaccuracies and by the fairly random incorporation of nucleotides (N-region diversity) mediated by the enzyme TdT. The primary RNA transcript is processed into mRNA, with splicing of the rearranged VDJ next to the downstream C $\beta$  constant region gene. This mRNA will encode a TCR  $\beta$  chain which is placed on the surface of the pre-T cell together with an invariant pre-T $\alpha$  chain. As the pre-T cell undergoes further maturation, the TCR  $\alpha$  gene segments (for simplicity not shown in the figure) recombine to produce the TCR  $\alpha$  chain. This replaces the pre-T $\alpha$  chain in order to produce a mature  $\alpha\beta$  TCR on the cell surface. The complementarity-determining regions CDR1 and CDR2 within the  $\alpha$  and  $\beta$  chain variable regions bind to MHC while CDR3 binds to the peptide. Although the detailed organization of the germ-line genes for the TCR  $\alpha$  chain, Ig heavy chain, Ig  $\kappa$  light chain, and Ig  $\lambda$  light chain are somewhat different to each other, they all consist of pools of V, J, and, for IgH as well as TCR  $\beta$  chain and TCR  $\delta$ -chain, D gene segments that undergo recombination to create antigen receptor diversity. The same general principles regarding the rearrangement process, therefore, apply to the generation of the  $\gamma\delta$  TCR on  $\gamma\delta$  T cells and to the BCR on B cells.

Recombination-activating genes encode the enzymes recombination activating gene (RAG-1) and RAG-2 which mediate these processes following the recognition of the recombination signal sequence (RSS) nucleotide motifs flanking the V, D, and J gene segments (Teng and Schatz, 2015). Splicing inaccuracies and the insertion of additional nucleotides around the V–D–J junctions by the enzyme terminal deoxynucleotidyl transferase (Tdt) further increase diversity (Benedict et al., 2000).

Recombination, and subsequent expression, of the TCR genes does not occur until the precursor T cells reach the thymus. Developing  $\alpha\beta$  T cells switch on expression of both CD4 and CD8 cell surface molecules and are therefore referred to as “double positive” T cells. This dual expression permits the TCR on  $\alpha\beta$  T cells to potentially interact with both MHC class I and MHC class II molecules. CD4 binds to conserved (nonpolymorphic) residues on the MHC class II molecule while CD8 binds to conserved residues on MHC class I. Positive and negative selections of the  $\alpha\beta$  T cells then occur (Klein et al., 2014). At this relatively early stage in their differentiation,  $\alpha\beta$  T cells are programmed to undergo apoptosis (Chapter 16: Cellular Injury and Apoptosis) and are only rescued from this default “death by neglect” if their TCR is capable of binding to self-peptide + self-MHC on the thymic epithelial cells (Fig. 4.8). Positive selection ensures that the randomly generated  $\alpha\beta$  TCR is able to interact with self-MHC molecules (i.e., those allelic variants of the MHC that are present in the individual). During positive selection, T cells lose expression of either CD4 or CD8 to become “single positive” CD4 or CD8 cells. Because of the random recombination of the TCR genes (which maximizes diversity), most T cells will be unable to recognize self-MHC and therefore will fail to be positively selected and are eliminated (Klein, et al., 2014). This leaves (1) potentially useful T cells that are capable of recognizing the individual’s own MHC variants presenting peptides derived from foreign pathogens and (2) potentially harmful T cells that are capable of recognizing the individual’s own MHC variants

**FIGURE 4.8** Positive and negative selection in the thymus. Following a productive recombination of their TCR  $\alpha$  chain and TCR  $\beta$  chain genes, T cells express a cell surface TCR together with both CD4 and CD8 to become double-positive T cells. Positive selection on thymic epithelial cells (TEC) that expresses both MHC class I and MHC class II will rescue T cells from a default pathway of apoptosis which occurs if these cells are neglected. As long as they have generated a TCR able to recognize self-MHC they are saved from neglect. The rescued cells are then protected from apoptosis unless they actively undergo negative selection due to high-affinity interaction of their TCR with self-MHC or self-MHC + self-peptides present on DC and macrophages. The  $CD4^+$   $CD8^-$  and  $CD4^-$   $CD8^+$  single-positive T cells that exit the thymus, therefore, possess an  $\alpha\beta$  TCR with the potential to detect foreign peptides presented by self-MHC. Source: Modified from Delves, P.J., Martin, S.J., Burton, D.R., Roitt, I.M., 2017. *Roitt's Essential Immunology*, 13th ed. Wiley-Blackwell.

presenting peptides derived from autoantigens. Apoptosis is therefore subsequently induced in any lymphocytes capable of high-affinity binding to self-peptide + self-MHC on DCs, macrophages, and thymic epithelial cells. This negative selection by the clonal deletion in the thymus constitutes central tolerance of autoantigen-reactive T cells (Chapter 5: Immunological Tolerance—T Cells) and, like failure to be positively selected, also results in extensive T-cell death within the thymus. Peptides are generated from a number of organ- and tissue-restricted self-antigens ectopically expressed in the thymus and peripheral lymph nodes under the transcriptional control of the autoimmune regulator (AIRE) protein (Conteduca et al., 2018). Not all autoantigen-reactive cells are eliminated. Those with an intermediate affinity for autoantigen can develop into Tregs (Klein et al., 2014). T cells that successfully pass through these hurdles exit the thymus and enter the periphery, a term used to denote any location outside of the primary lymphoid organs (bone marrow and thymus). These mature naïve  $\alpha\beta$  T cells will be capable of recognizing foreign peptides presented by self-MHC. Generally,  $\gamma\delta$  T cells, although also arising in the thymus, do not express either CD4 or CD8 and they recognize antigen directly rather than in the form of peptide–MHC.

## Functional Activities of T Cells

The  $\alpha\beta$  and  $\gamma\delta$  TCRs are not by themselves able to transmit activation signals into the cell, this function being assigned to the CD3 molecules (CD3 $\gamma$ , CD3 $\delta$ , CD3 $\epsilon$ ) and the CD3-associated  $\zeta$  chains. Receptor aggregation occurs within lipid rafts which also incorporate a number of adhesion and costimulatory molecules including lymphocyte function-associated antigen-1 (LFA-1), CD2, CD28, and CD45 to form the immunological synapse (Dustin and Choudhuri, 2016). Stimulation through the synapse results in the phosphorylation of tyrosines within immunoreceptor tyrosine-based activation motifs (ITAMs) present on the cytoplasmic tails of the CD3 complex and the  $\zeta$  chains. A number of protein kinases including Lck and ZAP-70, together with the adaptor proteins SLP-76 and LAT, are involved in initiating the signaling cascade (Smith-Garvin et al., 2009). The CD45 phosphatase also plays a critical role in lymphocyte activation by its ability to act as both a positive and negative regulator of the Lck kinase in T cells and of the Fyn kinase in B cells (Saunders and Johnson, 2010).

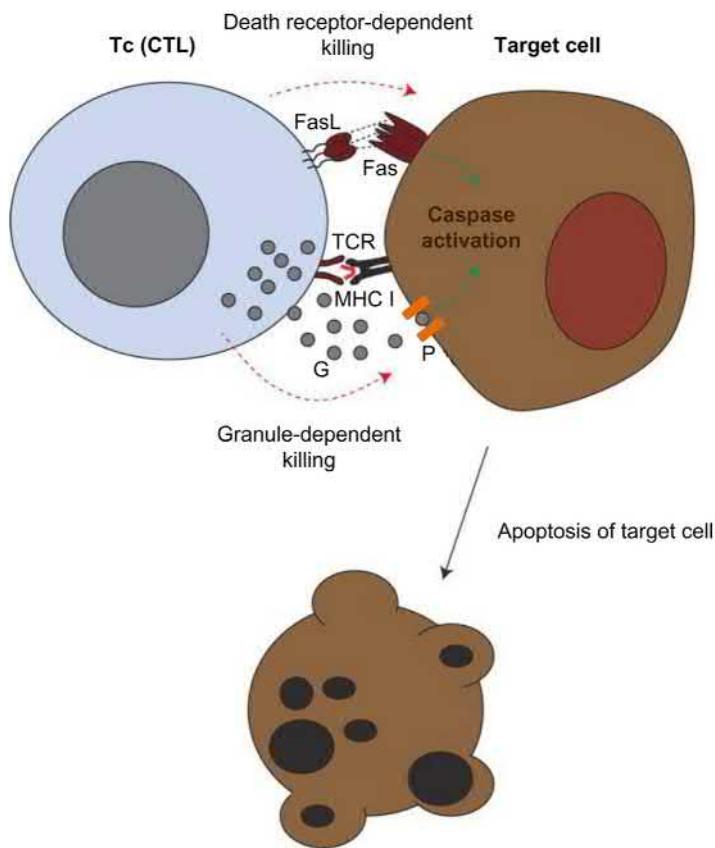

Broadly speaking,  $CD4^+$  T cells act as helper or regulatory T lymphocytes while  $CD8^+$  T cells are usually cytotoxic (Chapter 6: T Cells and Their Subsets in Autoimmunity). However, some  $CD4^+$  cells can exhibit cytotoxic

activity (Takeuchi and Saito, 2017), while CD8<sup>+</sup> cells secrete cytokines that can help in the generation of immune responses, be cytotoxic or be immunosuppressive (Woodland and Dutton, 2003).

The TCR on CD8<sup>+</sup> CTL binds to peptide–MHC class I on target cells. Endogenous antigens, including self-antigens and viral proteins, are broken down into peptides by a proteolytic structure known as the immunoproteasome (Krüger and Kloetzel, 2012). If the TCR recognizes the peptide–MHC combination and receives costimulation, then the CTL becomes activated to kill the target cell, for example, a cell infected with virus or a tumor cell (Tscharke et al., 2015). It does this by inducing apoptosis in the target via engaging the Fas molecule on the target cell with Fas ligand on the CTL or by using the perforin/granzyme pathway (Fig. 4.9).

In contrast to the ubiquitously expressed MHC class I, MHC class II is only present on a few specialized cells, including DCs, macrophages, and B cells (professional antigen-presenting cells). These cells generate peptides by proteolytic cleavage of engulfed antigens within endosomal vesicles and then present the peptide–MHC class II combination to CD4<sup>+</sup> T cells. Helper T cells can be divided into different populations based upon the cytokines they produce. Cells secreting IL-2, interferon- $\gamma$  (IFN $\gamma$ ), and tumor necrosis factor  $\beta$  (TNF $\beta$ , lymphotoxin) but not IL-4 and IL-5 are designated Th1 cells, those secreting IL-4, IL-5, IL-10, and IL-13 but not IL-2 and IFN $\gamma$  are classified as Th2 cells, and those secreting IL-17, IL-21, and IL-22 are termed Th17 cells (Patel and Kuchroo, 2015) (Fig. 4.10). In general, cytokine production by Th1 cells facilitates cell-mediated immunity, involving macrophage activation and T-cell-mediated cytotoxicity, and assists in the production of some humoral responses. Cytokines produced by Th2 cells are mostly involved in humoral immunity, particularly involving IgE and IgA responses, and cytokines from Th17 cells mediate inflammatory and a variety of other responses (Patel and Kuchroo, 2015). IL-12 from DCs drives T cells toward a Th1 phenotype (Schmitt and Ueno, 2015) and Th1/Th2 responses tend to become polarized because the IFN- $\gamma$  from Th1 cells downregulates Th2 activity, whereas IL-4 and IL-13 from Th2 cells downregulate Th1 cells.

A population of CD4 lymphocytes exist which have some properties of NK cells and some properties of T cells. Many of these NKT cells (Chapter 7: The Role of Invariant Natural Killer T Cells in Autoimmune Diseases) express an invariant TCR which recognizes lipid antigen presented by the nonclassical MHC molecule CD1d. NKT cells are multifunctional and secrete a range of cytokines (Godfrey and Rossjohn, 2011).

**FIGURE 4.9** Cytotoxic T lymphocytes. Cytotoxic T-cells (Tc, CTL) can kill target cells by the granule-dependent pathway in which the CTL inserts perforin (P) into the target cell membrane to act as a channel for the passage of granzyme B (G) and other serine proteases into the target cell. They can also kill target cells by engaging Fas on the target using their cell surface FasL. Both pathways result in the activation of caspases leading to apoptotic cell death in the target cell. Primary function	Help CTL and macrophages (and some B cells) Inhibit Th2	Help B cells Inhibit Th1	Promote inflammation	Help germinal center B cells	Suppress immune responses

**FIGURE 4.10** T-cell subpopulations. The major subpopulations of CD4<sup>+</sup>  $\alpha\beta$  T lymphocytes are shown with key transcription factors, characteristic secreted or cell surface molecules, and functional attributes that distinguish them. Note that cytotoxic T cells can also be subdivided on the basis of cytokine production into Tc1, Tc2, etc. ICOS, Inducible T-cell costimulator (cell surface molecule); Tfh, follicular helper T cell; Th, helper T cell; Treg, regulatory T cell.

The antigen-specificities and functions of  $\gamma\delta$  T cells are less well characterized than that of  $\alpha\beta$  T cells (Chapter 5: Immunological Tolerance—T Cells) but some  $\gamma\delta$  TCRs recognize molecules that are upregulated in response to cellular infection or stress (Adams et al., 2015).  $\gamma\delta$  T cells take up residence throughout the body, being particularly prevalent in epithelia including the mucosal tissues. They can function as cytotoxic cells and mediate both inflammatory and suppressive activity via their ability to secrete a diverse range of cytokines including TNF $\alpha$ , IFN $\gamma$ , TGF $\beta$ , IL-4, IL-5, IL-10, IL-13, and IL-17 (Bonneville et al., 2010).

## B-Cell Development and Functions

A minor population of B cells (Chapter 8: B Cell Development: How to Become One of the Chosen Ones), B1 cells, develops early during ontogeny and often expresses the CD5 cell surface molecule (Hardy and Hayakawa, 2015). These cells secrete low-to-moderate affinity IgM antibodies which can exhibit polyreactivity, that is, recognize several different antigens, often including common pathogens and autoantigens. Such antibodies are often referred to as natural antibodies because of their existence in the absence of an obvious antigenic stimulus. The majority of B cells, B2 cells, lack CD5 and develop slightly later in ontogeny. Like T cells, these B cells are collectively capable of producing a huge number of different variable regions on their antigen receptors. They achieve this by recombining the immunoglobulin heavy and light chain gene loci in a process analogous to the recombination of TCR genes in T cells.

Early in B-cell development, pro-B cells mature into pre-B cells, at which stage they express RAG-1 and RAG-2. Random recombination of any one of the approximately 25 diversity (D) gene segments next to any one of the 6 joining (J) gene segments is followed by rearrangement of any one out of approximately 40 variable (V) gene segments next to the already recombined DJ segment. As with the TCR in T cells, additional diversity is brought about by splicing inaccuracies and the action of TdT. The heavy chain primary RNA transcript is processed into mRNA, with splicing of the rearranged VDJ next to the C $\mu$  constant region gene. This mRNA will encode a  $\mu$  heavy chain which is placed on the surface of the pre-B cell together with the surrogate light chain Vpre-B  $\lambda$ 5 encoded by two nonrecombining genes termed VpreB and  $\lambda$ 5. Expression of this pre-BCR on the immature B cell leads to ligand-independent signaling which drives B-cell differentiation toward the mature naïve B-cell coexpressing conventional IgM and IgD antibodies on the cell surface (Übelhart et al., 2016). As the pre-B cell undergoes maturation, the immunoglobulin light chain V (which number about 40 for V $\kappa$  and 30 for V $\lambda$ ) and J (of which there are 5 for each light chain isotype) gene segments rearrange to produce a  $\kappa$  or  $\lambda$  light chain. This light chain replaces the surrogate light chain in order to produce a mature IgM BCR on the cell surface. Expression of RAG-1 and RAG-2 is now switched off. Once the B cells express a mature antigen receptor, their survival and further differentiation become antigen-dependent. The BCR at this stage also comprises IgD antibodies of the same specificity, produced by alternative splicing of the rearranged VDJ to either the C $\mu$  or C $\delta$  constant region genes.

The cell surface immunoglobulin is associated with several molecules including Ig $\alpha$  (CD79a), Ig $\beta$  (CD79b), CD19, CD21 (the CR2 complement receptor), CD81 (TAPA-1), and CD225 (Leu13) which collectively transmit activation signals into the cell when receptor aggregation occurs following cross-linking of the antibody by antigen (Chapter 9: B Cell Activation and B Cell Tolerance). This signaling initially involves phosphorylation of ITAM sequences on the cytoplasmic tails of Ig $\alpha$  and Ig $\beta$  by the protein tyrosine kinase Lyn, with subsequent recruitment of additional kinases including Syk and Btk (Harwood and Batista, 2010). Upon binding to the BCR, antigen is endocytosed and then processed within acidified endosomes for presentation by MHC class II to CD4 $^+$  helper T cells (Clark et al., 2004). In addition to an antigen-presenting role, B cells secrete a variety of cytokines including IL-10, IL-12, IL-13, TNF $\alpha$ , TNF $\beta$  (lymphotoxin), transforming growth factor- $\beta$  (TGF $\beta$ ), and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Wilson and Barker, 2013). Following the encounter with antigen in the presence of costimulatory signals, the B cells undergo rounds of proliferation and then differentiate into memory cells or alternatively into plasma cells which produce high levels of soluble antibody. Many plasma cells are short lived, but others survive for long periods of time, particularly in the bone marrow (Lam and Bhattacharya, 2018).

## Antibodies

The immunoglobulin antibody molecules are composed of two identical heavy polypeptide chains and two identical light polypeptide chains, held together by interchain disulfide bonds. All immunoglobulins are glycoproteins, containing between 2% and 14% carbohydrate depending on the antibody class (Arnold et al., 2007). The N-termini of the light and heavy chains are each folded into a variable domain containing three hypervariable loops, constituting the complementarity determining regions (CDRs) responsible for noncovalent binding to the antigen. Most protein epitopes recognized by antibodies are discontinuous, comprising amino acids that are only brought together upon protein folding (Kirpach and Muller, 2015). The heavy chain C-terminal domains form the constant region which specifies the class/subclass of antibody. The light chain constant domain determines the  $\kappa$  or  $\lambda$  isotype. The human antibody classes are IgG, IgA, IgM, IgD, and IgE, with four IgG (IgG1–4) and two IgA (IgA1–2) subclasses (Schroeder and Cavacini, 2010) (Table 4.2). Each antibody can be produced either with a C-terminal hydrophobic transmembrane sequence to anchor the molecule in the B-cell membrane where it functions as the BCR or as a secreted molecule lacking the transmembrane sequence and released from plasma cells.

The basic antibody monomer (biochemically a tetramer) of two identical heavy chains and two identical light chains is bivalent with two antigen-binding arms of identical specificity. Secretory IgA at mucosal surfaces is a

**TABLE 4.2** Antibodies—the Main Properties and Approximate Serum Concentration of Human Antibodies

Antibody class/ subclass	Serum conc. (approx.)	Major features include
IgM	1.5 mg/mL	Constitutes, together with IgD, the BCR on naïve B cells. Secreted IgM acts mainly in the circulation and is the first antibody class to be produced in an immune response. Activates complement. Powerful agglutinin
IgG1	9 mg/mL	Most abundant antibody in the blood. Activates complement and enhances phagocytosis. Can cross the placenta
IgG2	3 mg/mL	Activates complement. Poorly transported across placenta
IgG3	1 mg/mL	Activates complement and enhances phagocytosis. Can cross the placenta
IgG4	0.5 mg/mL	Can undergo Fab arm exchange to become bispecific. Can cross the placenta
IgA1	3 mg/mL	In secretory form protects mucosal surfaces
IgA2	0.5 mg/mL	In secretory form protects mucosal surfaces
IgD	30 $\mu$ g/mL	Constitutes, together with IgM, the BCR on naïve B cells
IgE	0.05 $\mu$ g/mL	In presence of antigen triggers release of inflammatory mediators from mast cells and basophils

BCR, B-cell receptor.

tetravalent dimer comprising two identical IgA molecules, whereas circulating IgM is most frequently a decavalent pentamer of five identical IgM molecules with a minor proportion of hexamers and tetramers. IgA and IgM polymerization is stabilized by a polypeptide J (joining) chain (Johansen et al., 2000).

Antibodies that are capable of inhibiting the binding of microorganisms or biological molecules (toxins, hormones, cytokines, and so forth) to their cellular receptors exert their effect independently of other immune system components and are referred to as neutralizing antibodies. Usually, however, antibodies do not function in isolation but are employed to activate the classical complement pathway and/or link antigen to Fc receptor-bearing cells. Antigens opsonized with IgG, IgA, or IgE bind to the appropriate Fc receptors ( $Fc\gamma R$ ,  $Fc\alpha R$ , or  $Fc\epsilon R$ ) on phagocytic cells (Hogarth, 2015). Alternatively, both IgG and IgE can mediate ADCC in which NK cells, monocytes, macrophages, and neutrophils bearing  $Fc\gamma$  receptors or macrophages, eosinophils, and platelets bearing  $Fc\epsilon$  receptors are focused onto antibody-coated target cells or parasites (Graziano and Guyre, 2006). IgE antibodies are also able to sensitize mast cells and basophils via the high-affinity IgE receptor  $Fc\epsilon RI$  and if cross-linked by antigen will trigger the release of inflammatory mediators.

The epithelial cell poly-Ig receptor transports dimeric secretory IgA produced by plasma cells underlying mucosal surfaces (Johansen and Brandtzaeg, 2004). On the luminal side of the epithelium, the IgA is released by proteolytic cleavage of the receptor, leaving a fragment called secretory component still attached to the IgA. Secretory IgA acts to prevent microbial adhesion to the epithelial cell wall (Corthésy, 2010).

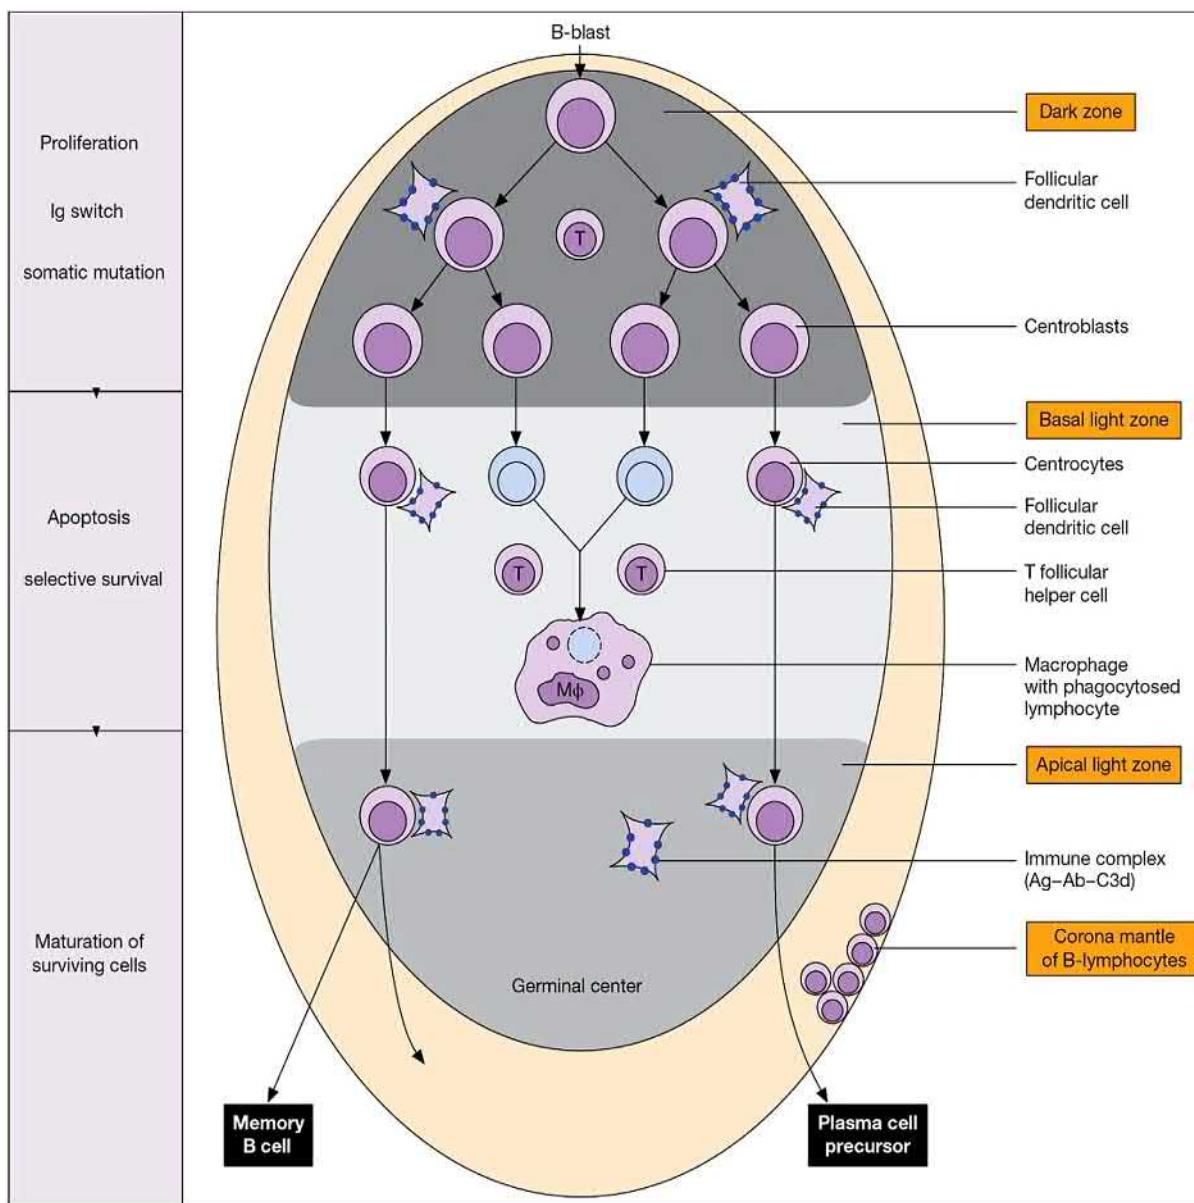

Another type of receptor,  $FcRn$ , is expressed on vascular endothelium where it is involved throughout life in the recycling of IgG in order to increase the circulating half-life of this class of immunoglobulin. It is also present in the placenta, where it transports IgG from the maternal to the fetal circulation, and on the intestinal epithelium of the neonate where it is involved in the uptake of IgG from maternal milk (Stapleton et al., 2015).

## Secondary Lymphoid Tissues

The primary lymphoid organs, the bone marrow and thymus, are where fully differentiated mature naïve T and B cells are generated. However, activation of lymphocytes occurs in structurally organized B- and T-cell compartments in the secondary lymphoid tissues; the mucosa-associated lymphoid tissues, lymph nodes, and spleen. Large numbers of lymphoid cells are present throughout the lung (Lloyd and Marsland, 2017) and in the lamina propria of the intestinal wall (Faria et al., 2017). Because only a handful of lymphocytes will be specific for a given antigen, T and B cells recirculate through the different lymphoid tissues in order to increase the chances of encountering antigen. While responses to blood-borne antigens are usually initiated in the spleen, those to antigens in the tissues are stimulated in the local draining lymph nodes.

Lymphoid follicles within the secondary lymphoid tissues contain germinal centers where B-cell activation occurs within a meshwork of FDCs displaying immune complexes on their surface (Fig. 4.11). T follicular helper cells are specialized for providing help to germinal center B cells (Webb and Linterman, 2017). Germinal centers are at the heart of the generation of adaptive responses for it is here that B cells proliferate, class switch, undergo affinity maturation, and differentiate into memory cells and into plasma cell precursors (Mesin et al., 2016). B cells can increase the binding affinity of their BCR by somatic hypermutation (SHM) of the V(D)J genes. Higher affinity clones will then be preferentially selected by antigen. Class switching from IgM to IgG, IgA, and IgE involves switch sequences composed of highly repetitive nucleotide motifs present immediately upstream of each constant region gene (except C $\delta$ ; IgM and IgD being coexpressed as the BCR on naïve B cells). Both somatic hypermutation and class switch recombination (CSR) require the expression of activation-induced cytidine deaminase (AID) and the utilization of the nonhomologous DNA end-joining machinery (Methot and Di Noia, 2017). A process referred to as receptor editing enables self-reactive B cells to replace the variable region gene in the recombined VDJ heavy or VJ light chain sequence with a different variable region gene in order to eliminate autoreactivity (Lang et al., 2016).

Most pathogens enter the body through mucosal surfaces. The palatine tonsils and adenoids are the sites for induction of responses to intranasal and inhaled antigens (Brandtzaeg, 2011). Antigens from the gut are taken up by specialized epithelial microfold (M) cells which transport the antigens across the epithelium for access to the Peyer's patches where mucosal responses are initiated (Lo, 2018). Activated lymphocytes exit the Peyer's patches via the efferent lymphatics, traffic through the blood, and then home to the lamina propria and other mucosal effector sites (Brandtzaeg, 2009). Intraepithelial lymphocytes are interspersed between the gut epithelial cells, have a diverse phenotype, and can be either cytotoxic or immunoregulatory (Cheroutre et al., 2011).

**FIGURE 4.11** The germinal center. During the initiation of the adaptive immune response, these structures form in the secondary lymphoid tissues in order to generate a microenvironment where all the necessary antigen-specific and innate antigen-presenting cells can interact. Antigen-stimulated B-cell proliferation occurs in the dark zone and is accompanied by affinity maturation, due to SHM of the immunoglobulin V(D)J genes, and CSR. Both SHM and CSR are associated with the expression of AID in the B cell. Upon passage into the basal light zone, high-affinity antigen-specific B cells are positively selected by interaction with antigen, which is present in the form of immune complexes on the surface of follicular dendritic cells. B cells which fail to be positively selected undergo apoptosis and are phagocytosed by macrophages. The positively selected cells migrate to the apical light zone where proliferation continues, and memory cells and plasma cell precursors are generated. Source: From Delves, P.J., Martin, S.J., Burton, D.R., Roitt, I.M., 2017. Roitt's Essential Immunology, 13th ed. Wiley-Blackwell.

Lymphocytes enter lymph nodes, tonsils, and Peyer's patches either via the afferent lymphatics or from the blood via high endothelial venules (HEV). L-Selectin is constitutively expressed on lymphocytes and constitutes a ligand for adhesion molecules referred to as peripheral lymph node addressins (McEver, 2015). If increased expression of LFA-1 is induced on the lymphocytes, their adhesion to HEV is further enhanced and they migrate across the HEV into these lymphoid tissues. Lymphocytes leave the lymph nodes via the efferent lymphatics. Although the spleen lacks HEV, circulating lymphocytes can directly access the marginal zone of this organ from the blood vessels. T cells locate mostly to the periarteriolar lymphoid sheaths, while B cells enter the lymphoid follicles. Lymphocytes exit the spleen via the splenic vein.

When naïve lymphocytes first encounter antigen in the secondary lymphoid tissues, they mount a primary immune response, generating both effector and memory cells. The memory cells are responsible for the quantitatively and qualitatively superior secondary immune response that occurs upon any subsequent encounters with the same antigen (Zielinski et al., 2011). Memory cells have a lower activation threshold than naïve cells and the secondary response is more rapid, involves larger numbers of lymphocytes, and, for B cells, produces higher levels of antibody with a superior affinity for antigen.

The term T-independent antigen is used to refer to antigens which are capable of generating an antibody response without a requirement for helper T cells. Polysaccharides, polymerized flagellin, and a number of other antigens have repetitive determinants which can extensively cross-link the BCR and thereby directly activate the B cell (Möller, 2001). Because they do not recruit T cells, T-independent antigens fail to provoke the formation of germinal centers and therefore are unable to induce B-cell memory, class switching, or significant amounts of affinity maturation. Thus low-affinity IgM antibodies are produced in response to T-independent antigens and, although involving B cells, the response does not go on to exhibit the characteristics of adaptive immunity. The majority of antigens that stimulate B cells are, however, T-cell dependent in that the B-cell response requires help from T cells. As mentioned earlier, the BCR on the surface of the B cell internalizes bound antigen which is then processed into peptides for presentation by MHC class II molecules. Upon recognition of the peptide–MHC complex by the T cells in the secondary lymphoid tissues, the costimulatory molecule CD154 (CD40 ligand) on the T cell engages CD40 on the B cell, leading to class switching (Ford and Larsen, 2009). In addition to cell surface molecules, cytokines play a key role in the mutual activation of the T and B lymphocytes. T cell help can also be recruited by DCs and macrophages presenting the relevant peptide–MHC class II combination to the helper T cell.

## RESOLUTION OF THE IMMUNE RESPONSE

Antigen stimulates the immune response and, therefore, for foreign antigen, its clearance by the immune system will naturally lead to a waning of the response. However, there are additional mechanisms which initially amplify and subsequently downregulate the response. Once high levels of class-switched antigen-specific IgG are produced, the antibody can inactivate the antigen-specific B cells in a manner reminiscent of classical negative feedback loops in the endocrine system. Cross-linking of the BCR to Fc $\gamma$ RIIB on B cells by immune complexes results in the transmission of inhibitory signals into the B cell (Smith and Clatworthy, 2010). A number of signals from cytokines and cell surface molecules can also be inhibitory. Ligation of the T-cell surface molecule CTLA-4 by CD80 and CD86, and of PD-1 by PD-L1 and PD-L2, provides downregulating signals (Bour-Jordan et al., 2011). Inhibition of these “immune checkpoints” has proved of benefit in the immunotherapy of subsets of cancer patients (Nishino et al., 2017). Some Foxp3 $^{+}$  Tregs secrete IL-10, IL-35, and TGF $\beta$  which can act in an immunosuppressive capacity, while others suppress responses by cell-contact-dependent mechanisms (Mohr et al., 2018).

Neuroendocrine interactions with the immune system provide a further level of regulation (Del Rey and Besedovsky, 2017). For example, TLR ligands and inflammatory mediators such as IL-1 $\beta$  result in efferent nerve signaling in the spleen, triggering the release of acetylcholine from splenic T cells which in turn inhibits the release of proinflammatory cytokines from macrophages in order to maintain immune homeostasis and thereby avoid an excessive inflammatory response (Andersson and Tracey, 2012).

## INTRODUCTION

To be effective and potent guardians against the plethora of environmental pathogens, T and B lymphocytes are characterized by an unprecedented diversity, which enables them to recognize a virtually unlimited repertoire of molecular structures in a rapid and specific manner. Such repertoire diversity is achieved by an elaborate, semirandom rearrangement of the genes encoding their respective antigen-specific receptors. Consequentially, the immune system inevitably generates many T and B cells that recognize not only foreign and potentially harmful antigens, but also the body's own components. Therefore to deal with this problem and to prevent autoimmune destruction, the immune system has evolved a comprehensive network of several complementary mechanisms that ensure tolerance to the body's own antigens, while allowing effective immune responses to diverse pathogens (Mathis and Benoist, 2010; Mueller, 2010; Walker and Abbas, 2002).

Historically, immunological tolerance mechanisms have been segregated into two main categories—central and peripheral. More recently, however, this simplistic dichotomous division has been brought into question. First, over the past two decades, it has become rather clear that self-proteins, which were assumed to be expressed only in parenchymal tissues, are also ectopically expressed in the thymus (Derbinski et al., 2001). Furthermore, in contrast to the initial belief, recent evidence suggests that the “central tolerance” mechanisms in the thymus rely more on the conversion of self-reactive thymocytes into the FOXP3<sup>+</sup> T regulatory cell (Treg) lineage (Aschenbrenner et al., 2007; Davis, 2015; Yang et al., 2015), rather than their clonal deletion

(Anderson et al., 2005; Kappler et al., 1987). Since Tregs constitute one of the key mediators of peripheral tolerance (Josefowicz et al., 2012a), the classical segregation of tolerance into central and peripheral becomes even more fuzzy and possibly obsolete. For this reason, in this chapter, we shall try to provide a fresh look at the key concepts and mechanisms underlying the establishment, maintenance, and breakdown of T-cell tolerance to the body's own components, while avoiding the classical dichotomous categorization.

As will be discussed in detail below, the induction and maintenance of T-cell tolerance to self-antigens is guided by four major principles: (1) complete physical elimination of the self-reactive T-cell clone from the repertoire (clonal deletion) (Fig. 5.1A and E), (2) conversion of the self-reactive clone into a tolerogenic and/or harmless T-cell subtype (anergy, phenotype skewing) (Fig. 5.1B and D), (3) prevention of its encounter with its specific self-antigen in the immune periphery (ignorance, antigen sequestering) (Fig. 5.1C), and (4) prevention of its clonal expansion or reactivation upon self-antigen (re)encounter (immunosuppression, T-cell intrinsic inhibitory mechanisms) (Fig. 5.1F). While the induction of T-cell tolerance in the thymus mainly relies on the two former principles, its subsequent maintenance in the immune periphery is mediated by all of the above principles. Specifically, self-reactive T cells that have escaped the first filter in the thymus can also undergo clonal deletion or conversion in the periphery. In addition, there are several other mechanisms (both cell intrinsic and extrinsic) that prevent their self-antigen-mediated activation, expansion or reactivation once they have left the thymus. First, all naïve T cells (i.e., including self-reactive ones) are retained only within the bloodstream and secondary lymphoid organs and thus do not have direct access to peripheral tissues expressing unique self-antigens (antigen sequestering).

Second, naïve T cells cannot become activated unless they are provided with additional costimulatory signals from dendritic cells during their priming in the secondary lymphoid organs. Without such additional “danger” signals, naïve T cells that recognize a specific antigen fail to proliferate, differentiate, and survive and are thereby either eliminated from the repertoire or become unresponsive (anergic). Moreover, even in the presence of costimulation, not all self-reactive T cells have to differentiate into pathogenic effector subtypes (e.g., Th<sub>1</sub> or Th<sub>17</sub>), which will ultimately cause autoimmune destruction. Indeed, specific release of certain cytokines (e.g., IL4, IL10, TGFβ) and the absence of others (IL6, IL12, IL23) during T-cell priming may skew their differentiation into T-cell subtypes that are either unable to cause autoimmune damage or can actively prevent it.

Finally, even if self-reactive T cells become activated in the periphery, they are efficiently suppressed by populations with immunoregulatory properties (immunosuppression), the best characterized of which are the thymus-derived CD4<sup>+</sup>FOXP3<sup>+</sup> Tregs (tTregs) or their peripherally induced counterparts (pTreg). It is important to realize, however, that every cell type probably inhibits another, even if it is not primarily defined as regulatory or immunosuppressive. For instance, immunosuppression can simply stem from the normal balance between effector functions that tend to inhibit each other, such as the mutual antagonism between Th<sub>1</sub> and Th<sub>2</sub> effectors (Benoist and Mathis, 2012).

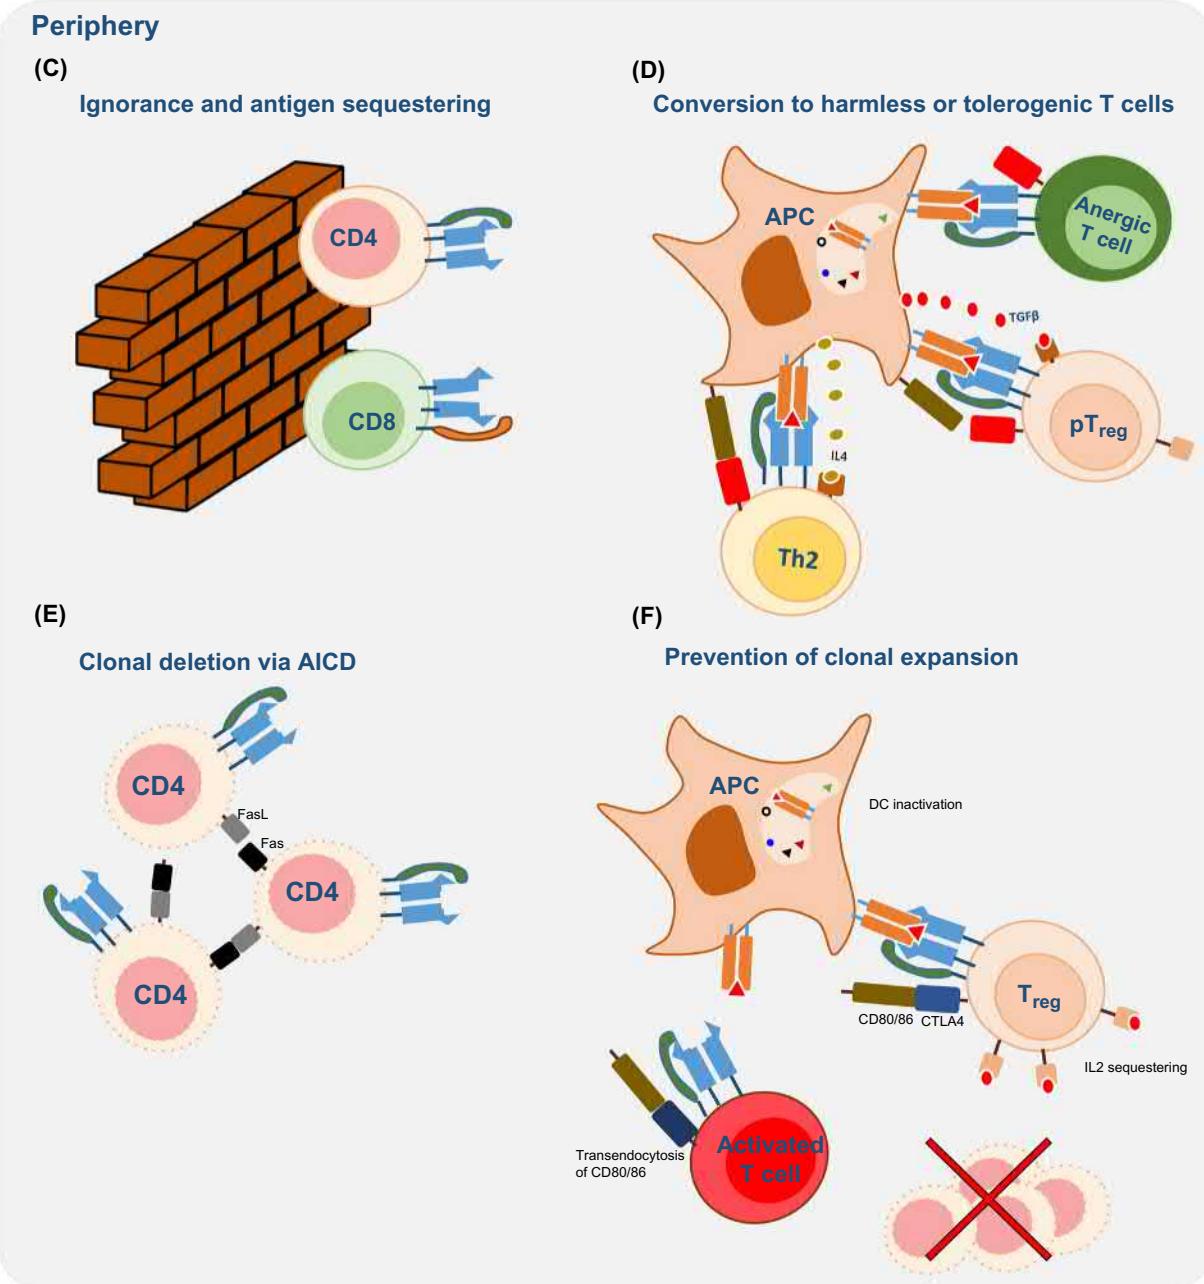

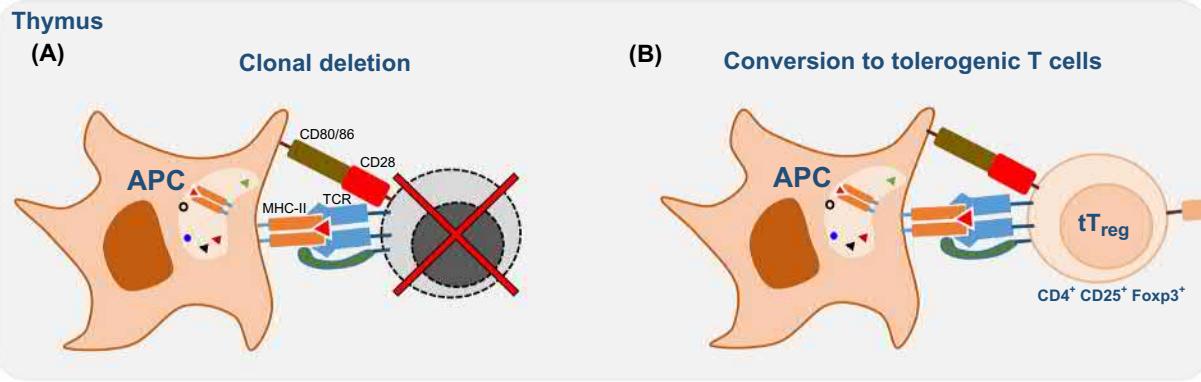

It should also be stressed that in addition to tolerating the body's own components, an effective and balanced immune response is also characterized by the induction and maintenance of immunological tolerance to exogenous, nonpathogenic antigens present ubiquitously in the environment, including food antigens, commensal microorganisms, and harmless airborne antigens. In this chapter, however, we shall focus only on concepts and mechanisms underlying the establishment, maintenance, and breakdown of T-cell tolerance to the body's own components and will not elaborate in detail on mechanisms responsible for induction of tolerance to nonself-antigens.

## T-CELL TOLERANCE—A BRIEF HISTORICAL PERSPECTIVE

### From Fetal Tolerance to Central Tolerance

The dilemma of how the immune system can distinguish self from nonself belongs to one of the most fundamental questions in immunology that has been debated for more than a hundred years. Paul Ehrlich, one of the founding fathers of immunology, already proposed that organisms must have a natural aversion to immunological self-destruction, which he called “horror autotoxicus.”

The first mechanistic insights into how the immune system becomes tolerant to self-antigens paradoxically stem from studies describing the acquisition of immunological tolerance to nonself-antigens, such as the lympho-choriomeningitis virus (LCMV), a natural mouse pathogen. Specifically, Traub et al. observed that mice infected with LCMV in utero did not mount an immune response against it, although the virus persisted throughout their

**FIGURE 5.1** Key principles for induction of T-cell tolerance. The induction and maintenance of T-cell tolerance to self-antigens is guided by four major principles that occur in the thymus and/or in the immune periphery: complete physical elimination of the self-reactive T-cell clone from the repertoire via clonal deletion (A and E); conversion of the self-reactive clone into a tolerogenic and/or harmless T-cell subtype via induction of Tregs, T-cell anergy, or T-cell phenotype skewing into harmless effector subsets (B and D); prevention of its encounter with its specific self-antigen in the immune periphery via antigen ignorance and/or antigen sequestering (C) or prevention of its clonal expansion or reactivation upon self-antigen (re)encounter via T-cell intrinsic mechanisms induced upon T-cell activation and/or Treg-mediated immunosuppression (F).

lives (Traub, 1938), suggesting that a host could become tolerant to foreign antigens, as long as they had been “seen” early enough in development. Nevertheless, the term “tolerance” was first coined by Ray Owen, who experimented with dizygotic cattle twins and found that they became hematopoietic chimeras in utero and thereby tolerant to each other’s blood antigens (Owen, 1945). This suggested that the host can “tolerate” nonself cells if it was exposed to them during ontogeny. These pioneering observations of tolerance were then further validated and broadened by a series of independent studies in the early 1950s. Specifically, in 1953, the group of Peter Medawar extended Owen’s observations by noting that nonidentical twin cattle could also accept skin grafts from each other, suggesting that this tolerance is not restricted only to blood-borne antigens, but also to solid tissues (Billingham et al., 1953). Moreover, injection of allogeneic blood cells from one mouse strain into newborn mice from a different inbred strain led to engraftment of these cells and subsequent induction of tolerance to skin grafts of the donor strain, but not of grafts from a third party (Billingham et al., 1953). Similar results were obtained in chickens with parabiosis experiments in which the circulatory systems of the two embryos were joined (Hasek and Hraba, 1955). The resulting adult birds were found to be hematopoietic chimeras that did not reject each other’s skin grafts.

These experiments supported the Burnet and Fenner hypothesis that exposure of the developing immune system to foreign antigens prevented the system from responding to those antigens. The results were interpreted at the cellular level in terms of the clonal selection theories of Burnet and Talmage, which postulated that self-specific lymphocytes were disposed of, or clonally deleted (Burnet, 1959, 1962). Thus tolerance ensued because there were no self-reactive cells left in the adult animal that were capable of responding to the self-antigen. In the T-cell world, clonal deletion soon became known as “negative selection,” to distinguish it from “positive selection,” which is the process by which T cells are selected to be able to recognize peptide antigens in the context of one’s own major histocompatibility complex (MHC) molecules. These original ideas were, however, not validated experimentally for several decades until the experimental tools for studying individual lymphocyte clones became available. Indeed, the first experimental evidence that self-reactive T cells are negatively selected in the thymus was provided in the late 1980s by two independent studies (Kisielow et al., 1988; Sha et al., 1988). By utilizing antigen-specific T-cell receptor (TCR) transgenic mice, both studies were able to demonstrate that thymocytes expressing the given antigen-specific receptor were deleted in the thymus in the presence of antigen. Thus negative selection of self-reactive T cells in the thymus has subsequently become synonymous with central T-cell tolerance and dominated the field till relatively recently (Davis, 2015). Several subsequent studies, however, demonstrated that negative selection is not foolproof, as almost half of the thymocytes that were positively selected did not subsequently undergo negative selection (Ignatowicz et al., 1996; van Meerwijk et al., 1997; Tourne et al., 1997). Thus there seemed to be at least two complementary mechanisms for how organisms dealt with self-reactive T-cell clones: either during their development in the thymus, known as central tolerance, or in the periphery, known as peripheral tolerance (discussed in more detail in the following section). Moreover, not all self-antigens were assumed to be expressed in the thymus, suggesting that T-cell clones specific to self-antigens that are exclusively expressed by parenchymal tissues (e.g., certain hormones and enzymes) must be either eliminated or silenced in the immune periphery. This hypothesis dominated the field until 2001 when a landmark study by Klein et al. established that medullary thymic epithelial cells (mTECs) ectopically express a large fraction of tissue-specific antigens (TSAs) and thereby induce tolerance to hundreds of self-antigens that are exclusively expressed by peripheral tissues (Derbinski et al., 2001). Interestingly, this study validated an earlier hypothesis by Linsk et al. (1989) and several other reports that had attracted little attention at that time (Jolicoeur et al., 1994; Pribyl et al., 1996; Smith et al., 1997; Sospedra et al., 1998). The discovery of promiscuous gene expression (PGE) in the thymus was shortly followed by another landmark study demonstrating that many of these TSA transcripts are induced by a single mTEC-specific factor, the autoimmune regulator (Aire) (Anderson et al., 2002) whose loss of function results in a multiorgan autoimmune syndrome in both humans (Nagamine et al., 1997) and mice (Anderson et al., 2002). Collectively, these studies brought about a new paradigm shift, which has dramatically reshaped our understanding of how T cells acquire tolerance to self-antigens in the thymus.

## From Neonatal Thymectomy to Tregs

The key role of the thymus in the induction of self-tolerance was also supported by results of studies on neonatally thymectomized mice (Miller, 1961; Nishizuka and Sakakura, 1969). Specifically, removal of a mouse thymus before day 3 after birth (but not after day 10) resulted in an organ-specific autoimmune syndrome. Importantly, subsequent studies by Gershon et al. suggested that the thymus is (in addition to its role in clonal

deletion of self-reactive T cells) also critical for the production of cells that can promote self-tolerance and suppress autoimmunity in the periphery (Gershon and Kondo, 1970, 1971). Indeed, the hypothesis that T cells are capable of not only promoting but also suppressing immune responses was validated a year later by the identification of thymus-derived “suppressor T cells” (Gershon et al., 1972). The molecular characterization of such suppressor T cells has, however, remained mysterious and controversial for several decades. While an earlier study by Cantor et al. (1978) suggested that suppressor T cells constitute a subset of CD8<sup>+</sup> T cells, a later study from Sakaguchi et al. demonstrated that these cells are rather Thy1<sup>+</sup>, Lyt-1<sup>+</sup>, Lyt-2<sup>-</sup> (i.e., CD90<sup>+</sup>, CD5<sup>+</sup>, CD8<sup>-</sup> T cells) (Sakaguchi, 1982; Smith et al., 1991; Tung et al., 1987) and appear at day 3 after birth. Subsequent studies by Sakaguchi et al. provided more detailed molecular and functional characterizations of these cells and suggested that they are a subset of CD4<sup>+</sup> T cells expressing high levels of CD25 and/or low levels of CD45RB (Morrissey et al., 1993; Powrie and Mason, 1990; Sakaguchi et al., 1982, 1995; Smith et al., 1991). Importantly, adoptive transfer of these CD4<sup>+</sup>CD25<sup>+</sup> T cells was sufficient to prevent both autoimmunity caused by neonatal thymectomy (Asano et al., 1996; Suri-Payer et al., 1998), as well as autoimmunity provoked by the transfer of CD25-depleted CD4 cells into nude mice (Sakaguchi et al., 1995; Suri-Payer et al., 1998).

Unfortunately, even in spite of this substantial body of evidence, the controversy regarding the specific markers that would molecularly define the suppressor T-cell population and the fact that some of the key markers were also shared with activated T cells eventually resulted in a considerable skepticism regarding their actual existence and/or their functional importance. Such skepticism and controversy lasted for almost two decades until the identification of the transcription factor FOXP3 as the master regulator of CD4<sup>+</sup>CD25<sup>+</sup> T cells development (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003), whose loss of function results in X-linked neonatal enteropathy and endocrinopathy (IPEX) in humans and scurfy phenotype in mice (Godfrey et al., 1991; Wildin, 2002). Consequently, the concept of “suppressor” T cells, as the gatekeepers of self-tolerance and immune homeostasis, has been resurrected and widely accepted. Nevertheless, to distinguish them from their “flopped” predecessors, the suppressor T cells have been renamed to Treg.

## From Adjuvants to T-Cell Anergy

In parallel to the suppressor T-cell paradigm, numerous groups have investigated additional/alternative mechanisms, which could explain the induction and/or maintenance of T-cell tolerance in the periphery. It has been recognized for a long time that the immune system is able to mount a much stronger immune response if an antigen is administered with specific adjuvants (e.g., Freund’s complete adjuvant) (Dresser, 1962; Kabat et al., 1946). For instance, when antigen (soluble bovine gamma globulin) was administered in the presence of lipopolysaccharide (LPS; a component of Gram-negative bacteria), a functional immune response was induced in mice, while when the very same antigen was administered in the absence of LPS, it induced immunological tolerance (Claman, 1963; Dresser, 1961). This suggested that existence of an additional antigen-nonspecific signal could boost the immune response, while its absence could possibly result in tolerance induction (Baxter and Hodgkin, 2002). The first experimental evidence supporting this hypothesis was provided by Lafferty et al., who studied the mechanisms of allograft rejection and demonstrated that in addition to the alloantigen (signal 1), the presenting cells have to provide a second, antigen-nonspecific signal that they called costimulation (Lafferty and Woolnough, 1977; Lafferty et al., 1974). Subsequent work showed that such costimulatory signal is provided by antigen-presenting cells (APCs) expressing the B7 (i.e., CD80/CD86) molecules, which specifically bind to the CD28 receptors on T cells (Linsley et al., 1990). Importantly, the expression of B7 molecules on APCs was later shown to be induced by “danger” signals (Janeway, 1992) through a series of pattern recognition receptors, such as Toll-like membrane receptors (TLRs) or Non-obese diabetic (NOD)-like cytoplasmic receptors (NLRs). Correspondingly, absence of danger signals was shown to result in low-level expression of B7 molecules on the APC surface and their consequent inability to provide sufficient costimulatory signal to the specific T-cell clone (Janeway, 1992; Jenkins et al., 1987; Johnson and Jenkins, 1993; Mueller et al., 1989). Such a lack of costimulation in the presence of a specific antigen signal was shown to result in T-cell anergy, a phenomenon characterized by T-cell unresponsiveness (IL2 production and proliferation) upon antigen reencounter (Jenkins et al., 1987; Mueller et al., 1989). Since then, the phenomenon of T-cell anergy has been validated by many independent studies both in vitro and in vivo (Dubois et al., 1998; Pape et al., 1998) and has become one of the major and most popular paradigms explaining and underlying the induction and maintenance of tolerance of self-reactive T-cell clones in the periphery.

## ESTABLISHMENT OF SELF-TOLERANCE IN THE THYMUS

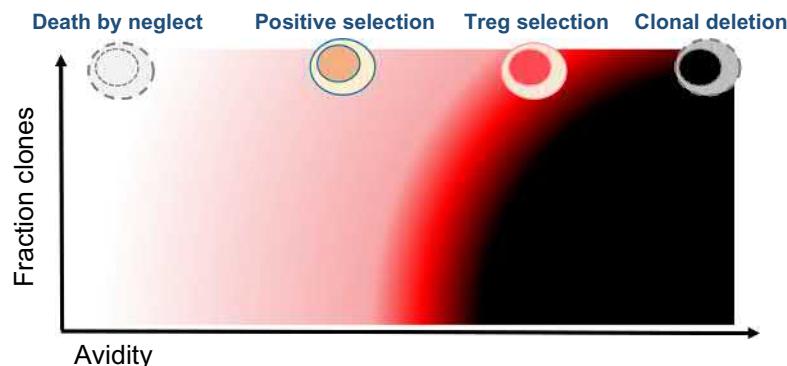

T-cell development and selection occur in the specialized environment of the thymus, which has evolved to support the differentiation of early thymic immigrants from the bone marrow, into competent naïve T cells. This complex process is aimed at creating a powerful army of T cells, so diverse it would harbor soldiers capable of recognizing virtually any pathogen-derived antigen the organism may encounter, while tolerating the body's own components. Such T-cell repertoire diversity is attained through the random process of V(D)J recombination of the locus encoding both  $\alpha$  and  $\beta$  chains of the TCR. However, during this process, which can theoretically give rise to  $\sim 10^{18}$  possible TCR permutations (Market and Papavasiliou, 2003), the immune system generates large numbers of useless TCRs that are incapable of recognizing peptide-MHC (pMHC) complexes, as well as self-reactive TCRs that could potentially cause autoimmunity. Thus a thorough screening system is necessary for purging both the useless and the potentially pathogenic TCRs in order to establish effective T-cell-mediated immunity while maintaining immunological tolerance to self.

### Positive Selection of Immunocompetent T Cells

The first selection checkpoint that a developing thymocyte encounters in the thymus is aimed at positive selection of immunocompetent T-cell clones expressing nascent TCR $\alpha\beta$  capable of binding to antigen peptides presented in the context of MHC molecules. Positive selection takes place in the cortex and is exclusively mediated by cortical thymic epithelial cells (cTEC), which present self-pMHC to the “auditioning” CD4 $^+$ CD8 $^+$  double positive (DP) thymocytes. The avidity of the TCR for the self-pMHC has crucial consequences for the subsequent fate of each T-cell clone (Fig. 5.2). As proposed by the “classical affinity model,” DP thymocytes harboring TCR $\alpha\beta$  that have no or very weak avidity for the self-pMHC are deemed useless and consequently die by neglect due to insufficient TCR signaling. In contrast, thymocytes with functional TCR $\alpha\beta$  that engage either pMHCI or pMHCI $\text{I}$  with low-intermediate avidity will differentiate either into single positive CD8 $^+$  (CD8SP) or CD4SP, respectively. Finally, TCR:pMHC interactions with high avidity will result in the elimination of the specific T-cell clones via the process of clonal deletion (Daley et al., 2017; Gascoigne and Palmer, 2011; Jameson et al., 1995; Palmer, 2003; Xing et al., 2016). This is in striking contrast to the consequences of high-affinity TCR:pMHC interactions in the periphery, which (in conjunction with CD28 costimulation) result in T-cell activation and proliferation. It is estimated that  $3.7 \times 10^5$  thymocytes will pass these auditions for positive selection every hour in the murine thymus (Stritesky et al., 2013).

### Negative Versus Agonist Selection of Self-Reactive T Cells

Those CD4SP and CD8SP thymocytes that survive positive selection in the cortex then migrate to the medullary part of the thymus. There, they are exposed to a second selection checkpoint, which is required for pruning the number of potentially harmful self-reactive T-cell clones that will, eventually, be released to the immune periphery. This is achieved either by their clonal deletion or their conversion into tTregs through a process called agonist selection (Wirnsberger et al., 2011) (Fig. 5.1A and B). Both outcomes are facilitated by medulla-resident APC, such as thymic dendritic cells (tDCs), B cells and in particular mTECs, which all present self-pMHC complexes to the developing CD4SP and CD8SP thymocytes (Frommer et al., 2010; Hinterberger et al., 2010;

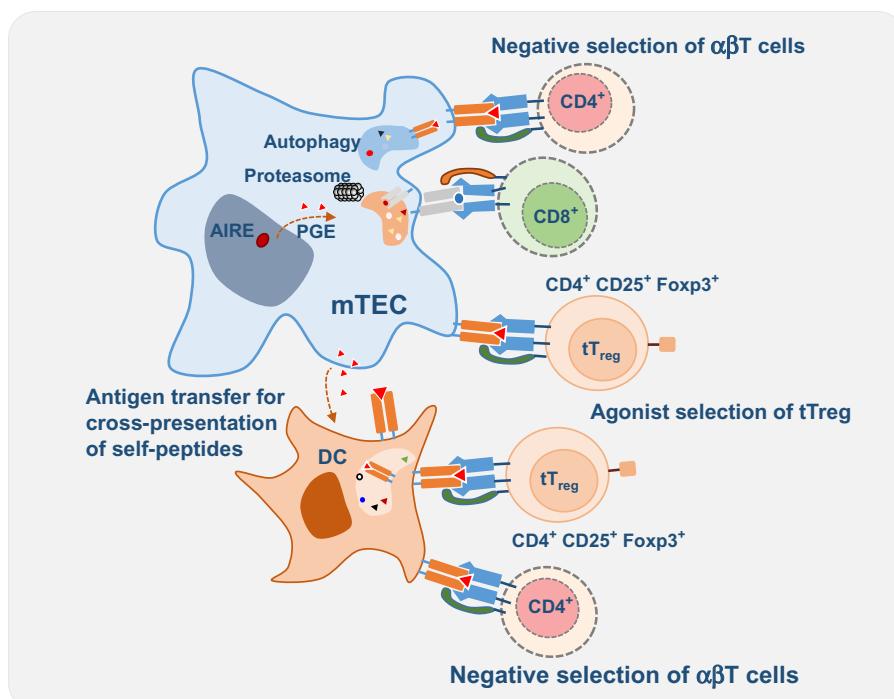

**FIGURE 5.2** The avidity model of thymocytes selection. The TCR $\alpha\beta$  avidity of DP thymocytes for self-peptides largely determines their fate. Thymocytes with TCR $\alpha\beta$  lacking or bearing very weak avidity for the self-pMHC die by neglect, whereas thymocytes with functional TCR $\alpha\beta$ s that engage pMHC with low-intermediate avidity will be positively selected and will differentiate into single positive CD8 $^+$  or CD4 $^+$  naïve T cells. In contrast, very high avidity self-TCR:pMHC interactions will result in the negative selection of the specific clone by apoptosis. Clonal deviation into the tTreg fate occurs across varying avidity intensities.

McCaughtry et al., 2008; Taniguchi et al., 2012; Yamano et al., 2015). Importantly, to be able to effectively screen for self-reactivity to as many self-peptides as possible, mTECs are equipped with a unique capacity to express almost 90% of the coding genome (this phenomenon will be discussed in detail in the following section). Furthermore, in order to subsequently present the corresponding plethora of self-peptides on both MHC I and MHC II molecules, mTECs (and cTECs) were found to have a high constitutive rate of macroautophagy, which enables them to load endogenous peptides onto MHC II molecules and thereby to accommodate selection of CD4<sup>SP</sup> thymocytes (Nedjic et al., 2008) (Fig. 5.3). Moreover, to make the process of self-antigen presentation even more effective, mTECs have been shown to unidirectionally transfer self-Ag to tDCs for cross-presentation (Fig. 5.3). Such unidirectional transfer is believed to be mediated through membrane transfer of self-pMHC II complexes, exosomes, or apoptotic bodies (Koble and Kyewski, 2009) and is thought to prolong the time of antigen presentation and/or broaden the self-pMHC repertoire. Indeed, a recent study by Perry et al. (2014), demonstrated that the self-pMHC repertoire of different thymic APCs is at least partially nonredundant; thus each population can uniquely affect the Ag specificity of the resulting TCR repertoire (Klein et al., 2014). In addition to the presentation of self-antigens that are ectopically expressed in the thymus, the self-repertoire is further potentiated through the import of soluble self-Ag from the periphery into the thymus by plasmacytoid DCs (Hadeiba et al., 2012).

The exact mechanisms that determine the choice between negative and agonist selection of self-reactive thymocytes are still incompletely understood. The currently accepted view is that while thymocytes that express TCRs with very high avidity for the self-pMHC complexes are preferentially eliminated by negative selection, those that express TCRs with low-to-high avidity for self-pMHC are preferentially converted into the tTreg lineage (Fig. 5.2) (Klein et al., 2014).

It should be stressed, however, that measuring self-reactivity of individual thymocytes to the endogenous peptides in an accurate manner under in vivo conditions has been rather challenging. Several molecules have been suggested to be expressed in a manner that correlates with the avidity of the TCR:pMHC interaction, including CD69 (Stritesky et al., 2012), CD5 (Azzam et al., 1998), or Helios (Daley et al., 2013). Nevertheless, probably the most widely accepted model to date for assessment of self-reactive thymocytes in vivo is the Nur77<sup>GFP</sup> reporter, which has been shown to accurately reflect the extent of TCR activation (Moran et al., 2011). Indeed, by crossing mice expressing this reporter with mice lacking the key inducer of apoptosis Bim, Stritesky et al. (2013) were able to determine the number of negatively selected T cells, which undergo apoptosis due to high avidity TCR–pMHC interactions to be  $\sim 7 \times 10^5$  per hour. Paradoxically, this number seems to be  $\sim 6$ -fold higher than

**FIGURE 5.3** mTECs and DCs orchestrate negative and agonist selection. mTECs and thymic DCs cooperate to optimize clonal deletion of self-reactive thymocytes, as well as in the agonist selection of tTregs. mTECs are equipped with a unique capacity to express almost 90% of the coding genome and in order to subsequently present the corresponding plethora of self-peptides on both MHC I and MHC II molecules, mTECs utilize macroautophagy, which enables them to load endogenous peptides onto MHC II molecules and thereby to accommodate the selection of CD4<sup>SP</sup> thymocytes. To make the process of self-antigen presentation even more effective, mTECs have been shown to unidirectionally transfer self-antigen to thymic DCs for cross-presentation. The cooperation between these two cell populations continues as both have a pivotal role in tTreg generation by both presenting the necessary selecting self-pMHC along with the required costimulation.

the estimated total number of positively selected cells (Stritesky et al., 2013), suggesting that positive and negative selection do not occur sequentially but rather in parallel (Laufer et al., 1996; van Meerwijk et al., 1997). Historically, there has been some controversy about the anatomical site of negative selection and the cell populations responsible for mediating this process (Boehmer, 1990; Laufer et al., 1996; van Meerwijk et al., 1997; Murphy et al., 1990). While early studies using transgenic TCR models demonstrated that massive clonal deletion takes place in the thymic cortex (Murphy et al., 1990), other works [based on analysis of specific V $\beta$  deletions of endogenous superantigens (Hengartner et al., 1988; Woodland et al., 1990)] suggested that this process occurs primarily in the medulla (Surh and Sprent, 1994). More recently, it has been demonstrated that the process of T-cell negative selection occurs in both the cortical and the medullary regions of the thymus in two subsequent stages (waves) (Daley et al., 2013; Hu et al., 2016). Specifically, by utilizing the transcription factor Helios as a marker for negative selection, Daley et al. demonstrated that while the first wave involves negative selection of CCR7 $^{-}$  CD24 $^{+}$  CD4 $^{+/\text{lo}}$  CD8 $^{+/\text{lo}}$  DP thymocytes in the cortex, the second wave involves deletion of CCR7 $^{+}$  CD4 $^{+}$  CD8 $^{-}$  SP thymocytes in the medulla (Daley et al., 2013; Hu et al., 2016).

Agonist selection and development of the tTreg lineage is facilitated by APCs in the thymic medulla (Cowan et al., 2013; Hu et al., 2016). While different T-cell populations have been suggested to contribute to tTreg development, including mTECs (Akiyama et al., 2014; Bonito et al., 2013; Cowan et al., 2013; Hauri-Hohl et al., 2014; Hinterberger et al., 2010; Mouri et al., 2014), tDCs (Aschenbrenner et al., 2007; Perry et al., 2014), B cells (Walters et al., 2014), apoptotic thymocytes (Chen and Konkel, 2015; Konkel et al., 2014), or even cTECs (Bensinger et al., 2001; Liston et al., 2008), it seems that the key populations that have the most important role in tTreg generation are mTECs and tDCs (Fig. 5.3), which can both present the necessary selecting self-pMHC along with the required costimulation (Hinterberger et al., 2011; Mahmud et al., 2014). The first experimental evidence of agonist selection of tTregs came in 2001 from the Caton group that elegantly showed that tTreg conversion can occur when a self-reactive TCR meets its cognate antigen, as no agonist selection occurred when the cognate antigen was not expressed by a second transgene (Jordan et al., 2001). Furthermore, TCR  $\times$  neo-self-antigen double transgenic mice were shown to have increased generation of tTreg when the TCR had a high affinity for the neo-self-antigen, but when the affinity was low, agonist selection of tTreg did not ensue. This, along with other studies from the same group (Larkin et al., 2008; Lerman et al., 2004; Picca et al., 2009), prompted their proposition of a modified avidity model (Simons et al., 2010) for T-cell selection in the thymus. Specifically, according to their model, the avidity required for tTreg generation is higher than that of positive selection, but not necessarily lower than that of negative selection and thus the TCR signal strength of thymocytes that are converted into tTreg and those deleted from the repertoire overlap. Nevertheless, other studies have found the TCR signaling threshold for tTreg generation different than that suggested by the Caton group. For example, the Nur77<sup>GFP</sup> model for gauging TCR activation strength has been instrumental in showing that the signaling strength for agonist selection of the natural polyclonal tTreg pool is indeed strong, but just below the threshold for clonal deletion (Stritesky et al., 2013). Correspondingly, Lee et al. have demonstrated that thymocytes with varying TCR affinities for their cognate antigen can develop into tTreg (Lee et al., 2012), indicating that the spectrum of affinities required for agonist selection seems to be quite broad (Fig. 5.2).

Moreover, in line with the above findings, tTregs were found to have a very distinct, mostly nonoverlapping, TCR repertoire in comparison to conventional T cells (Hsieh et al., 2004; Pacholczyk et al., 2006) (at least in mice). Although tTregs are assumed to be characterized mainly by self-reactive TCRs (Hsieh et al., 2012), elucidating the actual identity of the naturally selecting self-antigens has been very challenging. The first identification of such naturally occurring Treg self-antigen peptides was recently reported by the Savage group, who identified two different Treg clones that recognize peptides of a prostate-specific protein, which is ectopically expressed in the thymus in an Aire-dependent manner (Leonard et al., 2017; Malchow et al., 2013, 2016).

Interestingly, the appearance of tTreg in the mouse thymus takes place only at days 2–3 after birth, which is several days later than the appearance of conventional CD4SP T cells (Fontenot et al., 2005). Although the reasons for such a delayed tTreg development are still incompletely understood, one possible explanation is that the development and selection of tTreg take longer than that of conventional T cells. Remarkably, however, the perinatal tTreg population seems to have an indispensable role in the induction of self-tolerance, as its depletion prior to 10 days of age results in detrimental multiorgan autoimmunity in mice (Yang et al., 2015). These and other findings collectively argue that agonist selection of tTreg is superior to clonal deletion for the effective induction and maintenance of immunological self-tolerance. The mechanisms by which tTreg facilitate self-tolerance in peripheral tissues is discussed in detail in one of the subsequent sections of this chapter.

## Promiscuous Expression of Self-Antigens in the Thymus

The grand task of both negative and agonist selection necessitates presentation of the entire self-peptidome to developing thymocytes. As mTECs are essential players in this endeavor, they have uniquely developed the capability of promiscuously expressing thousands of TSA genes in a manner independent of their regulated expression in the periphery (Sansom et al., 2014; Tykocinski et al., 2010; Villaseñor et al., 2008). The contribution of such TSA expression in the thymus to the establishment of self-tolerance is best evidenced by Aire deficiency, which leads to multiorgan autoimmunity due to impaired expression of hundreds of TSA genes in mTECs (Anderson et al., 2002) or by the autoimmune manifestations seen following thymic specific deletion of individual TSA genes (DeVoss et al., 2006; Fan et al., 2009). Importantly, the extent and features of this PGE have been understood in more depth due to the advent of high-throughput sequencing technologies, both on the population and single-cell levels. Remarkably, as a population, mature mTECs express roughly 19,000 protein-coding genes, which corresponds to ~85% of the coding genome, ranking them as a population with the highest levels of genome expression that has been documented (Danan-Gothold et al., 2016; Sansom et al., 2014). In comparison, all other tissues and cell types examined expressed between 12,000 and 15,000 genes (Danan-Gothold et al., 2016) (~60%–70% of the protein-coding genes). Interestingly, representation of all tissues is not created equal in mTECs, as studies have found underrepresentation of odorant receptor genes (Sansom et al., 2014), while others have reported underrepresentation of genes from immunologically privileged organs such as brain and testes, suggesting that negative selection might take into account the likelihood of antigen encounter in the periphery, as these sites undergo less immunological surveillance than nonprivileged sites (Danan-Gothold et al., 2016). Nevertheless, mTECs also significantly enhance the depth of their self-antigen repertoire by using extensive RNA editing and processing (Danan-Gothold et al., 2016).

Examination of the mTEC transcriptome at the single-cell level has revealed that in contrast to the almost complete genomic expression at the population level, each individual mTEC only transcribes a fraction of TSAs resulting in a remarkably heterogeneous population such that only 1%–9% of the entire population will express a given gene at any given moment (Derbinski et al., 2008; Klein et al., 2014; Sansom et al., 2014). This expression pattern was initially reported to be stochastic (Derbinski et al., 2008; Villaseñor et al., 2008); however, later studies showed that there is some order to the “madness,” as mTECs coexpress groups of TSAs that are clustered both intra- and interchromosomally (Brennecke et al., 2015; Pinto et al., 2013) in what has now been described as “ordered stochasticity” with substantial variability between individuals (Meredith et al., 2015). Nevertheless, this process is estimated to be so efficient that encountering a mere 200–500 mTECs should suffice in presenting the entire TSA repertoire to a developing SP thymocyte (Klein et al., 2014).

How mTECs are capable of ectopically expressing genes that are otherwise restricted to specific parenchymal tissues has been a major focus of many independent studies, with most research concentrating on Aire, as the master regulator of this process. Although Aire was originally proposed to induce expression of hundreds of genes (Anderson et al., 2002), over the years, the scope of Aire-dependent targets has been shown to be an order of magnitude larger (i.e., ~4000 Aire-dependent genes) (Danan-Gothold et al., 2016; Sansom et al., 2014). Given that Aire’s primary role is to promote expression of genes that are normally silenced in the vast majority of cells in the body (i.e., they are tissue-specific), it is not surprising that its target gene recognition was found to utilize epigenetic marks, specifically those associated with silenced chromatin. To this end, Aire has been shown to bind unmethylated lysine 4 on histone 3 (H3K4me0) (Koh et al., 2008; Org et al., 2008), a histone modification that typically marks transcriptionally inactive chromatin. Aire was also shown to have the capacity to bind to H3K4me1 (Koh et al., 2008), a histone modification highly enriched in gene enhancer regions (Pott and Lieb, 2014). Indeed, more recent data demonstrate that Aire preferentially binds to superenhancer regulatory regions in bona fide mTECs (Bansal et al., 2017). Furthermore, other studies have demonstrated that Aire-dependent genes are depleted of active chromatin marks at their promoters (Org et al., 2009; Sansom et al., 2014), while they are enriched for additional repressive chromatin marks such as H3K27me3 and H3K9me3 (Sansom et al., 2014). Collectively, these data suggest that Aire preferentially binds to inactive/poised enhancers of silenced genes (characterized by H3K4me1 and H3K27me3) and subsequently activates them (i.e., H3K27me3 → H3K27ac) through recruitment of various chromatin modifying enzymes. Aire’s attraction to repressed chromatin is further supported by its association with the repressive ATF7IP–MBD1 complex, which is recruited to methylated CpG sites, known to be enriched at promoters of inactive genes (Waterfield et al., 2014).

Following its recruitment to the relevant TSA genes Aire induces the derepression of silenced chromatin and activates transcription by interacting with proteins of the DNA damage machinery, including DNA-PK, Top2a,

$\gamma$ H2AX, Trim28, or Sirt1 (Abramson et al., 2010; Bansal et al., 2017; Chuprin et al., 2015; Guha et al., 2017). Interestingly, Trim28 was recently suggested to have a central role in linking the DNA damage response with release of paused RNA Pol II (Bunch et al., 2015), which is in line with several studies demonstrating an important role for Aire in releasing stalled RNA polymerase II at its target genes for PGE (Giraud et al., 2012; Owen et al., 2007).

While Aire was shown to induce/boost expression of thousands of different genes in mTECs, part of the TSA gene repertoire seems to be regulated in an Aire-independent manner. Recently, the transcription factor Fezf2 was suggested to take on such a role and was proposed to induce the expression of a significant proportion of Aire-independent TSA genes (Takaba et al., 2015). Appropriately, its deletion was reported to result in multiorgan autoimmunity, though distinct from that observed in Aire-deficient mice. However, independent analysis of Fezf2-dependent genes in mTECs failed to corroborate these findings, suggesting that further studies are needed to determine the specific contribution of Fezf2 to tolerance induction (Y. Herzig and J. Abramson, unpublished data).

## INDUCTION AND MAINTENANCE OF IMMUNOLOGICAL TOLERANCE IN THE PERIPHERY

A significant body of evidence suggests that not all self-reactive thymocytes are efficiently deleted or converted into FOXP3<sup>+</sup> tTreg during their development in the thymus. As already discussed above, thymic negative selection most effectively deletes thymocytes that express TCRs with very high avidity for self-pMHC complexes presented by mTECs and tDCs. Correspondingly, thymocytes that express TCRs with low-to-high avidity for self-pMHC complexes were shown to give rise to FOXP3<sup>+</sup> tTregs. Nevertheless, many self-reactive T-cell clones (typically bearing TCRs of relatively low avidity for self-pMHC complexes) were shown to escape to the periphery (Liblau et al., 1991; Sun et al., 1991). More recently, Legoux et al. demonstrated that only ~60% of the Cre recombinase-specific CD4<sup>+</sup> T cells are deleted in the thymus and periphery of mice transgenic for ubiquitous expression of Cre. In contrast, no deletion of Cre-specific T-cell clones was observed when Cre expression was restricted to specific peripheral tissues but not to the thymus (Legoux et al., 2015). Similarly, recent analyses of self-reactive T-cell clones in the periphery of wild-type mice using a tetramer reagent further reinforced the notion that many (or even most) self-reactive T cells escape negative selection in the thymus (Davis, 2015; Yu et al., 2015b). Therefore these self-reactive escapee clones must be kept in check by additional tolerance mechanisms in the periphery to prevent autoimmune damage (discussed next).

This phenomenon has been validated in animal models by several independent studies, including that of Liu et al., who created TCR-transgenic mice specific to myelin basic protein (MBP) acetylated peptide Ac1-9 presented in the context of MHC class II (Liu and Wraith, 1995). This peptide is highly immunogenic and, when administered in the presence of adjuvant, it induces experimental autoimmune encephalomyelitis (EAE) in mice, a model for human multiple sclerosis. Remarkably, although these TCR-transgenic mice have self-reactive CD4<sup>+</sup> T cells in their peripheral blood, the mice do not spontaneously develop autoimmune disease. Therefore this study clearly demonstrates that even if a self-reactive T cell escapes the first thymic filter, it is efficiently kept in check by additional tolerance mechanisms in the periphery. Moreover, repeated immunization with the peptide in the absence of adjuvant lead to the development of specific tolerance. In contrast, the break of tolerance resulting in EAE was observed only after immunization with MBP Ac1-9 in the presence of an adjuvant (Pertussis toxin), nicely illustrating that the context of antigen presentation determines whether tolerance will be enforced or broken down (discussed in more detail in one of the following sections).

### Ignorance and Antigen Sequestering

The first line of tolerance mechanisms that prevents self-reactive T cells to mount an autoimmune attack upon their release from the thymus is their physical separation from the parenchymal tissues (Fig. 5.1C). After leaving the thymus, naïve T cells circulate from blood to secondary lymphoid organs, to efferent lymph, and then back again to the blood. Such restricted migration is guided by several chemokines (CCL21) and adhesion molecules (ICAM1, GlyCAM1), which are specifically expressed by the high venule endothelium of the secondary lymphoid organs. Since naïve T cells express high levels of CCR7 (i.e., receptor for CCL21), LFA1, and CD62L (receptors for ICAM1 and GlyCAM1, respectively), they can exit the bloodstream only to the secondary lymphoid organs,

but not to other nonlymphoid tissues. In the lymph nodes, the naïve T cells scan DCs for the presence of pathogen-derived peptides presented on MHC molecules (Mempel et al., 2004). If TCR ligation does not occur, desensitization of CCR7 and recognition of efferent lymph sphingosine 1-phosphate eventually drives naïve T cells out of the lymph node back to the bloodstream. Thus naïve T cells are excluded from nonlymphoid peripheral tissues, in which the likelihood of coming in contact with various TSAs is considerably higher.

Unlike naïve T cells, antigen-experienced effector T cells can migrate to virtually all peripheral tissues of the body; in particular, if these tissues are infected and/or inflamed. To this end, effector T-cell upregulate several adhesion molecules on their surface (e.g., P- and E-selectin ligands, integrin  $\alpha 4\beta 1$ ), which allow their subsequent egress from postcapillary venules into the individual parenchymal organs, particularly in the context of local inflammation or infection (Austrup et al., 1997; Masopust et al., 2004). It should, however, be stressed that in order to become activated, naïve T cells first need to be “licensed” by lymph node–resident DCs, which can effectively discriminate between harmless and harmful antigens (discussed in detail in the following section).

Importantly, some key vital organs in the body such as the brain, eye, and testis are characterized by reduced lymphatic drainage, which consequently limits the surveillance of these sites by the immune system, and its ability to become activated in response to local infection/inflammation (Galea et al., 2007). Therefore these vital structures are thought to have evolved an “immune privilege,” which protects them from the potentially damaging effects of an inflammatory immune response. However, even sequestered antigens in these immunologically privileged sites can become exposed to the immune system in response to local tissue damage (disrupting their physical separation) accompanied by local inflammation (whether pathogen-induced or sterile). As a result, this leads to the activation of “ignorant” self-reactive T cells, which circulate in the bloodstream and treat the exposed self-antigen as nonself. This, in turn, triggers an autoimmune reaction that may ultimately progress to disease development. Naturally, the strengths of such an autoimmune response will depend on a number of factors, including the nature of the self-antigen, the level of its exposure, number of activated T cells specific to the given self-antigen and the level of expression of MHC and costimulatory molecules in the affected tissues. Therefore local tissue damage (e.g., following physical injury and/or local infection) may greatly increase the risk that a potentially self-reactive T-cell will gain access to the given parenchymal tissue in general and immunologically privileged sites in particular and thereby initiate a specific autoimmune response. This can be very well illustrated by several good examples. For instance, bilateral testicular injury in mice was shown to result in the exposure of sequestered testicular antigens and local inflammation. This is followed by autoimmune reaction against the autologous testicular cells ultimately causing autoimmune orchitis and male infertility (Sakamoto et al., 1995).

Moreover, as already discussed above, tolerance to immunologically privileged sites can be easily broken down by mere administration of a given TSA in the presence of an adjuvant (i.e., even without the requirement of causing local tissue injury). The best example is that immunization with myelin or myelin-derived peptides in the presence of an adjuvant (i.e., danger signal) is sufficient to activate self-reactive, yet ignorant, T cells that are specific to the respective peptide and circulate in a quiescent state in the periphery. Such activated myelin-specific T-cell clones can then subsequently cross the blood–brain barrier and initiate an autoimmune destruction of myelin sheets that insulate neurons in the brain (Steinman, 2015).

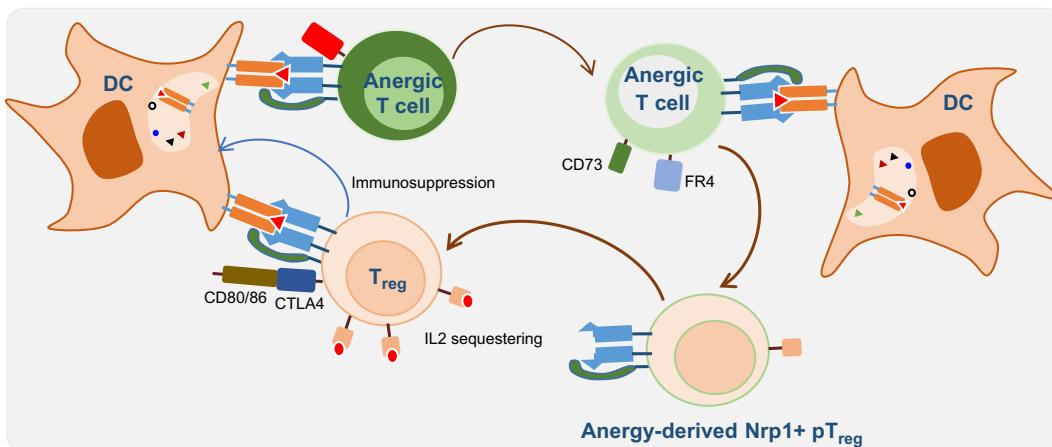

## Dendritic Cells, the Key Inducers of Peripheral T-Cell Tolerance

The context in which a naïve T-cell clone will encounter a specific antigen in the secondary lymphoid organs determines whether it will become activated or rendered unresponsive (i.e., tolerant) (Banchereau and Steinman, 1998). Specifically, a T cell will become activated only if it recognizes a peptide antigen presented (in the context of MHC-I or MHC-II molecules) by lymph node resident–activated DCs expressing high levels of B7 costimulatory molecules, which will then engage the corresponding CD28 coreceptors on the T-cell surface (Linsley et al., 1990). In contrast, if a T-cell clone recognizes a peptide antigen presented by nonactivated DCs that express low levels of costimulatory molecules, the clone will fail to proliferate and will become unresponsive to further stimulation. Thus the maturation state of the DC (characterized by expression of B7 costimulatory molecules) determines whether a specific T-cell clone will undergo activation and differentiation or rendered tolerant to the specific antigen (Dhodapkar et al., 2001; Garza et al., 2000; Hawiger et al., 2001; Mempel et al., 2004) (Fig. 5.1D).

Specifically, before their recruitment to the lymph node, nonactivated immature DCs reside within peripheral tissues, in which they continuously look for potentially harmful elements (e.g., pathogens, injury, necrosis) (Banchereau and Steinman, 1998). To this end, they utilize macropinocytosis, which allows them to engulf and process surrounding antigens (both self and nonself) and subsequently present them on their surface in the context of MHC-II molecules. Importantly, if the antigen is marked by a “danger” signal, which is recognized via specific receptors (e.g., TLR, NLR, RIG-I-like receptors) that detect either pathogen-associated molecular patterns or damage-associated molecular patterns that are released within tissues as a consequence of cellular distress, the immature DC becomes activated and migrates to the draining lymph node. This is accompanied by upregulation of several costimulatory molecules (e.g., CD80/86, CD40) and of MHC-II (presenting specific peptide antigens) on the DC surface, as well as by simultaneous downregulation of macropinocytosis and antigen processing. The high expression of CD80/CD86 costimulatory molecules on activated DCs provides a critical signal to the naïve LN (or splenic) resident T cell via its CD28 coreceptor expressed on the T-cell surface. Such costimulation leads to activation of several key transcription factors (e.g., NF- $\kappa$ B, NFAT, and AP-1), which in turn promote expression of various genes (e.g., IL2, CD25) that are critical for full T-cell activation (Müller and Rao, 2010; Rudensky et al., 2006). Furthermore, based on the specific “danger” signal, the activated DCs will produce diverse proinflammatory cytokines (e.g., IL4, IL6, IL12, IL23), which in turn determine the specific Th subset into which the responder T-cell clone will differentiate.

However, if the engulfed antigen is not marked by a “danger” signal (e.g., self-antigen or harmless antigen), the resting DC will not become activated. Consequently, the DC will be unable to provide the necessary costimulatory signals that would induce proliferation and differentiation of the naïve T-cell clones that bear a TCR specific for antigen peptides presented by the DC. It has been demonstrated that most naïve T-cell clones that have just emigrated from the thymus to the periphery (recent thymic emigrants) become tolerized by lymph node–resident DCs due to lack of costimulation (Friesen et al., 2016). Interestingly, DC activation was also shown to be suppressed by uptake of cellular material from dead or dying cells, suggesting that macropinocytosis of apoptotic (but not necrotic) cells, is one of the key mechanisms for the induction of T-cell unresponsiveness (i.e., tolerance) to self-antigens in the periphery (Gallucci et al., 1999). The state of such long-term functional unresponsiveness to antigen recognition is called T-cell anergy (Jenkins et al., 1987). Although anergy was originally thought to be simply caused by lack of costimulation, subsequent studies have demonstrated that it is also induced/maintained by activation of various inhibitory receptors [e.g., CTLA-4, programmed cell death 1 (PD-1), Lag3] on the T-cell surface that counteracts proximal TCR signaling/costimulation and thereby T-cell activation (Müller and Rao, 2010). Specifically, TCR signaling with insufficient CD28 costimulation was found to result in activation of the NFAT, but not of the AP-1, transcription factor (Müller and Rao, 2010). Consequently, activated NFAT cannot form transcriptional complexes with AP-1, and instead forms homodimers, which are directly responsible for the induction of anergy-associated genes such as ubiquitin ligases *GRAIL*, *ITCH*, and *CBLB*, as well as to active transcriptional silencing of several genes critical for T-cell activation (e.g., the *IL2* locus) (Müller and Rao, 2010; Soto-Nieves et al., 2009).

Although anergy-associated transcriptional programs have been well characterized, the identification of specific and reliable surface markers that would enable identification and isolation of anergic T cells has been much more challenging (Kalekar and Mueller, 2017). More recently, Mueller et al. have identified a panel of predictive markers for anergic CD4<sup>+</sup> T cells (Kalekar et al., 2016; Martinez et al., 2012). Specifically, they have demonstrated that CD4<sup>+</sup> T cells that have persistently recognized self-antigen in the periphery enter a CD44<sup>hi</sup> CD73<sup>hi</sup> FR4<sup>hi</sup> FOXP3<sup>-</sup> unresponsive state and are enriched for self-antigen–specific TCRs. Most importantly, however, these anergic CD4<sup>+</sup> T cells could subsequently differentiate into functional FOXP3<sup>+</sup> NRP1<sup>+</sup> pTregs *in vivo* (discussed in more detail in the following section), which in turn, can promote anergy of pathogenic CD4<sup>+</sup> T cells and inhibit autoimmunity (Kalekar and Mueller, 2017; Kalekar et al., 2016) (Fig. 5.4). Thus the induction of anergy not only serves to diminish the proliferative responsiveness of potentially dangerous self-reactive CD4<sup>+</sup> T cells but also seems to be an important prerequisite for generation of pTregs (Kalekar and Mueller, 2017; Kalekar et al., 2016). Moreover, the crosstalk between anergic and Tregs is further reinforced by the fact that Tregs were found to induce and/or maintain T-cell anergy (Fig. 5.4) (Martinez et al., 2012). Such a positive feedback loop in which anergic T cells give rise to Tregs, which, in turn, promote that generation of more anergic T cells is quite reminiscent of the *in vivo* “infectious tolerance” model previously proposed by Kendal and Waldmann (2010). Moreover, such a model could also explain the rather overlapping requirements for DC-mediated generation of anergic and pTregs, which both depend on presentation of very low levels of self-antigen along with insufficient costimulation (CD80/86/40) and absence of proinflammatory cytokines (IL6 and IL12) (Kretschmer et al., 2005; Maldonado and von Andrian, 2010).

**FIGURE 5.4** The relationship between anergic T cells and pTreg generation. Self-Ag-specific CD4<sup>+</sup> T cells that escape into the periphery can recognize peripheral self pMHCII, and through the suppressive actions of Tregs become anergic cells that express CD73 and FR4. Reencounter(s) of self-Ag induces Nrp1 expression and partial demethylation of Treg-specific loci in some of the anergic T cells. Nrp1<sup>+</sup> anergic T cells then become precursors for Treg differentiation. Upon conversion to a stable pTreg lineage, anergy-derived Tregs join the tTreg pool to suppress immunopathology and reinforce anergy induction.

### Intrinsic Mechanisms Suppressing Clonal Expansion and/or Reactivation

Although a specific T-cell clone is allowed to dramatically expand in numbers at the expense of other clones (clonal expansion) after antigen encounter, most activated T-cell clones eventually undergo apoptosis (with a small fraction surviving as memory cells), in order to preserve the diversity of the repertoire and immune homeostasis (Marrack et al., 2000). Such a mechanism has obvious implications in the maintenance of self-tolerance in the periphery, where repeated/chronic encounter with self-antigen could result in uncontrolled expansion of self-reactive T-cell clones.

Activation-induced cell death (AICD) is an intrinsic regulatory mechanism used by certain types of lymphocytes, including T cells, to undergo apoptosis upon their clonal expansion. A key mechanism underlying AICD in T cells is the upregulation of Fas receptors on their surface in response to their activation and its subsequent interaction with its ligand, which leads to apoptotic death (Lenardo, 1996; Piazza et al., 1997) (Fig. 5.1E). Thus activated T cells that express both Fas and FasL undergo apoptosis, which is mediated through their mutual contact. Such an intrinsic regulation is critical in maintaining immune tolerance in the periphery. This is best evidenced by a loss of function of either *Fas* or *Fasl* genes, which results in autoimmune lymphoproliferative syndrome (Puck and Sneller, 1997).

Furthermore, T-cell activation also results in dramatic upregulation of CTLA-4 on its surface, which is critical for keeping the expansion of the specific T-cell clone in check (Fig. 5.1F). This is most clearly demonstrated by experimentally induced CTLA-4 deficiency, which results in massive fatal lymphoproliferation and multiorgan autoimmunity in mice (Tivol et al., 1995; Waterhouse et al., 1995). Therefore CTLA-4-mediated inhibition of T-cell expansion is essential for the maintenance of self-tolerance and immune homeostasis. The molecular mechanisms of how CTLA-4 prevents T-cell expansion are complex and still somewhat controversial. While earlier studies suggested that CTLA-4 operates as a classical inhibitory immune receptor, which counteracts TCR signaling through recruitment of phosphatases to the TCR (Lee et al., 1998), more recent studies argue against this model. Specifically, Sansom et al. have suggested that CTLA-4 operates through capturing and removing CD80/CD86 molecules from the membranes of antigen-presenting cells, thus making these unavailable for CD28 costimulation (Qureshi et al., 2011). Consequently, additional T-cell clones would not be activated and would not be able to undergo clonal expansion (Fig. 5.1F).

While CTLA-4 predominantly regulates activation of naïve T-cell clones and their subsequent clonal expansion, the inhibitory receptor PD-1 was shown to negatively regulate effector T-cell functions (Freeman et al., 2000; Ishida et al., 1992). PD-1 expression levels are transiently upregulated upon activation of naïve T cells; however, its sustained expression is most characteristic of effector T cells that have become functionally exhausted (Barber et al., 2006). T-cell exhaustion is an intrinsic mechanism that prevents further activation of effector T cells upon repetitive (chronic) antigen encounter (Wherry and Kurachi, 2015). Given that self-antigens may induce repetitive

T-cell activation, such an intrinsic regulation seems critical for the maintenance of immune tolerance in the periphery. This is best evidenced by an experimental inactivation of the gene encoding PD-1, or the genes encoding its two ligands PD ligand 1 (PD-L1) and PD-L2, which result in the development of systemic autoimmunity (Freeman et al., 2000; Keir et al., 2006; Nishimura et al., 1999). Therefore PD-1–PD-1 ligand interactions are critical for restraining self-reactive effector T cells that enter the peripheral tissues and find self-pMHC.

## Dominant Tolerance Through Treg-Mediated Immunosuppression

As discussed and illustrated above, the effective induction and maintenance of self-tolerance in the periphery is underlain by multiple sophisticated regulatory mechanisms, which complement and reinforce each other. Among these, Tregs are regarded as the chief mediators of peripheral tolerance, due to their powerful immunosuppressive capacity, which allows them to counteract the effects of both helper and cytotoxic T cells in a dominant fashion (as opposed to clonal deletion, ignorance, or anergy). Their physiological significance in this process is best illustrated by the development of a severe autoimmune syndrome in humans and mice that lack Tregs as a result of FOXP3 loss of function or CD4<sup>+</sup>CD25<sup>+</sup> T-cell depletion (Fontenot et al., 2003; Hori et al., 2003; Wildin, 2002). This means that deficiency or dysfunction of Tregs alone is sufficient to break self-tolerance and cause severe autoimmunity.

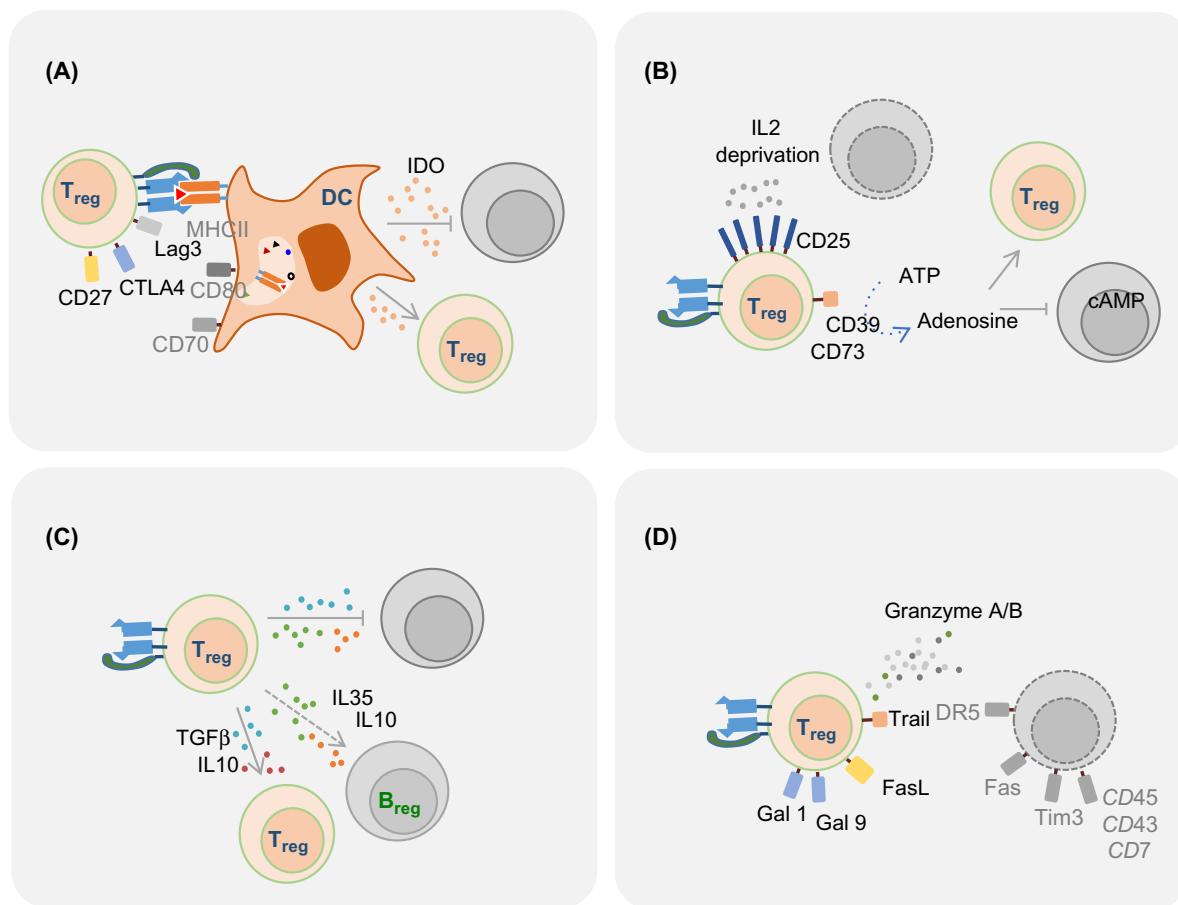

### Treg Mechanisms to Maintain Tolerance

Despite the clear importance of Treg in the induction of peripheral tolerance, the molecular and cellular mechanisms of their immunosuppressive potential remain incompletely understood and controversial. A body of evidence demonstrates that Treg can suppress self-reactive lymphocytes by several different (and likely complementary) mechanisms at multiple checkpoints. For instance, Treg can suppress activation, expansion, and differentiation of naïve T cells in lymphoid organs, restrict the traffic and recruitment of effector T cells to specific parenchymal tissues, or suppress proliferation and function of effector T cells within the peripheral tissues. To achieve maximal suppressive capacity, Tregs require TCR signaling (Levine et al., 2014; Vahl et al., 2014). However, Tregs were also shown to exert their suppressive capacity in an antigen-independent, bystander manner. The immunosuppressive mechanisms utilized by Treg (discussed in detail below) can be both direct and indirect and mainly include (1) modulation of antigen presentation, (2) metabolic disruption, (3) cytokine production, and (4) induction of cytolysis/apoptosis (Vignali et al., 2008) (Fig. 5.5).

Modulation of antigen presentation is considered to be one of the key mechanisms by which Treg indirectly suppress effector T cells. This mechanism is mainly facilitated by CTLA-4, which is highly and constitutively expressed on the surface of Treg, and which directly competes with CD28 for binding to CD80/86 ligands on DCs. Strikingly, recent studies demonstrate that CTLA-4 does not just passively block the CD80/86 ligands, but rather literally rips them off the DC surface and facilitates their subsequent engulfment by Treg, in a process called transendocytosis (Qureshi et al., 2011; Wing et al., 2008). Such a dynamic and continuous process seems to be much more efficient in downmodulation of CD80/86 expression on the DC surface than a passive blockage and seems to constitute one of the key mechanisms by which Treg suppress activation of effector T cells. More recently, an analogous mechanism was observed also for Treg-dependent CD27-mediated endocytosis of CD70 from the DC surface (Dhainaut et al., 2015), which further limits the level of costimulatory signals required for T-cell activation. In addition to CTLA-4, Tregs were also shown to utilize the inhibitory receptor Lag3 for modulation of antigen presentation on DCs. Lag3 is highly and constitutively expressed on the surface of Treg and directly binds MHCII molecules on APC, including DC. This was shown to suppress DC activation and their subsequent capacity to activate T cells (Liang et al., 2008).

Tregs also utilize various key metabolites to facilitate and/or potentiate their immunosuppressive capacity. For instance, Tregs were shown to induce production of immunosuppressive molecules such as Indoleamine 2,3-dioxygenase by DCs through CTLA-4 binding to CD80/86 ligands (Fallarino et al., 2003; Grohmann et al., 2002). This enzyme catabolizes tryptophan to kynurenine, which induces Treg differentiation via aryl hydrocarbon receptor (Mezrich et al., 2010; Opitz et al., 2011). In addition, Tregs express CD39 and CD73, two different ectoenzymes, which mediate breakdown of ATP or ADP into adenosine. Adenosine can then bind the A2A receptor on activated effector T cells, which in turn results in their direct suppression due to increased levels of cAMP (Borsig et al., 2007; Deaglio et al., 2007; Kobie et al., 2006).

The immunosuppressive potential of Treg is further mediated by their capacity to produce various immunosuppressive cytokines such as TGFβ, IL10, and IL35 that can either inhibit effector T cells or DCs

**FIGURE 5.5** Treg mechanisms to maintain tolerance. The immunosuppressive mechanisms utilized by Tregs can be both direct and indirect and mainly include (A) modulation of antigen-presenting cells, (B) metabolic disruption, (C) cytokine production, and (D) induction of cytosis/apoptosis. (A) Modulation of antigen-presenting cells includes altering DC maturation and function through CTLA-4, CD27, or Lag3, resulting in inhibition of effector cells and induction of Tregs. (B) Metabolic disruption includes IL2 consumption that inhibits effector cells and immunosuppression via CD39- and CD73-generated adenosine that increase cAMP in effector cells that can also be transferred through gap junctions. (C) Inhibitory cytokines include TGF $\beta$ , IL10, and IL35. In addition, TGF $\beta$  and IL10 induce more Tregs, while IL35 and IL10 may, in addition, induce other immunosuppressive subsets such as Bregs. (D) Cytosis mechanisms include the production of Granzyme A and B. Induction of apoptosis is mediated by TRAIL-DR5, FasL-Fas, Galectin-9-Tim3, and Gal-1 with an unknown ligand (probably CD45, CD43, or CD7). Source: Adapted from Vignali, D.A.A., Collison, L.W., Workman, C.J., 2008. How regulatory T cells work. *Nat. Immunol. Rev.* 8, 523–532.

(Andersson et al., 2008; Asseman et al., 1999; Collison et al., 2007; Fahlén et al., 2005; Nakamura et al., 2001). In addition, some of these cytokines (e.g., TGF $\beta$ ) are critical for Treg induction, while others (IL10 and IL35) may also contribute to induction of other immunosuppressive subsets such as regulatory B cells (Chen and Wahl, 2003; Collison et al., 2010; Hsu et al., 2015; Wang et al., 2014). In addition to cytokine production, several studies provided evidence that Tregs also consume certain cytokines, such as IL2, to exert their suppressive functions (De La Rosa et al., 2004). Although Treg cannot produce IL2, they express high levels of receptors that bind IL2 with high affinity (CD25). Therefore Tregs deprive local effector T cells from the IL2 required for their growth and survival (de la Rosa et al., 2004). Some studies also argue that IL2 deprivation is critical for direct induction of apoptosis (i.e., clonal deletion) of effector T cells in the periphery (Pandiyan et al., 2011). Recently, however, it has been demonstrated that while IL2 deprivation is dispensable for CD4 suppression it is necessary for limiting CD8 activation (Chinen et al., 2016).

Finally, Tregs were also shown to directly induce clonal deletion of effector T cells in the periphery. To this end, Tregs produce and secrete powerful weapons such as Granzyme A and Granzyme B that cause cytosis of effector cells in perforin-dependent and independent manners (Cao et al., 2007; Gondevi et al., 2005; Grossman et al., 2004; Zhao et al., 2006). Similarly, Tregs express additional molecules that can directly induce apoptosis of effector T cells in their proximity, including TRAIL-DR5, (Ren et al., 2007), FasL-Fas, (Weber et al., 2006; Zhang et al., 2000),

galectin-1 (Garín et al., 2007), and galectin-9 (Liberal et al., 2012; Wang et al., 2009). In addition to inhibiting or inducing death of the effector cell, there is evidence of Treg influencing traffic and recruitment of effector T cells into the tissue (Davidson and Shevach, 2011; Fu et al., 2014).

Despite all the recent progress in elucidating the mechanisms of Treg-mediated suppression, our understanding remains incomplete. For instance, it is still unclear whether there is a key superior mechanism that would account for most of their suppression potential, whether multiple mechanisms are required, whether some of the mechanisms are redundant and most importantly what is their relative importance *in vivo*. It seems likely that the broad variety of suppressive mechanisms observed is linked to diverse Treg subsets with different activation status that act at distinct times and locations.

### **Treg Diversity and Their Role in Self-Tolerance**

In recent years, it has been widely recognized that Tregs are extremely heterogeneous. Initially it was believed that Tregs are uniquely produced in the thymus (tTreg, former natural Treg discussed in detail in the section “Negative Versus Agonist Selection of Self-Reactive T Cells”). A recent body of evidence, however, demonstrates that Tregs also develop in the periphery from conventional CD4<sup>+</sup> T cells (pTreg, former induced Treg) (Abbas et al., 2013). The development of pTreg occurs preferentially from recent thymic emigrants (Paiva et al., 2013), under certain conditions such as presence of immunosuppressive cytokines like TGFβ or other environmental factors like diet- and microbiota-related antigens (Arpaia et al., 2013; Atarashi et al., 2011; Benson et al., 2007; Chen et al., 2003; Furusawa et al., 2013; Smith et al., 2013). The Treg is further potentiated by their different antigen-specificities, tissue-tropisms, and specialized functions including tissue repair or metabolic regulation (Ali et al., 2017; Arpaia et al., 2015; Burzyn et al., 2013; Cipolletta, 2014; Dombrowski et al., 2017; Feuerer et al., 2009; Gratz and Campbell, 2014; Nosbaum et al., 2016; Panduro et al., 2016). Although large strides have been made in Treg biology over the last decades, definitive data regarding the role and relative contributions of individual Treg subsets in tolerance is difficult to obtain at this point, mainly due to the lack of consensus markers to define such a plastic and heterogeneous subset of cells.

Traditionally, tTregs have been considered to play a dominant role in the induction/maintenance of tolerance to self-antigens, while pT<sub>res</sub> have been thought to play a key role in the induction of tolerance to harmless foreign antigens (e.g., fetus, food, microbiota) (Samstein et al., 2012) and the maintenance of immune homeostasis, mainly at barrier sites where they accumulate (Lathrop et al., 2011). This later assumption is supported by the observation that mice deficient for pTreg (*Foxp3* enhancer CNS1 deficient mice) develop Th2-dependent inflammation at mucosal sites rather than generalized autoimmunity (Josefowicz et al., 2012b). However, other reports suggest that pTreg also perform essential functions in induction of self-tolerance. For instance, it has been shown that gut microbiota induces the production of a peptide by pancreatic beta cells, resulting in Treg production and protection from type-1 diabetes (Sun et al., 2015). Correspondingly, TCR sequencing made evident that a significant proportion of Treg clones in the colon were of thymic origin indicating that tTregs also promote tolerance to microbiota (Cebula et al., 2013). More recently, two distinct tTreg subsets have been identified: (1) a “triple<sup>hi</sup>” (GITR<sup>hi</sup>PD-1<sup>hi</sup>CD25<sup>hi</sup>) population, which is highly self-reactive and limits lymphoproliferation in lymph nodes; and (2) a “triple<sup>lo</sup>” population (GITR<sup>lo</sup>PD-1<sub>lo</sub>CD25<sup>lo</sup>), which is less self-reactive and limits the development of colitis (Wyss et al., 2016). Altogether, these studies suggest that the functional separation between tTreg and pTreg populations is not rigid and that both populations express different nonredundant TCR repertoires (Haribhai et al., 2011) and are thus both required for the induction of self-tolerance.

Furthermore, (regardless of their thymic or peripheral origin) Tregs were shown to differentiate to functionally distinct effector Treg coopting the same transcription factors that drive helper T-cell differentiation. Strikingly, the very same transcription factor required for helper T-cell differentiation is also required by the corresponding Treg to suppress the specific helper T-cell subset (Cretney et al., 2013). Thus Tbet-, Irf4- or ROR $\gamma$ T-, Gata3- or Stat3-, and Bcl-deficient Tregs are defective in their ability to suppress Th<sub>1</sub>, Th<sub>2</sub>, Th<sub>17</sub>, and T<sub>fh</sub>, respectively (Chaudhry et al., 2009; Duhen et al., 2012; Koch et al., 2009; Ohnmacht et al., 2015; Wang et al., 2011; Wohlfert et al., 2011; Yu et al., 2015a; Zheng et al., 2009). Nevertheless, it is still unclear whether these are true stable subsets of Treg or just a mirror of Treg plasticity. A recent report provides evidence to support the former hypothesis (Levine et al., 2017). In this report, Tbet<sup>+</sup> Treg shows a unique transcriptional profile, stability, and specific capacity to limit Th<sub>1</sub> responses that might be extended to other effector Treg. Altogether these data suggest that naïve Treg can differentiate into effector Treg with unique immune-modulatory functions specific to distinct microenvironments, therefore limiting undesired bystander suppression. Besides, it predicts that the appropriate effector Treg subset is needed to maintain tolerance and prevent autoimmunity in different contexts.

Recently, it has been described that Treg produced early in life have a major role in preventing autoimmunity. Using an NOD *Foxp3* DTR mouse model, Yang et al. observed that mice develop fatal autoimmunity only when Tregs are depleted during the first 10 days of life and not at later timepoints. They also observed that the production of this perinatal Treg subset is Aire dependent as only the transfer of *Aire-WT* Treg, but not *Aire-KO* Treg protects Treg-depleted perinates from autoimmunity (Yang et al., 2015). This observation, however, contradicts previous work from Rudensky et al. describing that Tregs are important throughout the lifespan of mice (Kim et al., 2007). Despite these contradictory results that might stem from the different animal models utilized, the study nicely highlights that perinatal Tregs are crucial for establishing tolerance to self. Similarly, it has been shown that Tregs accumulate in the skin hair follicles during the first weeks of age promoting tolerance to commensal bacteria (Sanchez Rodriguez et al., 2014; Scharschmidt et al., 2017) and that Tregs are induced in the lungs during the first weeks of life to facilitate tolerance to a broad spectrum of allergens (Gollwitzer et al., 2014). Collectively, these reports suggest that Treg developed early in life (either in the thymus or in the periphery) are uniquely important for the establishment of tolerance to self, and harmless antigens such as our “microbial-self”.

### **Treg at Barrier Sites**

Tregs play a major role in establishing immune tolerance at barrier sites such as the intestine (Morrissey et al., 1993; Powrie et al., 1993), lungs (Curotto de Lafaille et al., 2008; Ostroukhova et al., 2004), and skin (Scharschmidt et al., 2015, 2017), which are bursting with commensal microbiota or other harmless antigens (e.g., food or inhaled antigens). While Tregs constitute ~10% of the CD4<sup>+</sup> T cells in most organs in the body, in the intestinal lamina propria, they constitute 20%–30% of the CD4<sup>+</sup> T cells (Tanoue et al., 2016). Moreover, the intestinal Treg population seems to be very heterogeneous as it is composed of at least three different subsets including: (1) ROR $\gamma$ t<sup>+</sup> Tregs that are induced by microbiota and mediate tolerance to microbial-self in steady state (Sefik et al., 2015; Yang et al., 2016), (2) ROR $\gamma$ t<sup>−</sup> NRP1<sup>−</sup> Tregs that are induced by solid dietary antigens and maintain homeostasis to diet antigens as shown by increased susceptibility to food allergy upon depletion (Kim et al., 2016), and (3) GATA3<sup>+</sup> Tregs that are produced in the thymus and probably function under inflammatory conditions as they express high levels of IL33 receptor (Schiering et al., 2014; Wohlfert et al., 2011). Therefore in the gut, both tTreg and pTreg populations cooperate to maintain tolerance to “microbial-self” and to innocuous food antigens. This state of unresponsiveness induced by Treg is vital to preventing various intestinal disorders, such as food allergy, inflammatory bowel disease, or celiac disease (Cebula et al., 2013; Haribhai et al., 2011; Lathrop et al., 2011).

In addition to FOXP3<sup>+</sup> Treg, other subsets of FOXP3<sup>−</sup> regulatory T cells play a role in maintaining tolerance in the intestine. Nevertheless, these FOXP3<sup>−</sup> regulatory T cells are not sufficient to control immune homeostasis in the gut. This is evidenced by the development of enteropathy in IPEX patients that present mutations in *Foxp3* gene and therefore presumably intact FOXP3<sup>−</sup> regulatory T cells. Probably the best characterized subset of FOXP3<sup>−</sup> cells is a unique population of CD4<sup>+</sup>CD8aa<sup>+</sup> regulatory T cells, which are characterized by their capacity to produce high levels of IL10. Moreover, these cells were shown to accumulate in human gut in response to microbiota such as *Faecalibacterium prausnitzii* (one of the major *Clostridium* species in human gut) and are decreased in patients with inflammatory bowel disease, which suggests that they may contribute to prevent the disease (Das et al., 2003; Sarrabayrouse et al., 2014). FOXP3<sup>−</sup> regulatory T cells also include IL10-producing Tr<sub>1</sub> cells and TGF $\beta$ -producing Th<sub>3</sub> cells. It should be stressed, however, that there is a certain level of controversy about whether these Tr<sub>1</sub> and Th<sub>3</sub> cells represent unique cell lineages and not only different states of Treg. This notion is further reinforced by the fact that both Tr<sub>1</sub> cells and Th<sub>3</sub> cells were mainly described prior to the discovery of *Foxp3* and thus their characterization largely relied only on high IL10 or TGF $\beta$  secretion. While it seems that there are both FOXP3<sup>+</sup> and FOXP3<sup>−</sup> IL10 secreting regulatory T cells (Maynard et al., 2007), the existence and identity of Th<sub>3</sub> remain less defined.

Although the role of Treg in maintaining tolerance at barrier sites is undisputed, the responsible Treg subsets and the mechanisms utilized still remain poorly characterized. Therefore expanding our knowledge about Treg generated throughout life at different anatomical sites will be invaluable to understanding Treg tolerance induction and its failure. This might also enable to design effective therapies to treat immune disorders in the future.

### **Other Tolerogenic Cells in the Periphery**

For many years, the role of stromal cells in secondary lymphoid organs was believed to be limited to organ structure and maintenance. However, this notion has been put to rest with several independent findings

implicating these heterogeneous stromal cell populations in active modulation of immune responses through extensive crosstalk with hematopoietic populations (reviewed in [Malhotra et al., 2013](#)). Such crosstalk extends to the context of peripheral tolerance induction as all lymph node stromal cell (LNSC) populations have been shown to have the capability of directly presenting self-antigen to CD8<sup>+</sup> T cells for the purpose of their tolerization ([Cohen et al., 2010; Fletcher et al., 2010; Lee et al., 2007; Magnusson et al., 2008; Nichols et al., 2007](#)). Remarkably, LNSCs ectopically express and present various TSA genes in a manner reminiscent of PGE in mTECs ([Lee et al., 2007; Magnusson et al., 2008; Nichols et al., 2007](#)). However, the expression of the TSAs in LNSCs has been reported to be independent of Aire and by far not as broad as in mTECs ([Fletcher et al., 2010](#)). It has yet to be determined whether LNSCs can influence CD4<sup>+</sup> T-cell tolerance, as their basal levels of MHCII expression is quite low, though significantly increased under inflammatory conditions ([Malhotra et al., 2012](#)). Nevertheless, another unique bone marrow–derived APC population has been directly implicated in CD4<sup>+</sup> T-cell tolerance within lymph nodes. These cells express Aire and were thus named extrathymic Aire-expressing cells, and appropriately express TSAs in a promiscuous fashion, though their repertoire was reported to be separate and limited as compared to that found in mTECs ([Gardner et al., 2008, 2013](#)).

## CONCLUDING REMARKS

While research over the last decades has led to a better understanding of how T-cell tolerance is regulated in the thymus and periphery, much remains unknown. As we benefit from the genomics era, a clearer understanding of the molecular pathways that regulate the cellular functions that keep tolerance in check will undoubtedly lead to a detailed understanding of human autoimmunity. Ideally, key discoveries will provide novel strategies to utilize the physiological processes of immunological tolerance to prevent transplant rejection, allergies, and autoimmunity and to promote rejection of tumor cells.

## Acknowledgments

We would like to thank members of the Abramson lab and Prof. Eystein S. Husebye for their critical reading of this manuscript. J.A. is an incumbent of the Dr. Celia Zwilloburg-Fridman and Dr. Lutz Fridman Career Development Chair. Research in the Abramson lab is kindly supported by European Research Council Consolidator grant (ERC-2016-CoG-724821), Israel Science Foundation (1796/16 and 722/14), the Sy Syms Foundation; US–Israel Binational Foundation, Maurice and Vivienne Wohl Charitable Foundation; Goodman Family Charitable Lead Annuity Trust; Ruth and Samuel David Gameroff Family Foundation.

## INTRODUCTION

The immune system has evolved to defend against a wide array of pathogens, and optimal immune function requires coordinated responses from both the innate and adaptive systems. While the innate immune system utilizes a relatively small number of invariant receptors specific for conserved microbial products, such as the cell wall components of bacteria, the adaptive immune system makes use of a nearly unlimited repertoire of receptors generated by random recombination of the T- and B-cell receptor loci. Although random recombination allows for incredible lymphocyte receptor diversity, it comes at the price of generating potentially autoreactive receptors. The risk for self-reactivity is in part mitigated by checkpoints during lymphocyte development that eliminate most of the self-reactive clones (referred to as central tolerance) as well as mechanisms that limit the ability of self-reactive clones to mount responses in the periphery (referred to as peripheral tolerance). However, the existence of lymphocyte-dependent autoimmune disease is a clear indication that these mechanisms are imperfect and some self-reactive lymphocytes are able to initiate destructive autoimmune inflammation.

**FIGURE 6.1** Generation and function of Th subsets. Naïve CD4<sup>+</sup> T cells are capable of differentiating into various effector and regulatory subsets. Th subsets are shown, along with the cytokines critical for differentiation, lineage-defining transcription factors, and effector cytokines. *Th*, T helper.

Self-reactive CD4<sup>+</sup> T helper (Th) cells play a crucial role in the pathogenesis of many human autoimmune diseases. This is in part due to the unique ability of Th cells to undergo further differentiation into distinct subsets that are specialized at recruiting and coordinating different immune effector mechanisms, largely via the secretion of specific combinations of cytokines and chemokines (Fig. 6.1). The differentiation of naïve Th cells into distinct subsets is dependent both upon recognition of cognate antigen–MHC complexes as well as environmental cues, particularly cytokines, that drive different transcriptional modules. Although multiple factors are important for Th differentiation, in many cases a single transcription factor is crucial for initiating and stabilizing the expression of the transcriptional module that defines a given Th subset (Fig. 6.1). In addition, there is a complicated interplay between the different Th subsets, as factors that are produced by one subset may inhibit the differentiation of another. Thus, understanding the factors that drive differentiation of Th subsets and the effector mechanisms those Th subsets utilize to promote or inhibit tissue inflammation is important for understanding the mechanisms that drive induction of autoimmune disease.

## T HELPER 1 CELLS

In 1986 Tim Mosmann and Robert Coffman published a seminal paper describing the heterogeneity of effector CD4<sup>+</sup> T cells, which they divided into two distinct subsets, called Th1 and Th2 cells, so named because they were the first two to be described (Mosmann et al., 1986). Th1 cells play a critical role in inducing protective immune responses to extracellular pathogens such as *Mycobacterium tuberculosis* or intracellular pathogens such as *Listeria monocytogenes* (Mosmann and Coffman, 1989a,b; Neighbors et al., 2001; Geginat et al., 1998; Viegas et al., 2007; Wan and Flavell, 2009). In response to certain microbial stimuli, dendritic cells and macrophages produce cytokines, including interleukin (IL)-12, IL-18, and type 1 interferons (IFNs), that promote Th1 development by inducing the expression of the transcription factor T-bet, the key transcriptional regulator of Th1 cells (Nakanishi et al., 2001; Szabo et al., 2003; Wan and Flavell, 2009). While multiple cytokines are important for Th1 differentiation, IL-12 is particularly crucial. Thus, mice deficient for either IL-12 or the IL-12 receptor (IL-12R)

chain have impaired Th1 differentiation and are extremely susceptible to intracellular pathogens (Mosmann and Coffman, 1989a,b). Upon binding to its receptor, IL-12 promotes Th1 lineage commitment by activating STAT4, which then enhances production of IFN- $\gamma$ , the hallmark cytokine of Th1 cells (Oh and Ghosh, 2013; Yamane and Paul, 2013; Mucida and Cheroutre, 2010). IFN- $\gamma$  signals in an autocrine manner via activation of STAT1 to enhance T-bet expression, thus further promoting Th1 polarization. T-bet then maintains IFN- $\gamma$  production, in part by inducing chromatin remodeling of the IFN- $\gamma$  locus (Szabo et al., 2003; Oh and Ghosh, 2013; Yamane and Paul, 2013; Mucida and Cheroutre, 2010). Finally, IFN- $\gamma$  also inhibits the differentiation of naïve CD4 $^{+}$  T cells into other subsets, such as Th2 or Th17 cells (Schoenborn and Wilson, 2007). Thus Th1 differentiation utilizes a feed-forward loop, in which IFN- $\gamma$  is first induced and then acts to amplify Th1 differentiation and, at the same time, suppresses the differentiation of other T-cell subsets. Notably, T-bet also exerts a repressive function toward the type I IFN transcriptional program, further highlighting the complex transcriptional response mediated by T-bet (Iwata et al., 2017).

Pathways that are crucial to innate immune cell function were recently described to also play a vital role in the induction and function of human Th1 cells. For example, the inflammasome component NLRP3 and the complement protein C5 work in conjunction to stabilize Th1 cell differentiation and prevent alternative fates (Arbore et al., 2016). In addition, complement controls nutrient influx to regulate cellular metabolism during Th1 responses (Kolev et al., 2015). Similarly, recent studies indicate that aerobic glycolysis directs Th1 differentiation in the gut, highlighting the importance of metabolism in Th cell differentiation (Peng et al., 2016). Finally, retinoic acid signaling stabilizes the Th1 lineage and represses genes that are important for other Th lineages, such as Th17 cells (Brown et al., 2015). Therefore multiple molecular and metabolic pathways are responsible for promoting the unidirectional development of Th1 cells, both by supporting Th1 cell differentiation and also suppressing alternate cell fates.

The role of Th1 cells in inflammation and autoimmune pathology has been extensively studied and Th1 cells have been shown to play an important role in many organ-specific autoimmune diseases, including insulin-independent type 1 diabetes mellitus (IDDM), multiple sclerosis (MS), inflammatory bowel disease (IBD), and rheumatoid arthritis (RA) (Szabo et al., 2003). Prior to the discovery of Th17 cells, an imbalance between Th1/Th2 subsets was proposed to be a key driver of autoimmunity, with skewing toward a Th2 phenotype being considered protective, while Th1 predominance appeared to be pathogenic (Adorini et al., 1996a,b). For instance, animal studies revealed that transgenic expression of IL-4 on pancreatic islets protected nonobese diabetic mice from developing IDDM, while adoptive transfer of Th1 cell clones induced diabetes (Katz et al., 1995; Mueller et al., 1996). IFN- $\gamma$ -producing Th cells were often found within the target tissue in multiple other organ-specific human autoimmune diseases, thereby implicating Th1 cells in disease pathogenesis. Subsequent studies in animal models of human diseases have further validated the importance of Th1 cells in causing immunopathology (Szabo et al., 2003; Lafaille, 1998; Oppmann et al., 2000; Neurath et al., 2002; Kuchroo et al., 1993). Moreover, IL-18, another cytokine associated with the Th1 lineage, is important for the induction of colitis, as deletion of IL-18 specifically in the epithelium protected animals from disease development (Nowarski et al., 2015). However, how exactly IL-18 is involved in Th1 regulation and function remains unknown.

In an animal model of MS, experimental autoimmune encephalomyelitis (EAE), Th1 cells have been shown to induce disease and play an important role in propagating epitope spreading, whereby infiltrating Th1 cells in the CNS induce inflammation and demyelination causing the release of new, previously sequestered antigens (Katz-Levy et al., 2000; Mack et al., 2003; Yin et al., 2001). Newly released antigens are then picked up and presented by antigen presenting cells (APCs) to induce activation of additional autoreactive T cells (McMahon et al., 2005). It is unknown how myelin-specific T cells are initially activated, particularly as myelin-associated antigens are sequestered within the CNS behind the blood–brain barrier. One hypothesis is that a viral infection may induce the activation of T cells that cross-react with myelin components, a mechanism termed molecular mimicry (Rose, 2017). These cross-reactive T cells then attain a pathogenic effector phenotype, traffic to the target organ, and induce inflammation and tissue destruction, resulting in CNS autoimmunity (Schreiner et al., 2007; Chastain and Miller, 2012). Furthermore, IFN- $\gamma$  has been shown to enhance effector function of scavenger APCs which may promote molecular mimicry as well as epitope spreading by the autoreactive T cells and enhance autoimmune pathology (Schoenborn and Wilson, 2007; Smith and Miller, 2006; Karni et al., 2006). However, there is evidence that IFN- $\gamma$  may not be the key cytokine responsible for pathogenic effector functions of Th1 cells in many autoimmune conditions (Zhang et al., 2012; Trembleau et al., 2003; Chu et al., 2000; Matthys et al., 1998). In particular, the loss of IFN- $\gamma$  does not prevent the development of EAE; in fact, IFN- $\gamma$  deficient mice are even more susceptible to disease development (Ferber et al., 1996). These conflicting data could only be understood in context with the discovery of Th17 cells (see “T Helper 17 Cells” section).

## T HELPER 17 CELLS

### Identification

Although Th1 cells were thought to be the main drivers of organ-specific autoimmunity, animals lacking the Th1 signature cytokine IFN- $\gamma$  or other molecules involved in the Th1 differentiation pathway, including IFN- $\gamma$  R and STAT1, are in fact not resistant, but actually more susceptible to multiple autoimmune diseases including EAE, experimental autoimmune uveitis, and collagen-induced arthritis (CIA) (Ferber et al., 1996; Jones et al., 1997; Matthys et al., 1998). Even more surprising, mice deficient for the IL-12 chain p35 were also more susceptible to EAE, whereas loss of the other chain of IL-12, p40, conferred resistance to EAE. This conundrum was solved when it was shown that p40 does not only pair with p35 to form IL-12, but can also pair up with another cytokine chain, p19, to form a novel cytokine called IL-23 (Oppmann et al., 2000). In a seminal study, Cua and colleagues showed that loss of both p40 and p19 (IL-23) protected animals from EAE, whereas IL-12-p35-deficient animals, which lacked IL-12 and Th1 responses, remained susceptible to EAE (Cua et al., 2003; Langrish et al., 2005). These data provided the foundation for the hypothesis that IL-23, rather than IL-12, is crucial for the development of autoimmunity. It was later revealed that IL-23 is involved in the generation of a unique T-cell subset, named Th17 cells owing to their production of the effector cytokine IL-17 (Korn et al., 2009).

### Differentiation

A unique subset of IL-17-producing T cells, termed Th17 cells, was first predicted in 2005 (Bettelli and Kuchroo, 2005; McKenzie et al., 2006). Generation of Th17 cells was initially thought to be driven by IL-23, however, naïve T cells do not express the receptor for IL-23 (IL-23R); instead, Th17 differentiation requires the presence of the cytokines TGF- $\beta$  and IL-6 (Bettelli et al., 2006; Veldhoen et al., 2006; Mangan et al., 2006). Exposure of naïve T cells to TGF- $\beta$  alone leads to the expression of the transcription factor Foxp3 and differentiation into immunosuppressive regulatory T cells (Tregs). However, in the presence of the proinflammatory cytokine IL-6, which signals via STAT3, TGF- $\beta$ -signaling results in the induction of the Th17 lineage transcription factor ROR $\gamma$ t and promotes Th17 differentiation (Bettelli et al., 2006; Veldhoen et al., 2006). The molecular basis for the reciprocal relationship between Tregs and Th17 cells lies in the ability of ROR $\gamma$ t/ROR $\alpha$  and Foxp3 to physically bind to each other and antagonize each other's function (Zhou et al., 2008; Du et al., 2008). Thus, many factors including IL-2, IL-21, retinoic acid, and aryl hydrocarbon receptor (AHR) ligands, have been shown to have opposing effects on Tregs and Th17 cells and modulate immune responses by shifting the balance between Tregs and Th17 cells (Laurence et al., 2007; Liu et al., 2011; Mucida et al., 2007; Veldhoen et al., 2008a; Quintana et al., 2008). In addition, recent studies reported that HIF1 $\alpha$ , a metabolic sensor of hypoxia, enhances Th17 differentiation on a transcriptional level, while simultaneously attenuating Treg development by targeting Foxp3 for proteasomal degradation (Shi et al., 2011; Dang et al., 2011).

Aside from IL-6, and particularly in its absence, TGF- $\beta$  can also cooperate with IL-21 to induce Th17 differentiation, and since Th17 cells also produce IL-21, it promotes the self-amplification of Th17 cells in a feed-forward loop (Korn et al., 2007; Nurieva et al., 2007; Zhou et al., 2007). In addition, IL-1 $\beta$  can synergize with IL-6 to promote murine Th17 cell differentiation, in part by expanding the population via mammalian target of rapamycin (mTOR), and IL-1R1 signaling is crucial for the generation of pathogenic Th17 cells in vivo (Chung et al., 2009; Gulen et al., 2010; Sutton et al., 2006). In conjunction with TGF- $\beta$ , IL-6, IL-23, and IL-21, IL-1 $\beta$  has also been described as a critical differentiation factor for human Th17 cells (Manel et al., 2008; Yang et al., 2008; Volpe et al., 2008).

### Pathogenicity

Although initial in vitro and in vivo differentiation of naïve T cells into Th17 cells does not require IL-23, generation of pathogenic Th17 responses in vivo is impaired in both IL-23 and IL-23R deficient mice (Langrish et al., 2005; McGeachy et al., 2009; Awasthi et al., 2009; Lee et al., 2012). Furthermore, several studies have demonstrated genetic linkage of IL23R to susceptibility to human autoimmune diseases, including psoriasis, ankylosing spondylitis, and Crohn's disease (Duerr et al., 2006; Cargill et al., 2007; Liu et al., 2008; Burton et al., 2007), suggesting that IL-23 may be critical for the generation of autoimmune T-cell responses in humans. Expression of the IL-23R, which is composed of IL-12R $\beta$ 1 and the specific chain IL-23R (Parham et al., 2002), is induced by IL-6 and TGF- $\beta$  during Th17 differentiation and is further upregulated by IL-23 itself (Awasthi et al., 2009). Moreover,

recent data show that the canonical Notch signaling pathway drives IL-23R expression on Th17 cells via RBPJ and thereby controls Th17 pathogenicity (Meyer Zu Horste et al., 2016).

IL-23 induces pSTAT3 and thus reinforces the Th17 transcriptional program. In addition, IL-23 induces de novo production of the Th17 effector cytokine IL-22 (Liang et al., 2006; Zheng et al., 2007), which promotes epithelial growth and induces expression of acute-phase reactants and  $\beta$ -defensins, thus promoting barrier function (Wolk et al., 2010). IL-23 also drives re-expression of IL-7R $\alpha$  on Th17 cells (McGeachy et al., 2009), thus rendering Th17 cells responsive to IL-7, which may be important for terminal differentiation and the survival/expansion of pathogenic Th17 cells (Liu et al., 2010). Furthermore, IL-23R signaling activates the salt-sensitive kinase Sgk-1, which deactivates the transcriptional repressor Foxo1 and thereby allows ROR $\gamma$ t to transactivate target genes to a greater degree (Wu et al., 2013). The protein–protein interaction network that is induced by IL-23R signaling is not fully understood, but research into this pathway holds promise for understanding the mechanisms by which IL-23R signaling induces pathogenic Th17 cells.

In addition to expanding and stabilizing Th17 cells, IL-23 is essential for inducing pathogenic effector functions in Th17 cells. Adoptive transfer studies in EAE have shown that Th17 cells generated with TGF- $\beta$ 1/IL-6 in the absence of IL-23 are nonpathogenic despite their production of IL-17 (Ghoreschi et al., 2010; McGeachy et al., 2007; Lee et al., 2012). In contrast, Th17 cells generated in the presence of TGF- $\beta$ 1/IL-6/IL-23 or IL-1 $\beta$ /IL-6/IL-23 are capable of inducing severe autoimmune tissue inflammation (Ghoreschi et al., 2010; Jäger et al., 2009; Lee et al., 2012; McGeachy et al., 2007), indicating that abundance of TGF- $\beta$ 1 together with relative lack of IL-23 during differentiation favors generation of nonpathogenic Th17 cells, while the presence of IL-23 promotes the generation of pathogenic Th17 cells. Interestingly, the type of TGF- $\beta$  may be important for pathogenicity, since differentiation in the presence of or TGF- $\beta$ 3/IL-6 generates encephalitogenic Th17 cells (even in absence of IL-23), whereas differentiation with TGF- $\beta$ 1/IL-6 does not (Lee et al., 2012). In addition, other factors fine-tune the effector phenotype of Th17 cells; thus IL-1 $\beta$  enhances IL-23R expression via MyD88 and mTOR and thereby promotes responsiveness of Th17 cells to IL-23 (Chang et al., 2013; Gulen et al., 2012). Interestingly, it was shown that IL-1 $\beta$  is produced intrinsically by Th17 cells in an ASC-NLRP3 inflammasome-dependent manner (Martin et al., 2016).

While multiple cytokines modulate the Th17 effector phenotype, at the molecular level this phenotype is a result of transcription factors that are differentially expressed in pathogenic versus nonpathogenic Th17 cells. Transcriptional profiling, including at the single cell level, has identified pathogenic and nonpathogenic signature genes in Th17 cells, which determine the functional properties of Th17 cells (Lee et al., 2012; Yosef et al., 2013; Gaublomme et al., 2015). A prominent example for a pathogenic signature gene is *Csf2*, which encodes the cytokine GM-CSF. GM-CSF has been associated with Th17 pathogenicity during EAE in two independent studies, and IL-23 and IL-1 $\beta$  drive GM-CSF production in Th17 cells (El-Behi et al., 2011; Codarri et al., 2011). GM-CSF prompts APCs to produce proinflammatory cytokines including IL-6 and IL-23, which amplify Th17 responses, and it also attracts a wave of secondary cells, primarily macrophages, which further propagate tissue inflammation (El-Behi et al., 2011; Codarri et al., 2011). In contrast, important examples of nonpathogenic signature genes are *cMaf* and *Il10*. Consistent with the role of IL-23 in promoting pathogenicity, expression of c-Maf and IL-10 is diminished by IL-23 and enhanced by TGF- $\beta$ 1 (McGeachy et al., 2007; Ahern et al., 2010). IL-10 can limit autoimmune tissue inflammation by enabling Tregs to suppress Th17-induced inflammation (Chaudhry et al., 2011), and also by directly inhibiting the proliferation of Th17 cells (Huber et al., 2011). Finally, genes such as *Cd5l* are upregulated in nonpathogenic Th17 cells and prevent the development of a pathogenic phenotype by modulating cellular lipid metabolism (Wang et al., 2015).

The Th1 transcription factor T-bet, which controls the expression of IFN- $\gamma$  is also part of the pathogenic signature in Th17 cells. Although Th17 cells do not produce much IFN- $\gamma$  in vitro, IL-17 $^+$ IFN- $\gamma$  $^+$  double producers are commonly seen in target organs of various autoimmune disease models, including the CNS during EAE (Ivanov et al., 2006; Abromson-Leeman et al., 2009) and the colon during colitis (Hue et al., 2006; Kullberg et al., 2006). Whether these cells arise from Th1 or Th17 cells has been much debated, however, fate-mapping experiments now indicate that IL-17 $^+$ IFN- $\gamma$  $^+$  double producers are derived from Th17 cells in an IL-23 dependent fashion (Hirota et al., 2011). This plasticity can have important physiological function and has been shown to be important for IgA production in the intestinal epithelium (Hirota et al., 2013). In addition, Th17 cells generated in the absence of IL-23 lose expression of IL-17 relatively easily and switch over/de-differentiate into IFN- $\gamma$  producers (Shi et al., 2008; Lee et al., 2009; Bending et al., 2009; Jäger et al., 2009), while Th17 cells generated in the presence of IL-23 maintain stable IL-17 production but often coproduce IFN- $\gamma$  in the target organ (Mangan et al., 2006; McGeachy et al., 2009; Jäger et al., 2009; Liu et al., 2010). The co-production of the Th1 cytokine IFN- $\gamma$  by Th17 cells emphasizes that Th17 cells are potentially more plastic than other Th subsets. However, whether the production of IFN- $\gamma$  by Th17 cells is beneficial or detrimental for the development of tissue inflammation and

autoimmunity remains unclear. In humans, IL-17<sup>+</sup>IFN- $\gamma$ <sup>+</sup> double producers have also been described and have been termed Th1\* cells (Acosta-Rodriguez et al., 2007). Analogous to the variety of Th17 effector phenotypes described in mice, human Th17 cells also show different effector phenotypes depending on the microenvironment. For instance, *Candida albicans* infection generates an IL-1 $\beta$ -rich cytokine milieu that prompts Th17 cells to co-produce IL-17 and IFN- $\gamma$ , whereas *Staphylococcus aureus* infection primes Th17 cells to produce IL-17 together with IL-10 (Zielinski et al., 2012). A transcriptomic analysis of human Th17 cells has shown that Th17 cells induced by *C. albicans* are similar to pathogenic murine Th17 cells and Th17 cells with specificity for *S. aureus* are transcriptionally similar to murine nonpathogenic Th17 cells (Hu et al., 2017). These findings support the concept that various subtypes of Th17 cells are naturally derived to counteract various types of infections but may play different roles if they are directed against an autoantigen. While nonpathogenic Th17 cells are key regulators of tissue homeostasis, pathogenic Th17 cells are the drivers of autoimmune inflammation. Therefore, next-generation therapeutics would ideally include agents that target pathogenic Th17 cells while keeping nonpathogenic Th17 cells intact.

Evidence that IL-23 induces important effector functions in humans comes from clinical trials in Crohn's disease: blockade of the IL-12/23 p40 subunit via ustekinumab was beneficial, whereas neutralization of IL-17 only via secukinumab did not improve health, and in some patients even worsened disease activity (Hueber et al., 2012; Sandborn et al., 2012). These data emphasize that production of IL-17 cannot be used as a measure for the presence of pathogenic Th17 cells, which must be defined via many additional effector functions. This is especially true for the intestine, where Th17 cells play an important role in homeostasis.

## Transcriptional Regulation

Upon engagement with their respective receptors, IL-6, IL-21, and IL-23 all induce phosphorylation of STAT3 via Janus kinases, which is absolutely crucial for proper Th17 differentiation (Yang et al., 2007; Harris et al., 2007). Phosphorylated STAT3 dimerizes, translocates to the nucleus, and activates transcription of many Th17-specific genes including *Il17a*, *Il17f*, *Il21*, *Il23r*, and *Rorc*, which encodes for the Th17 lineage-specific transcription factor ROR $\gamma$ t. STAT3 also enables epigenetic changes that reinforce the Th17 transcriptional program and promote survival and proliferation (Chen et al., 2006; Durant et al., 2010).

ROR $\gamma$ t is the master transcription factor for Th17 cells and, together with the related ROR $\alpha$ , transactivates Th17 signature genes including *IL17a*, *IL17f*, *Il23r*, and the Th17-specific chemokine receptor *Ccr6* (Zhou and Littman, 2009; Hsu et al., 2008; Ciofani et al., 2012; Xiao et al., 2014). As expected for a lineage-defining transcription factor, expression of ROR $\gamma$ t is a prerequisite for Th17 differentiation in vitro and in vivo but is dispensable for the differentiation of other lineages (Bettelli et al., 2008).

To ensure optimal conditions for the transcriptional activity of STAT3 and ROR $\gamma$ t, other factors are needed. The transcription factors IRF4 and BATF mediate the effects of IL-21 on Th17 differentiation and self-amplification and are required for proper induction of ROR $\gamma$ t (Huber et al., 2008; Schraml et al., 2009; Brüstle et al., 2007). More recent studies demonstrated that BATF and IRF4, which are induced early upon TCR signaling, act as pioneer factors which bind to DNA and regulate chromatin accessibility, allowing for cooperative binding of pSTAT3 and ROR $\gamma$ t at Th17-specific loci. In addition, they facilitate recruitment of other enhancers and stabilizers of the Th17 transcriptional program, most importantly HIF1 $\alpha$  and the histone acetyltransferase p300 (Ciofani et al., 2012; Li et al., 2012; Vahedi et al., 2012).

Another factor that is involved in certain aspects of Th17 cell differentiation and regulation is c-Maf, which promotes the production of IL-21 and thereby facilitates the self-amplification of Th17 cells (Bauquet et al., 2009). However, transcriptional analysis showed that c-Maf expression supports the generation of nonpathogenic Th17 cells (Ghoreschi et al., 2010; Lee et al., 2012) by repressing several proinflammatory Th17 genes, such as *Il22*, and transactivating antiinflammatory genes such as *Il10* and *Ctla4* (Rutz et al., 2011; Ciofani et al., 2012). Thus c-Maf is an important modulator of Th17 pathogenicity and effector functions.

Recent studies examining transcriptional networks with genome-scale profiling techniques have revealed that besides the above-described factors, many others participate in Th17 differentiation and have helped to understand how and in which sequence different factors work together or inhibit each other (Ciofani et al., 2012; Yosef et al., 2013). In particular, network analysis has demonstrated that a positive transcriptional module promotes Th17 differentiation and, at the same time, suppresses the development of other T-cell subsets, while a negative transcriptional module has the opposite effect. These mutually antagonistic modules provide insight into the molecular mechanisms of how different T-cell subsets antagonize each other (Yosef et al., 2013).

## Environmental Cues and T Helper 17 Cell Regulation in the Intestine

It has long been noted that many autoimmune diseases display genetic risk loci that predispose for developing diseases, and the human leukocyte antigen locus has emerged as the most important site for single nucleotide polymorphisms (SNPs) conferring risk (Jones et al., 2006). In addition, genome-wide association studies have shown that genes and pathways in immune cell function, most notably in Th cell development, represent high-risk loci for developing autoimmune disease (International Multiple Sclerosis Genetics Consortium et al., 2011). However, these SNPs are relatively common, raising the question as to what additional driving forces lead to the clinical manifestations of disease. Moreover, a common aspect of autoimmune diseases is to have periods of clinical disease activity along with periods of intermittent disease remission. One such prominent example is the relapsing-remitting form of MS (Dendrou et al., 2015). While the factors that trigger relapse are mostly unknown, this represents a highly active area of research (Olsson et al., 2017).

A multitude of environmental factors have been implicated in the induction and progression of autoimmune diseases, including diet, infection, and toxins. For example, vitamin D has been shown to be important for relapse rate in MS patients and studies suggest that simple dietary supplementation of vitamin D may lower disease activity (Miclea et al., 2017). However, it is not known how vitamin D levels influence the development of particular Th subsets and whether this contributes to the observed beneficial effects.

The intestine is the main site for Th17 cell differentiation under homeostatic conditions and certain commensal bacteria play a major part in this process. In particular, SFB (segmented filamentous bacteria) have been shown to be critical inducers of intestinal Th17 cell differentiation and the TCRs of intestinal Th17 cells show specificity for SFB antigens (Huber et al., 2012; Ivanov et al., 2009; Yang et al., 2014). Under nonpathologic conditions, these gut-resident Th17 cells protect the organism from microbial invasion in the intestine, strengthen intestinal barrier functions and maintain tissue homeostasis. However, if not controlled or activated to attain a pathogenic phenotype, Th17 cells in the intestine may induce autoimmune tissue inflammation both directly in the intestine (Huber et al., 2012) as well as in distant organs. Indeed, recent studies demonstrated that Th17 differentiation triggered in the intestine by commensals can promote autoimmune tissue inflammation in the CNS during EAE and in the joints during arthritis (Berer et al., 2011; Wu et al., 2010). Moreover, the transfer of fecal material from MS patients is sufficient to increase susceptibility to central nervous system disease to animals (Berer et al., 2017). It is tempting to speculate that a particular commensal bacterial strain could be targeted to provide clinical benefit in treating autoimmunity. Indeed, a recent study suggested that proinflammatory Th17 cells can be redirected to the gut and tolerized (Esplugues et al., 2011). A similar approach could potentially be beneficial in the therapy for human autoimmune diseases.

Key cytokines of the Th17 lineage, in particular IL-17 and IL-22, signal to epithelial cells to control barrier function and dysregulation of these signals may promote the development of autoimmune tissue inflammation. This is mediated in part by serum amyloid A (Sano et al., 2015). Certain T helper cell lineages have been shown to possess significant plasticity meaning that they can start expressing signature cytokines of other lineages and that this plasticity may be part of a physiological program to switch off inflammation once the pathogen has been cleared. One prominent example is the conversion of Th17 cells into type 1 Tregs (Tr1) in the intestine during the resolution of inflammation (Gagliani et al., 2015). This plasticity could be potentially exploited for therapeutic purposes.

Indeed, depending on individual niches within the intestine, the localization and differentiation of particular Th lineages can be manipulated. For example, certain microbiotas influence the trafficking and lineage conversion of intestinal Tregs which, in turn, influences intestinal homeostasis and potentially influences autoimmunity (Sujino et al., 2016). Moreover, particular microbiota can influence the emergence of ROR $\gamma$ t<sup>+</sup> Tregs within the intestine, highlighting that transcription factors for one lineage can modulate the function of other lineages as well (Sefik et al., 2015). These ROR $\gamma$ t<sup>+</sup> Tregs play an important role in balancing protective and autoimmune inflammatory responses, especially type 2 immunity (Ohnmacht et al., 2015). The increased incidence of autoimmune disease in industrialized civilizations has correlated with marked changes in diet, including increased sodium intake. Correspondingly, it was suggested that dietary sodium intake may contribute to the emergence of pathogenic T-cell subsets, in particular Th17 cells (Wu et al., 2013; Kleinewietfeld et al., 2013). Recent data have supported the effect of sodium on the differentiation of Th17 cells but also emphasized that the clinical consequence of environmental cues such as sodium need to be investigated in greater detail to understand combinatorial action, as no patient is exposed to any sole environmental cue that may affect the progression of autoimmune disease (Hammer et al., 2017; Cortese et al., 2017). Environmental toxins have also been suspected to influence immune responses. For example, AHR promotes Th17 cell differentiation and is activated by binding

phenol-derived chemical compounds, including microbial metabolites and environmental toxins (Quintana et al., 2008; Rothhammer et al., 2016). Thus toxin-mediated AHR-activation influences Th17 cell differentiation, potentially contributing to autoimmune tissue inflammation (Veldhoen et al., 2008a). Finally, it has been recognized that there is seasonality to disease activity in patients with autoimmune disease, with the disease worsening during winter when the days are shorter. Recent work has highlighted that melatonin may influence the differentiation of Th17 cells and thus, confer a seasonal increase in disease-inducing pathogenic Th subsets (Farez et al., 2015). However, much more research and a deeper understanding are needed to define how environmental cues such as diet, infections, and toxins influence the development of pathogenic T cells that drive autoimmunity.

## Function

The Th17 signature cytokines IL-17A and IL-17F can form homo- or heterodimers and are partly redundant in their effector functions. They signal through a receptor complex composed of IL-17RA and IL-17RC, which is expressed on both hematopoietic and nonhematopoietic cells. IL-17 receptor signaling induces production of proinflammatory cytokines and chemokines, including IL-6, IL-1, TNF, CXCL1, CCL20, GCP-2, and IL-8, as well as antimicrobial peptides and matrix metalloproteinases. Thus Th17 cells promote tissue inflammation and neutrophil recruitment (Bettelli et al., 2008). Th17 cells are important for host defense against a variety of pathogens, most notably bacteria such as *Citrobacter*, *Klebsiella pneumoniae*, and *S. aureus*, as well as fungi such as *C. albicans* (Bettelli et al., 2008). In humans, the critical role of IL-17 and Th17 cells in host defense is evident in the susceptibility of patients with genetic defects in the *IL17RA*, *IL17F*, or *STAT3* genes to *C. albicans* and *S. aureus* infections (Cypowij et al., 2012).

Aside from host defense, Th17 cells have been primarily associated with autoimmune tissue inflammation. Thus, elevated levels of IL-17 were detected in several autoimmune diseases including MS (Matusevicius et al., 1999), RA (Aarvak et al., 1999), and psoriasis (Teunissen et al., 1998). In EAE, treatment with IL-17 neutralizing antibodies ameliorates disease (Hofstetter et al., 2005) and IL-17 deficient animals developed attenuated CIA and EAE (Nakae et al., 2003; Ishigame et al., 2009). Many clinical studies have been conducted to investigate the potential benefit of using humanized monoclonal antibodies to interfere with IL-12 and IL-23 signaling in various autoimmune diseases (Teng et al., 2015). Some of these antibodies, such as ustekinumab, target both IL-12 and IL-23 by binding to the common p40 subunit, therefore impacting both Th1 and Th17 cell responses, while other antibodies such as secukinumab specifically target IL-17A. These therapies are highly efficacious and approved for treatment in psoriasis, psoriatic arthritis, and ankylosing spondylitis (Papp et al., 2008; Leonardi et al., 2008; Langley et al., 2014; McInnes et al., 2013; Baeten et al., 2013; Poddubnyy et al., 2014). In MS, initial clinical trials showed that in vivo administration of secukinumab had a significant impact on lesion load as detected by MRI (Havrdova et al., 2016). However, the drug has not been further developed as a multitude of new therapies, including those that are orally available, have recently been approved for relapsing-remitting MS.

Other autoimmune diseases, including RA (Genovese et al., 2013) and Crohn's disease, have shown more mixed results. For example, secukinumab did not show benefit in Crohn's disease, whereas ustekinumab did (Hueber et al., 2012; Sandborn et al., 2012). However, these results may be complicated by the fact that the selected patients did not respond to the standard treatment for Crohn's disease, anti-TNF therapy and, therefore, may suffer from more treatment-refractory disease. Finally, ustekinumab did not show a benefit in relapsing-remitting MS (Segal et al., 2008); however, this does not mean that an IL-23p19-specific agent could not work in MS. Additional clinical trials are required to specifically address this issue. Considering that the underlying disease mechanisms may be quite different among separate autoimmune diseases, these results emphasize the need for further investigation of the underlying molecular pathways involved in disease pathogenesis.

## T HELPER 22 CELLS

As described above, the cytokine IL-22 can be produced by Th17 cells in an IL-23 dependent manner. However, the detection of IL-22 producing Th cells that do not co-express IL-17, IL-4, or IFN- $\gamma$  in human skin have lent support to the idea that Th22 cells may exist as an independent T-cell subset (Duhen et al., 2009; Eyerich et al., 2009; Trifari et al., 2009). In vitro, differentiation of Th22 cells is driven by IL-6 and TNF $\alpha$  for human cells, and by IL-21 for mouse cells via STAT3 (Yeste et al., 2014), and critically depends on the transcription factor AHR. Accordingly, exposure to AHR ligands, such as FICZ, increases IL-22 production. However, AHR is not a classic lineage-defining transcription factor, since it is also expressed in other subsets, especially in

Th17 cells, and does not inhibit the differentiation of other lineages. Moreover, although expression of ROR $\gamma$ t and other lineage transcription factors is low or absent in Th22 cells or clones isolated ex vivo, in vitro experiments suggest that ROR $\gamma$ t nevertheless promotes the initial differentiation of Th22 cells (Trifari et al., 2009; Yeste et al., 2014). Rather than an independent lineage, Th22 cells may, therefore, represent a specialized subtype that primarily derives from the Th17 lineage, but switches off many of the Th17-specific modules under the influence of different environmental cues and cytokines. Accordingly, fate-mapping studies have shown the heterogeneity and plasticity of Th22 cells in terms of cytokine and transcription factor expression (Ahlfors et al., 2014).

Regardless of their origin, it is clear that Th22 cells exist and participate in different immune reactions including autoimmune inflammatory processes. Thus, increased frequencies of Th22 cells have been described in psoriasis (Eyerich et al., 2009; Kagami et al., 2010), ankylosing spondylitis, RA (Zhang et al., 2012), Hashimoto's thyroiditis (Bai et al., 2014), and also in MS (Rolla et al., 2014). In psoriasis, Th22 cells expressing the skin-homing receptors CCR4 and CCR10 on their surface are clearly pathogenic and drive acanthosis and hyperkeratosis via excessive production of IL-22, which acts directly on keratinocytes (Zheng et al., 2007). The role of Th22 cells in MS is less well understood. Although IL-22-deficient mice develop EAE normally (Kreyberg et al., 2007), Th22 cells are increased in the CSF of MS patients just before relapse, suggesting that they may be involved in early pathogenic processes. Of note, Th22 cells in the CSF express the chemokine receptor CCR6, rather than CCR4 and CCR10, indicating that chemokine receptor expression in Th22 cells is dependent on the disease context (Rolla et al., 2014). In contrast to psoriasis, Th22 cells play a protective role in IBD, where IL-22 promotes barrier function and stem cell-mediated regeneration of the epithelium (Lindemans et al., 2015; Sugimoto et al., 2008; Zenewicz et al., 2008). Taken together, whether Th22 cells are pathogenic or protective is highly dependent on the disease context.

## REGULATORY CD4<sup>+</sup> T CELLS

While Th1 and Th17 CD4<sup>+</sup> T-cell subsets have been implicated in inducing autoimmune disease, CD4<sup>+</sup> Tregs represent a distinct Th cell subset that maintains self-tolerance and controls immune responses. The importance of T cells for controlling autoimmunity was first suggested by neonatal thymectomy experiments carried out by Nishizuka and Sakakura (1969), who found that thymectomy prior to day 7 of life led to the development of multiorgan autoimmune disease. Subsequent adoptive transfer studies found that transfer of purified populations of CD4<sup>+</sup> T cells (CD45RB<sup>hi</sup> or CD5<sup>lo</sup>) into lymphopenic rodents led to the development of T cell-mediated autoimmunity that could be mitigated by cotransfer of CD45RB<sup>lo</sup> or CD5<sup>hi</sup> CD4<sup>+</sup> T cells, suggesting the existence of a subset of CD4<sup>+</sup> T cells with regulatory properties (Powrie and Mason, 1990; Sakaguchi et al., 1985). Sakaguchi and colleagues (1995) further demonstrated that within the CD5<sup>hi</sup> CD45RB<sup>lo</sup> CD4<sup>+</sup> T cell population the CD25<sup>+</sup> subset was uniquely able to inhibit the development of organ-specific autoimmunity, whereas depletion of CD25<sup>+</sup> cells was sufficient to cause multiorgan autoimmune disease. Subsequently, it was demonstrated that CD4<sup>+</sup>CD25<sup>+</sup> T cells express Foxp3, the lineage-defining transcription factor for Tregs (Hori et al., 2003), and spontaneous mutations in Foxp3 lead to the development of severe, multiorgan autoimmunity in both mice (*scurfy*) and humans (immunodysregulation polyendocrinopathy enteropathy X-linked syndrome) (Bennett et al., 2001; Wildin et al., 2001; Khattri et al., 2003). Thus Foxp3-expressing CD4<sup>+</sup>CD25<sup>+</sup> Tregs are critical for maintaining peripheral self-tolerance in both mice and humans.

The number of genes directly regulated by Foxp3 is relatively small and does not encompass the majority of the genes that regulate Treg development, suggesting that other factors are equally critical to maintaining the Treg transcriptional program (Hill et al., 2007; Fu et al., 2012). In addition, naïve human Th cells can upregulate Foxp3 upon activation without acquiring regulatory function (Gavin et al., 2006). Fate-mapping experiments in mice have also demonstrated a population of "ex-Tregs" that once expressed Foxp3, but no longer do so and readily produce effector cytokines, including IFN- $\gamma$  and IL-17 (Zhou and Littman, 2009). Intriguingly, adoptive transfer of such "ex-Tregs" leads to rapid development of autoimmune disease, consistent with loss of regulatory and acquisition of effector function. Thus, while expression of Foxp3 is a defining characteristic of Tregs, Foxp3 expression alone is not sufficient for stable regulatory function. Several groups have recently shown that Tregs possess a unique epigenetic pattern of DNA methylation (Floess et al., 2007; Ohkura et al., 2012; Schmidl et al., 2009; Wei et al., 2009). Acquisition of this methylation pattern begins during thymic development and does not require Foxp3 expression, although it does help to maintain Foxp3 expression and regulatory function in vivo and in vitro (Ohkura et al., 2012). Therefore, stable Treg differentiation depends upon both Foxp3 expression and a unique pattern of DNA methylation.

Tregs can develop both in the thymus (tTregs, formerly natural, or nTregs) and in the periphery (pTregs, formerly induced, or iTregs). Both tTregs and pTregs express Foxp3 and CD25; however, tTregs preferentially express the cell surface receptor neuropilin-1 and the transcription factor Helios (Thornton et al., 2010; Weiss et al., 2012; Yadav et al., 2012). Both tTregs and pTregs suppress effector cell proliferation in vitro; however, they may play distinct roles in vivo. tTregs appear to primarily maintain peripheral tolerance to organ-specific antigens, while pTregs are thought to be important in maintaining tolerance to exogenous but innocuous antigens the immune system encounters at mucosal sites, or dampening antigen-specific immune responses.

The neonatal thymectomy studies of Nishizuka and Sakakura highlighted the importance of thymus-derived tTregs in preventing organ-specific autoimmunity and raised the question of what drives their development in the thymus. One factor appears to be some degree of self-reactivity. On a recombination activating gene (RAG)-deficient background, foreign antigen-specific TCR transgenic mice had no tTregs, whereas on a RAG-sufficient background, tTregs were present and showed evidence of endogenous TCR $\alpha$  chain rearrangement (Itoh et al., 1999). Moreover, ectopic thymic expression of cognate foreign antigen was sufficient to allow tTreg differentiation in RAG-deficient TCR transgenic mice, and the unique DNA methylation pattern seen in Tregs depended on TCR recognition of cognate peptide (Ohkura et al., 2012; Kawahata et al., 2002). In the absence of AIRE, which promotes ectopic thymic expression of tissue-restricted antigens, mice develop T cell-mediated multiorgan autoimmunity, associated with the expansion of certain effector CD4 T cell clones. Many of the TCRs expressed by tissue-infiltrating effector CD4 T cells in AIRE $^{-/-}$  mice are typically found in Tregs, suggesting that during thymic development recognition of autoantigens can promote Treg differentiation in addition to negative selection (Malchow et al., 2016). This appears to be in part due to a conserved noncoding element within the Foxp3 locus, CNS3, which promotes Foxp3 expression in developing thymocytes. In the absence of CNS3, the TCR repertoire of Tregs is altered, and mice lacking both CNS3 and AIRE develop severe early-onset autoimmune disease (Feng et al., 2015). These data, therefore, suggest a model in which recognition of self-peptide/MHC complexes triggers the upregulation of Foxp3 and promotes the development of tTregs.

While specificity for self-antigen appears to be a critical factor in tTreg development and differentiation in the thymus, pTreg differentiation is controlled by the molecular context in which T cells are activated. The cytokine TGF- $\beta$  has been shown to be important for the development of pTregs both in vivo and in vitro via activation of SMAD3, which, in turn, binds to the CNS1 regulatory element within the *Foxp3* gene and promotes pTreg differentiation in concert with other factors (Chen et al., 2003; Fantini et al., 2004; Kim and Leonard, 2007; Zheng et al., 2010). Interestingly, TGF- $\beta$  can also promote Th17 differentiation in conjunction with inflammatory cytokines such as IL-6 (Bettelli et al., 2006). Therefore, depending on the context in which the antigen is encountered, a T cell may either be driven to differentiate into a potentially proinflammatory Th17 cell or a tolerogenic pTreg.

Treg expression of CD25, which along with CD122 and the common  $\gamma$ -chain ( $\gamma_c$ ) makes up the high-affinity IL-2 receptor complex, highlights the importance of IL-2 in Treg biology. Because IL-2 was initially described as a growth factor for activated T cells, the finding that mice deficient in IL-2, CD25, or CD122 developed autoimmune and lymphoproliferative disorders was surprising (Kramer et al., 1995; Schorle et al., 1991; Suzuki et al., 1995). This apparent conundrum was resolved when mice deficient in IL-2 or its receptor components were found to have markedly reduced numbers of Foxp3 $+$  Tregs in the periphery (Almeida et al., 2002; Malek et al., 2002; Papiernik et al., 1998). Subsequent studies revealed a critical role for IL-2-mediated activation of STAT5 in supporting the peripheral survival and function of Tregs (Fontenot et al., 2005; Thornton et al., 2004; Chinen et al., 2016). Recent imaging-based analysis has revealed that discrete clusters of phospho-STAT5 $+$  Tregs are found in secondary lymphoid organs, and these Tregs demonstrate increased expression of molecules associated with suppressive function, such as CTLA-4 (Liu et al., 2015). Notably, STAT5 phosphorylation is dependent upon locally produced IL-2 from activated effector CD4 T cells, while Treg clustering is TCR dependent. Thus, low-level activation of autoreactive conventional CD4 T cells leads to the production of IL-2 that, in turn, directly promotes Treg function, suppressing potentially pathogenic effector responses.

There is increasing evidence that it may be possible to therapeutically manipulate IL-2/IL-2R signaling in vivo and promote Treg function in patients with immune-mediated disease. Administration of blocking antibodies to IL-2 or CD25 resulted in a marked decline in Treg numbers, whereas administration of IL-2 at low doses augmented Treg numbers (Grinberg-Bleyer et al., 2010; Setoguchi et al., 2005). Moreover, Tregs that express a constitutively active STAT5 transgene have increased suppressive function in vitro and decreased severity of EAE, consistent with enhanced Treg function in vivo (Chinen et al., 2016). Modulating IL-2 to enhance Treg function has recently been extended to early phase clinical trials of immune-mediated diseases. For instance, administration of low dose IL-2 led to increased Treg frequency and clinical improvement in graft versus host disease (GvHD), hepatitis C-associated vasculitis, and systemic lupus erythematosus (SLE)

(Koreth et al., 2011; Saadoun et al., 2011; He et al., 2016). Thus, IL-2 functions to support the peripheral homeostasis and function of Tregs and is amenable to therapeutic modulation in T cell–mediated inflammatory conditions.

The means by which Tregs control effector T-cell responses is an area of active inquiry. In vitro proliferation suppression assays have demonstrated that Tregs can control effector responses both by acting directly on the responding effector T cell as well as indirectly, by modifying APC function. Regardless of the mechanism of action, Tregs require cell–cell interaction in order to exert their suppressive function in vitro. Direct suppressive mechanisms in vitro include release of inhibitory cytokines, such as IL-10 and TGF- $\beta$ , restricting the bioavailability of IL-2, either by decreasing IL-2 transcription or by preferentially consuming IL-2, and direct granzyme-mediated cytolysis (Collison et al., 2007; Grossman et al., 2004; Pandiyan et al., 2007; Thornton and Shevach, 1998). In contrast, Tregs indirectly reduce effector T-cell proliferation by altering APC function, either by inhibiting APC maturation (such as via LAG-3/MHCII interactions or catabolizing ATP released on tissue damage via CD39) or by reducing expression of B7-1 or B7-2 (Borsig et al., 2007; Liang et al., 2008; Onishi et al., 2008). B7-1 and B7-2 downregulation is dependent upon Treg expression of CTLA-4, which binds B7-1 and B7-2 and physically removes them from the APC via transendocytosis (Qureshi et al., 2011; Wing et al., 2008). Thus, Tregs are able to utilize a variety of molecular mechanisms to both directly and indirectly regulate effector T-cell activation and expansion in vitro.

An intriguing finding is that while *Foxp3*-mutant *scurfy* mice uniformly develop a spontaneous autoimmune disease, the nature of the pathogenic effector response varies depending on the genetic background of the mice (Lin et al., 2005; Suscovich et al., 2012). Thus, modifier genes can exert significant influence on the ability of Tregs to control immune responses in vivo, suggesting that Tregs may utilize distinct molecular mechanisms to control distinct effector responses. The hypothesis that Treg control of different effector subsets requires additional factors has been bolstered by the finding that Tregs can be induced to express transcription factors associated with these subsets and expression of these transcription factors is important for proper in vivo regulation of the associated effector subset. For instance, Tregs upregulate T-bet in response to either IFN- $\gamma$  or IL-27, and T-bet, in turn, drives expression of CXCR3, facilitating Treg responsiveness to IFN- $\gamma$ -dependent chemokines, such as CXCL10 (Hall et al., 2012; Koch et al., 2009, 2012). Interestingly, while T-bet-deficient Tregs had normal in vitro suppressive activity (Bettelli et al., 2004), they failed to prevent lethal Th1-mediated autoimmune disease upon adoptive transfer into *scurfy* mice (Koch et al., 2009), suggesting that Treg-specific T-bet expression is crucial for proper regulation of Th1 responses in vivo. Similarly, expression of IRF4 or STAT3 appears to be critical for Tregs to properly regulate Th2 or Th17 responses in vivo, while ROR $\gamma$ t expression in colonic Tregs modulates the severity of intestinal inflammation (Chaudhry et al., 2009; Zheng et al., 2009; Sefik et al., 2015). These findings support the idea that Tregs possess both a core module of regulatory factors that are generally required for their suppressive function, including *Foxp3* and CTLA-4, as well as modules specific for control of distinct effector Th subsets (Wing and Sakaguchi, 2012).

In addition to suppressing effector T-cell responses, Tregs also play a role in tissue repair after injury. After sterile injury, a transcriptionally distinct population of muscle-resident Tregs proliferates and promotes muscle regeneration (Burzyn et al., 2013). This is mediated in part via expression of the EGFR-family member amphiregulin (Areg) on Tregs, which can be induced by alarmins, such as IL-33 (Kuswanto et al., 2016). Areg is also induced by alarmins on Tregs residing in other tissues, including the lung and the gastrointestinal tract (Arpaia et al., 2015). Importantly, while Treg-specific deletion of Areg did not alter the effector T-cell response to influenza, it did result in increased lung injury and hypoxemia after influenza infection, suggesting that the ability of Tregs to promote tissue repair may be distinct from their ability to suppress effector T-cell responses. Tregs have also been shown to promote tissue repair and regeneration via other mechanisms. For instance, after focal injury, CNS-resident Tregs express CCN3, which promotes oligodendrocyte differentiation and remyelination (Dombrowski et al., 2017), while acute lung injury induces Tregs to express keratinocyte growth factor, which promotes epithelial cell proliferation (Dial et al., 2017). Similarly, a population of Tregs in the skin localize to the hair follicle, where they promote the survival and function of hair follicle stem cells via expression of Jagged1, a Notch ligand (Ali et al., 2017). Thus, tissue resident Tregs not only promote immune homeostasis but also directly promote tissue repair.

The multiorgan autoimmunity seen in both mice and humans with spontaneous mutations in *Foxp3* shows that Tregs are vital in restraining potentially autoreactive Th cells and suggests that defects in Treg function may underlie the development of other autoimmune diseases. Supporting this, SNPs in multiple genes important for Treg function, including *Ctla4*, *Il2*, *Il2ra*, and *Il10*, have been found to be risk alleles in genome-wide association screens for a number of autoimmune diseases, such as IDDM, RA, IBD, and MS (Howson et al., 2012; Vandenbroucke, 2012). Moreover, in some autoimmune diseases there is evidence for the altered frequency of

Tregs, such as the finding that in IBD Treg frequency in the peripheral blood inversely correlates with disease activity (Saruta et al., 2007; Takahashi et al., 2006). Similarly, careful immunophenotyping of circulating Tregs allowed resting and activated Treg populations to be distinguished, and the population dynamics of these cells were altered in patients with active SLE (Miyara et al., 2009). Finally, impaired Treg-mediated suppression of effector T-cell proliferation has been demonstrated in some patients with MS, SLE, and IDDM (Alvarado-Sanchez et al., 2006; Ferraro et al., 2011; Kumar et al., 2006; Viglietta et al., 2004). Thus, alterations in Treg frequency and function are observed in human autoimmune disease, and pathways regulating Treg survival and function may represent promising therapeutic targets for the treatment of human autoimmune diseases. Indeed, clinical trials have been performed examining the efficacy of passive transfer of *in vitro* expanded Tregs into patients with type 1 diabetes (Bluestone et al., 2015), while similar trials are planned in other autoimmune diseases.

## TYPE 1 REGULATORY T CELLS

Tr1 cells are a recently identified Th subset that possesses a regulatory function in the absence of Foxp3 expression, in large part via production of IL-10. Tr1 cell differentiation is dependent upon IL-27, a heterodimeric cytokine composed of Ebi3 and p28, and in addition, Tr1 cell differentiation can be amplified by TGF- $\beta$  (Hall et al., 2012; Pot et al., 2011a). IL-27 induces activation of STAT1 and STAT3, which have been shown to be essential for Tr1 cell differentiation (Hall et al., 2012). Exogenous IL-27 also promotes transcription of c-Maf, IL-21, and inducible costimulator (ICOS), and, subsequently, IL-21 acts as an autocrine growth factor (Hall et al., 2012; Pot et al., 2009, 2011a,b) indicating that IL-27 and IL-21 cooperate in the generation of Tr1 cells. Other transcription factors implicated in Tr1 cell differentiation include AHR, HIF1 $\alpha$ , IRF1, and BATF, but no single lineage-defining transcription factor has yet been identified (Karwacz et al., 2017; Mascanfroni et al., 2015). While to date detailed functional and phenotypic characterization of Tr1 cells has been hampered by lack of specific markers that can reliably differentiate Tr1s from other IL-10 producing regulatory and effector T-cell subsets, recent work suggests that coexpression of LAG-3 and CD49b may serve to identify such cells (Gagliani et al., 2013). Finally, it is unclear whether Tr1 cells are only generated in the periphery or whether Tr1 cells are also generated through thymic selection, analogous to tTregs (Fujio et al., 2010).

Functionally, IL-27 treatment ameliorated EAE by increasing the frequency of IL-10 producing T cells and thereby suppressing IL-17-producing Th17 cells, suggesting it may be useful therapeutically (Kastelein et al., 2007). Furthermore, IL-27R $\alpha$  deficient mice were shown to develop exacerbated EAE (Batten et al., 2006). Intriguingly, recent clinical trials suggested that IFN- $\beta$ , which is widely used as a first-line treatment for MS, increased serum IL-27 levels (Sweeney et al., 2011). Some MS patients have been reported to have decreased IL-10 production (Ozenci et al., 1999); thus, the clinical efficacy of IFN- $\beta$  in MS has been attributed to the induction of IL-27, consequently promoting an increased frequency of IL-10 producing Tr1 which can then potentially control autopathogenic T effector cells (Guo et al., 2008; Ramgolam et al., 2009; Sweeney et al., 2011). Another area where regulatory cells are of high therapeutic value is organ transplants, such as pancreatic islet transplants in IDDM, where inadequate immunosuppression gives rise to graft rejection. A strong correlation has been shown between transplant acceptance and frequency of circulating tTregs (Berney et al., 2009), as well as IL-10 production by peripheral blood mononuclear cells (Huurman et al., 2009), suggesting that tTregs play an important role in maintaining long-term tolerance. However, generation, expansion, and stability of antigen-specific Tregs remain a major challenge (Sagoo et al., 2008). Thus, an alternative to tTreg therapy is the adoptive transfer of *in vitro* generated IL-10 producing Tr1 cells that can sustain long-term survival *in vivo*. Indeed, the transfer of antigen-specific Tr1 cells prevented islet graft rejection in mouse models of islet transplant (Gagliani et al., 2010). In addition, preliminary data indicate that adoptive transfer of host-specific Tr1 cells may prevent GvHD in leukemia patients who underwent stem cell transplant (Allan et al., 2008; Bacchetta et al., 2010; Hippen et al., 2011; Roncarolo et al., 2011) supporting the potential value of Tr1 cell therapy in generating tolerance.

## FOLLICULAR T HELPER CELLS

T cell-dependent antibody responses occur in germinal centers (GCs) of lymphoid follicles and require interaction between antigen-specific B and Th cells (MacLennan et al., 1997; Garside et al., 1998). Recent evidence has demonstrated that this interaction is mediated by a distinct Th subset, termed follicular Th (TFH) cells. These TFH cells are activated by antigen in the T cell zone of lymphoid tissues and then migrate specifically to the

outer edge of the B cell follicles in order to encounter antigen-specific B cells that have also migrated to this location (Vinuesa and Cook, 2011). The homing of the TFH cells to the GC is dependent on a two-step chemotactic process that begins with the downregulation of CCR7, the receptor for the chemokines CCL19 and CCL21, which are produced in the T cell zone of the lymphoid tissue (Ansel et al., 2000; Luther et al., 2000; Gunn et al., 1998), followed by the induction of CXCR5, which allows TFH cells to migrate into the GCs along a gradient of CXCL13 (Haynes et al., 2007; Breitfeld et al., 2000). The downregulation of CCR7 and upregulation of CXCR5 is driven by the B cell lymphoma 6 protein (Bcl6), the master transcription factor regulating TFH cell differentiation. Bcl6 is a transcriptional repressor and while its main function is to repress other Th cell fates, it promotes TFH differentiation by regulating multiple transcriptional pathways (Hatzis et al., 2015). Recently, a second transcription factor, Ascl2, was identified that governs the upregulation of CXCR5 independently from Bcl6 and that may act earlier in the induction of TFH cell fate and the migration to GCs (Liu et al., 2014). The stable induction of Bcl6 is also critically dependent on the physical interaction of T and B cells (Liu et al., 2012, 2013). In addition to CXCR5, TFH cells express the costimulatory molecule ICOS and interaction of ICOS with ICOS ligand on B cells promotes the differentiation of T cells to TFH cells (Ramiscal and Vinuesa, 2013; Bauquet et al., 2009). TFH cell development also requires expression of the signaling molecule SAP and SLAM, an adaptor protein, as these are crucial for the induction of Bcl6 (Ramiscal and Vinuesa, 2013). The deletion of Bcl6 prevents the generation of TFH cells and inhibits GC reactions, including affinity maturation, isotype switching, B cell proliferation, and generation of memory B cells and plasma cells (Nurieva et al., 2009a). The differentiation of TFH cells is mediated by IL-21 and IL-6, and TFH cells require STAT3 (Nurieva et al., 2008) and c-Maf for their generation (Bauquet et al., 2009). With the activation of Bcl6, TFH cells begin secreting their signature cytokine IL-21, which has been shown to be essential for B cell survival and promoting GC reactions (Nurieva et al., 2008, 2009b). While other Th subsets also produce IL-21, the amount of IL-21 produced by TFH cells is far greater than that produced by Th1 and Th2 cells (Chtanova et al., 2004). In addition, IL-4 and CD40L are other key signals that TFH cells provide in help for developing B cells (Crotty, 2014). Lef1 and Tcf1 have been shown to orchestrate transcriptional profiles important for TFH development upstream of Bcl6 (Choi et al., 2015). Recently, an unexpected role of the neurotransmitter dopamine has been identified in the development of GCs. Indeed, TFH cells can produce high amounts of this neurotransmitter and it is important for a proper GC reaction (Papa et al., 2017). Apart from the factors that promote TFH cell fate, it has been shown that Blimp-1 and STAT5 have important antagonistic roles (Johnston et al., 2009, 2012; Nurieva et al., 2012). Furthermore, IL-2 has been identified as a cytokine that inhibits TFH cell induction (Ballesteros-Tato et al., 2012). Importantly, proper positioning within the GC is crucial for developing TFH cells to be shielded from IL-2 exposure and the G protein-coupled receptor Ebi2 mediates this spatial organization (Li et al., 2016). Other surface molecules such as PD-1 and SLAMF6 are crucially involved in regulating the extent of the help that TFH cells provide to B cells. This fine-tuning is achieved by limiting the proliferation of TFH cells within the GC. It is now appreciated that uncontrolled help can contribute to abnormal responses and influence disease (Cubas et al., 2013).

Immune responses that drive differentiation of other Th subsets also give rise to distinct subtypes of TFH cells (King et al., 2008), although the lineage relationship of these specialized TFH cells to effector CD4 T-cell subsets is not yet clear. In vitro generated Th1 and Th2 cells have been shown to develop into TFH cells upon adoptive transfer, suggesting that effector CD4 T cells can acquire the TFH program, including upregulating Bcl6 and CXCR5. Similarly, recent evidence suggests that Th17 cells can give rise to TFH cells in the intestinal mucosa due to significant developmental plasticity and that these cells play a crucial part in IgA production of GC B cells (Hiota et al., 2013).

During the early stages of TFH cell development, some cells may have upregulated CXCR5 but not yet turned on Bcl6 (Crotty, 2011). With an entry into the follicle and upon interaction with B cells, Bcl6 expression increases, and TFH lineage commitment stabilizes, commensurate with downregulation of the Th1, Th2, and Th17 associated genes (Crotty, 2011). However, adoptive transfer of TFH cells from an IL-21-reporter mouse indicated that TFH cells can also give rise to effector CD4 T cells (Luthje et al., 2012), and in a mouse model of asthma, effector Th2 cell differentiation appears to require the initial induction of type 2 TFH cells (Ballesteros-Tato et al., 2016), suggesting that there is considerable plasticity between TFH cells and effector CD4 T cells. The plasticity of TFH cells with other effector CD4 T-cell subsets is likely crucial to appropriately coordinate humoral and cellular immune responses (Crotty, 2011). Collectively, TFH cells have emerged as a distinct Th subset that provides critical help to B cells and regulates GC reactions, and, as a result, ultimately controls humoral immune responses.

In addition to TFH cells, there is also a population of  $\text{Foxp3}^+$  CD4 T cells within the B cell follicle, and these have been termed T follicular regulatory (TFR) cells (Sage and Sharpe, 2016). Similar to TFH, TFRs also express CXCR5, PD-1, and Bcl6 (Chung et al., 2011; Linterman et al., 2011; Sage et al., 2013) but restrain, rather than

promote, GC reactions. TFR differentiation requires both CD28 and ICOS expression, while the expression of PD-1 and CTLA-4 appear to inhibit TFR differentiation, even though CTLA-4 expression also represents an important pathway by which TFRs suppress B cell responses (Sage et al., 2013, 2014; Wing et al., 2014). TFRs are able to suppress B cell responses both indirectly, for example by modulating TFH cell function, as well as directly, by regulating B cell metabolism, and TFR-mediated inhibition can be overcome by IL-21 (Sage et al., 2016). Importantly, the TCR repertoire of TFH cells becomes oligoclonal after immunization, whereas the TCR repertoire of TFRs shows more similarity to the Treg repertoire, suggesting that TFR function is either independent of the inciting antigen, or that these cells may preferentially inhibit autoreactive B cell responses (Maceiras et al., 2017). This is consistent with recent observations that ablation of TFRs did not impact antibody responses to influenza infection, but did allow the production of antinuclear antibodies following infection (Botta et al., 2017). Thus, TFRs are a population of specialized Tregs that modulate TFH and B cell function and may play a particularly important role in inhibiting autoreactive antibody responses.

A number of autoimmune diseases are characterized by the presence of self-reactive autoantibodies, and it has been suggested that GCs may drive pathogenic generation of autoantibodies. In animal models for SLE, for example, spontaneous generation of GCs correlated with an increased serum concentration of autoantibodies (Luzina et al., 2001; Hsu et al., 2008). Cognate help from TFH cells has been demonstrated to promote the survival, expansion, and differentiation of self-reactive B cells, which ultimately resulted in autoantibody production and promoted tissue injury (Vinuesa et al., 2005; Zhang et al., 2013). In addition, aberrant TFH cell function has been shown to promote the development of disease in animal models of SLE and RA and is characterized by GC expansion, increased IL-21, and TFH cell expansion in extrafollicular sites (Zhang et al., 2013). In human autoimmune diseases, expansion of circulating TFH cells in patients with juvenile dermatomyositis, RA, SLE, and Sjögren's syndrome has been observed to strongly correlate with increased plasmablasts and serum concentrations of anti-dsDNA and antinuclear antibodies (Zhang et al., 2013; Morita et al., 2011; Ma et al., 2012). These observations are highly suggestive of the role that aberrant TFH cells may play in the pathogenesis of autoimmunity, particularly in diseases characterized by autoreactive antibodies.

## T HELPER 2 CELLS

Initially described for their distinct pattern of cytokine expression and their ability to promote IgE class-switching (Mosmann et al., 1986), Th2 cells are critical for amplifying and sustaining inflammation marked by eosinophil recruitment and mast cell activation. Th2 responses may be either protective, in the case of host defense against helminths and other extracellular parasites, or detrimental and lead to the development of asthma and environmental allergies (Paul, 2010; Pulendran and Artis, 2012). Th2 differentiation is induced by IL-4, which, upon binding a heterodimeric receptor consisting of IL-4R $\alpha$  and the  $\gamma_c$ -chain, results in the phosphorylation and activation of STAT6 and, in turn, induces expression of GATA-3. GATA-3 then transactivates many Th2-specific cytokines, most notably IL-4, IL-5, and IL-13, all of which share a common genetic locus (Zheng and Flavell, 1997). Th2 development results in significant chromatin remodeling at the *Il4* gene locus, such that IL-4 production by established Th2 cells can be seen even after the conditional deletion of GATA-3 (Baguet and Bix, 2004; Zhu et al., 2004). The same molecular pathways that promote Th2 differentiation simultaneously counterregulate the development of other effector Th subsets, particularly Th1 cells. For instance, GATA-3 can downregulate the expression of Th1-promoting genes such as STAT4 and IL-12R $\beta$ 2 (Zheng and Flavell, 1997). In addition, the transcription factor c-Maf both transactivates the *Il4* locus and induces downregulation of IFN- $\gamma$  (Ho et al., 1996, 1998). Th2 differentiation is thus a powerful counterregulator of Th1 differentiation.

The role of Th2 cells in autoimmune disease is complex. They have been implicated in facilitating isotype switching in SLE (Singh et al., 2003) and high levels of IL-4 and IL-13 are commonly seen in patients with systemic sclerosis, although the role of these cytokines in the pathogenesis of this disease is still unclear (O'Reilly et al., 2012). In contrast, many inflammatory autoimmune diseases show marked bias toward Th1 and Th17 responses and prior infection with a Th2 skewing pathogen can ameliorate EAE in mice (Sewell et al., 2003). Moreover, many inflammatory autoimmune diseases have lower incidences in areas where parasitic infections are more common, and longitudinal studies of MS patients with asymptomatic intestinal parasitemia suggest that these patients have milder disease than uninfected controls (Correale and Farez, 2007). These observations have been extended to clinical trials assessing the efficacy and safety of administering ova from *Trichuris suis*, a pig nematode that is unable to productively infect humans, to patients with ulcerative colitis (UC). Early studies showed clinically significant improvement in over 40% of the patients with severe UC, compared to a placebo

response rate of 17% (Summers et al., 2005); however, subsequent larger studies have not shown clear benefit (Garg et al., 2014). The efficacy of *T. suis* ova in MS has also been studied, although clear data indicating clinical efficacy are presently lacking (Fleming et al., 2017; Voldsgaard et al., 2015). However, glatiramer acetate, an immunomodulatory agent approved for use in MS, appears to be efficacious in part due to skewing the immune response toward a Th2-biased response (Arnon and Aharoni, 2004). Thus, Th2 counterregulation of other Th effector subsets can be utilized clinically in inflammatory autoimmune disorders.

## T HELPER 9 CELLS

Th9 cells, a recently identified Th subset generated by activating naïve Th cells in the presence of TGF- $\beta$  and IL-4, produce both IL-9 and IL-10 (Dardalhon et al., 2008; Veldhoen et al., 2008b). The requirement for IL-4 in Th9 differentiation raises the question of whether Th9 cells represent a distinct lineage or are a subset of specialized Th2 cells, particularly given that both Th2 and Th9 cells can readily induce allergic airway inflammation and IL-9 is implicated in asthma (Chang et al., 2010; Staudt et al., 2010). Similar to Th2 cells, Th9 cells also require the transcription factors IRF4 and STAT6; however, IL-9 production is uniquely dependent upon the TGF- $\beta$ -induced transcription factor PU.1, which, although expressed by other Th subsets, is not required for Th2 differentiation (Chang et al., 2010; Goswami and Kaplan, 2012; Staudt et al., 2010). The transcription factor Foxo1 is highly expressed by Th9 cells and can directly promote expression of IL-9 in multiple CD4 T-cell subsets (Bi et al., 2017; Malik et al., 2017). Thus, multiple transcription factors contribute to the development of IL-9-producing CD4 T cells.

In vivo, Th9 cells have been implicated in a variety of settings. While some of these also involve Th2 responses, such as anti-helminth responses (Licona-Limon et al., 2013) or allergic lung inflammation (Wilhelm et al., 2011), Th9 cells were also shown to play roles in antitumor responses (Purwar et al., 2012; Vegrán et al., 2014), as well as in mouse models of autoimmunity, including EAE and colitis. While myelin-specific in vitro differentiated Th2 cells failed to induce EAE upon adoptive transfer, transfer of Th9 cells resulted in robust disease, suggesting that Th9 cells have distinct functional properties from Th2 cells (Jäger et al., 2009). PU.1 and IL-9 are both highly expressed in T cells from patients with UC, and mice lacking either PU.1 or IL-9 have ameliorated oxalozone-induced colitis, suggesting that Th9 cells may contribute to disease pathogenesis (Gerlach et al., 2014; Nalleweg et al., 2015). Notably, Th9 cells do show considerable plasticity after adoptive transfer (Dardalhon et al., 2008; Jäger et al., 2009), and IL-9 can be produced by other CD4 T-cell subsets. It is therefore not entirely clear whether Th9 cells are a truly terminally differentiated Th subset, or represent a distinct but transient functional state.

## CONCLUDING REMARKS

The functional diversity and plasticity of CD4 $^{+}$  T cells is crucial for successful host defense against diverse environmental pathogens, but can also go dangerously awry in the setting of autoimmune disease. Recent years have seen the identification of novel Th subsets as well as a remarkable growth in our understanding of the molecular mechanisms that underlie Th cell differentiation. In particular, the identification of Th17 cells and Tregs as distinct lineages has greatly enhanced our knowledge of the pathobiology of a variety of autoimmune disorders and allowed the identification and development of novel therapeutic approaches. Recent work investigating the complex transcriptional networks involved in Th17 differentiation clearly illustrates the dynamic tension between transcriptional modules that enhance Th17 cell differentiation and inhibit the development of other T-cell subsets, thus providing the molecular basis for counterregulation between Th subsets (Ciofani et al., 2012; Yosef et al., 2013). Although impairment of counterregulatory mechanisms may lead to autoimmune tissue inflammation, these same pathways are amenable to modulation and offer opportunities for the development of novel immunomodulatory therapies for autoimmune diseases.

## THE CURIOUS CASE OF INVARIANT NATURAL KILLER T CELLS

### The Many Names of Natural Killer T Cells

Natural killer T (NKT) cells are a unique subset of T lymphocytes found in mice, humans, and other mammals that phenotypically and functionally resemble NK cells as well as T cells, and thereby exhibiting features of the innate as well as the adaptive immune system (Bendelac et al., 2007; Brennan et al., 2013; Cerundolo et al., 2009; Godfrey and Kronenberg, 2004; Godfrey et al., 2010; Kinjo and Kronenberg, 2005; Kronenberg, 2005; Kronenberg and Gapin, 2002; Salio et al., 2014; Tupin et al., 2007; Van Kaer et al., 2015; Yoshiga et al., 2011).

They were originally defined by coexpression of a T-cell antigen receptor (TCR) and NK cell receptors, especially NK1.1 (NKR-P1C) in certain mouse strains (Watanabe et al., 1995) and CD56 or CD161 (NKR-P1A) in

human (Doherty et al., 1999; Exley et al., 1998; Lanier et al., 1994). This classification, however, is an oversimplification, as conventional T cells can express NK receptors, especially after activation (Assarsson et al., 2000; Hammond et al., 1999; McMahon et al., 2002; Slifka et al., 2000) and the expression of NK markers by NKT cells varies with their maturity, activation state, and in mice, with the genetic background (Bendelac et al., 2007; Kronenberg, 2005). Although the term "NKT cell" is still sometimes used in this broad sense, nowadays it usually refers to T cells that express an  $\alpha\beta$  TCR that is reactive to antigens presented by CD1d, a nonpolymorphic major histocompatibility complex (MHC) class I-like antigen-presenting molecule. CD1d reactive  $\alpha\beta$  T cells are often divided into Type I and II NKT cells, based on the TCR they express (for reviews see: Bendelac et al., 2007; Brennan et al., 2013; Godfrey and Kronenberg, 2004; Godfrey et al., 2010; Kinjo and Kronenberg, 2005; Kronenberg, 2005; Salio et al., 2014; Tupin et al., 2007; Van Kaer et al., 2015).

Type I NKT cells are the largest and best-studied fraction of NKT cells and they carry a canonical V $\alpha$ 14 to J $\alpha$ 18 TCR rearrangement (V $\alpha$ 14*i*, *Trav11-Traj18*) in mice and an orthologous V $\alpha$ 24-J $\alpha$ 18 TCR chain (V $\alpha$ 24*i*, *TRAV10-TRAJ18*) in humans. This invariant TCR (*i*TCR)  $\alpha$  chain pairs predominantly with V $\beta$ 8, V $\beta$ 7, or V $\beta$ 2 in mice, and almost exclusively with V $\beta$ 11 in human, although these  $\beta$  chains have highly diverse rearrangements to J $\beta$  segments (Matsuda et al., 2001; Ronet et al., 2001). Considering the  $\beta$  chain variability, and the near complete absence of variability in the  $\alpha$  chain, in reality these cells have a semi-*i*TCR. However, they are typically referred to as invariant NKT (*i*NKT) cells, a designation we will use herein. The specificity of *i*NKT cells is remarkably conserved over at least 50 million years of evolution, since the divergence of hominids and rodents. In fact, there is a surprising degree of interspecies cross-reactivity, with mouse *i*NKT cells recognizing human CD1d and vice versa (Brossay and Kronenberg, 1999; Brossay et al., 1998; Kronenberg, 2005). This conservation suggests an important function for these cells in the mammalian immune system.

In contrast to *i*NKT cells, type II NKT cells, also termed variant NKT (*v*NKT) cells, encompass all other CD1d reactive T lymphocytes that utilize a more variable TCR. However, there is a degree of oligoclonality in these cells, with enrichment for some TCRs such as V $\alpha$ 3.2 and V $\alpha$ 8 (Park et al., 2001). The specificity of these cells is largely unknown, although some recognize sulfatide, a self-glycolipid antigen (Blomqvist et al., 2009; Jahng et al., 2004), and some phospholipids (Tatituri et al., 2013).

Sometimes, especially in older literature, a third group (type III) of NKT cells is listed. This group is more heterogeneous, as it subsumes all non-CD1d reactive T lymphocytes that express NK receptors (Kronenberg and Gapin, 2002; Taniguchi et al., 2003; Wingender et al., 2006). Furthermore, it should be noted that several other nonconventional T-cell subsets have been defined based on their TCR  $\alpha$  chain repertoire. Mucosal-associated invariant T (MAIT) cells express a fixed V $\alpha$ 19-J $\alpha$ 33 (*Trav1 Traj33*) TCR in mice, and a homologous V $\alpha$ 7.2-J $\alpha$ 33 (*TRAV1–2 TRAJ33*) in humans (Le Bourhis et al., 2010; Shimamura and Huang, 2002; Treiner et al., 2003). They are reactive to MR1, a highly conserved MHC class I homolog (Le Bourhis et al., 2011; Treiner et al., 2003). A third subset of cells utilizing a semi-*i*TCR is "Germline-Encoded, Mycolyl lipid-reactive" (GEM) T cells that express V $\alpha$ 7.2-J $\alpha$ 9 (*TRAV1–2 TRAJ9*) and are restricted by CD1b, which is found in humans but not in mice (Van Rhijn et al., 2013). Finally, V $\alpha$ 10 expressing NKT cells have been described in mice (Uldrich et al., 2011). These cells are also CD1d reactive and have a specificity similar to *i*NKT cells, although the complementarity determining regions (CDR3) of their  $\alpha$  chains are not invariant (Uldrich et al., 2011).

The focus of this review is exclusively on *i*NKT cells in rodents, nonhuman-primates, and humans and their roles in autoimmune disease pathogenesis and prevention.

## The Many Faces of Invariant Natural Killer T Cells

### **Phenotype**

Even as they differentiate in the thymus (for reviews see Constantinides and Bendelac, 2013; Engel and Kronenberg, 2014; Hu et al., 2011), *i*NKT cells begin to express a pattern of surface markers (CD69 $^+$ , CD44 $^{\text{high}}$ , CD11a $^{\text{high}}$ , CD62L $^{\text{low}}$ , CD122 $^+$ ) typically associated with activated or memory T cells (Bendelac et al., 1997; Godfrey et al., 2000; Kronenberg, 2005; Kronenberg and Gapin, 2002; Sprent and Surh, 2002). This effector/memory phenotype is also displayed by *i*NKT cells that are derived from umbilical cord blood (D'Andrea et al., 2000; van Der Vliet et al., 2000) or from germ-free animals (Park et al., 2000; Wingender et al., 2012b), and they maintain this pattern as mature cells.

In addition, these cells constitutively express for example detectable mRNA for IL-4 and IFN $\gamma$  (Matsuda et al., 2003; Stetson et al., 2003), although these transcripts increase dramatically following activation. The steady-state

transcripts have potential biologic effects. For example, the IL-4 produced by thymic *i*NKT cells contributes to the differentiation of a population of mature thymic CD8<sup>+</sup> T cells that is characterized by an activated or memory phenotype and by the expression of the transcription factor EOMES (Lee et al., 2013). Taken together, these data suggest that *i*NKT cells undergo a strong antigenic stimulation during their differentiation, consistent with the hypothesis that true TCR agonists mediate their positive selection (Kronenberg, 2005). However, two reports indicated that peripheral TCR-CD1d interactions aid the full maturation and reactivity of *i*NKT cells (McNab et al., 2005; Wingender et al., 2012b).

### **Distribution**

Vα14*i* NKT cells have the highest representation within the total T-cell population in the liver and the bone marrow (>10%), followed by significant numbers in thymus, peripheral blood, and spleen (1%–3%), whereas they are relatively rare in all other organs (<0.5%), including sites where conventional T lymphocytes are numerous, such as the lymph nodes and intestinal tissue (Bendelac et al., 2007; Kronenberg, 2005). Interestingly, in humans the frequency of *i*NKT cells is generally much lower, although a high degree of interindividual variability in peripheral blood mononuclear cell (PBMC) has been reported (Gumperz et al., 2002; Kita et al., 2002; Prussin and Foster, 1997; van der Vliet et al., 2001). Although the reason for this variability is unknown, nonetheless, the frequency of *i*NKT cells in the PBMC of an individual appears to be stable over time (Lee et al., 2002a; Wither et al., 2008). *i*NKT cells are also relatively infrequent, compared to mice, in human intrahepatic lymphocytes (Kenna et al., 2003; Kita et al., 2002), but evidence indicates that they are more abundant in adipose tissue (Lynch et al., 2009) and also to some extent in peritoneal fluid (Wingender et al., 2012a).

## The Many Effector Functions of Invariant Natural Killer T Cells

### **Activation**

*i*NKT cells recognize glycolipid antigens presented by CD1d (Bendelac, 1995a,b; Kawano et al., 1997; Zeng et al., 1997), and one of the best-studied antigens is the glycolipid α-galactosylceramide (αGalCer). αGalCer is a synthetic glycosphingolipid, a category of glycolipids that contains ceramide as the lipid portion. Glycosphingolipids are natural compounds found in many organisms, including mammals. αGalCer was originally purified from a marine sponge and was optimized by medicinal chemistry to yield an exceptionally strong agonist (Morita et al., 1995). αGalCer contains an unusual α-anomeric linkage of the sugar to the ceramide lipid, unlike mammalian glycosphingolipids (Morita et al., 1995), and this α-linkage is crucial for its great stimulatory capacity (Bendelac et al., 1997; Kawano et al., 1997). Numerous synthetic derivatives of αGalCer have been studied (Birkholz et al., 2015b; East et al., 2014), and natural antigens that can stimulate the majority of *i*NKT cells have been characterized as well from several bacteria, including glycosphingolipids from *Sphingomonas* spp. (Kinjo et al., 2005; Mattner et al., 2005), diacylglycerols from *Borrelia burgdorferi*, the causative agent of Lyme disease (Kinjo et al., 2006), diacylglycerols from *Streptococcus pneumoniae* and group B *Streptococcus* (Kinjo et al., 2011), cholesteryl α-glucosides from *Helicobacter pylori* (Chang et al., 2011; Ito et al., 2013), as well as asperamide B from the fungi *Aspergillus fumigatus* (Albacker et al., 2013; Godfrey et al., 2013). Antigens are found in pathogens such as *S. pneumoniae* and *B. burgdorferi*, environmental bacteria such as *Sphingomonas* sp., and in bacteria that are commensal organisms in the intestine such as *Bacteroides fragilis* (An et al., 2014; Wieland Brown et al., 2013). The biochemistry of lipid antigen binding to CD1d and recognition of the antigen CD1d complex by the TCR is very well understood as a result of biophysical and X-ray crystallographic studies. This topic has been reviewed elsewhere (Rossjohn et al., 2012; Zajonc and Girardi, 2015).

Activation of *i*NKT cells by TCR-mediated recognition of antigen bound to CD1d has been referred to as direct or antigen-dependent activation (Kinjo and Kronenberg, 2005; Parekh et al., 2005). It is known, however, that memory T cells can be activated by cytokines alone in a TCR-independent manner (Berg and Forman, 2006). Considering their constitutively activated phenotype, it is, therefore, not surprising that a similar cytokine-dependent activation was reported for *i*NKT cells as well (Nagarajan and Kronenberg, 2007; Tyznik et al., 2008). This so-called indirect or antigen-independent activation (Kinjo and Kronenberg, 2005; Parekh et al., 2005) can be induced by several proinflammatory cytokines, such as IFNα, IFNβ, IL-12, and IL-18, alone (Biron and Brossay, 2001; Leite-de-Moraes et al., 1999) or, more effectively, in combination (Dao et al., 1998; Holzapfel et al., 2014; Leite-de-Moraes et al., 1999, 2001; Ogasawara et al., 1998). Dendritic cells (DCs) and macrophages produce these

cytokines following engagement of Toll-like receptors or other stimuli for the innate immune system, like early after bacterial or viral infections.

One has to keep in mind, however, that the direct, TCR-driven and the indirect, cytokine-driven pathways of iNKT cell activation are not exclusive. The innate cell-derived cytokines IL-12 and IFN $\alpha/\beta$  have been reported to augment CD1d-dependent iNKT cell activation (Brigl et al., 2003; Mallevaey et al., 2006; Mattner et al., 2005; Paget et al., 2007), which was especially crucial for stimulation with presumably weak antigens.

Furthermore, in some cases, it has been shown that iNKT cells require the recognition of endogenous or self-ligands presented by CD1d for activation in a cytokine-dependent context (Brigl et al., 2003). This is exemplified by the activation of iNKT cells following *Salmonella* infection, which is not only dependent on IL-12 but also on CD1d (Brigl et al., 2003; Mallevaey et al., 2006; Mattner et al., 2005). As *Salmonella* is not known to express antigens that activate iNKT cells, these data demonstrate that self-antigens presented by CD1d acted in concert with IL-12 to activate iNKT cells. In line with the idea of recognition of “self” by iNKT cells is the observation that mature iNKT cells can under some circumstances display auto-reactivity (Hegde et al., 2010; Salio and Cerundolo, 2009). In addition, data with tumor-derived glycolipids suggest (Behar et al., 1999; Gumperz et al., 2000; Metelitsa et al., 2003; Metelitsa, 2011; Rauch et al., 2003; Wu et al., 2003) such self-antigens could provide an “altered-self” for iNKT cell activation.

The structure of such self-antigens important for the activation of mature iNKT cells is still debated, and there could be several types, but currently the best candidates are lysophospholipids (Fox et al., 2009), several types of glycosphingolipids including isoglobotrihexosylceramide (Zhou et al., 2004) and a still uncharacterized mammalian glycosphingolipid with an  $\alpha$ -linked sugar (Brennan et al., 2014; Kain et al., 2014). A lysophosphatidylethanolamine, with an ether bond or plasmalogen, has been suggested to be important for iNKT cell positive selection (Facciotti et al., 2012).

### Cytokine Production

In accordance with their constitutively activated phenotype is the remarkable ability of iNKT cells to rapidly (<1 hour) exert effector functions such as cytokine production and cytotoxicity (Wingender et al., 2010). After antigenic, TCR-driven activation, they rapidly produce copious amounts of various cytokines such as T helper type 1 (Th1, e.g., IFN $\gamma$ , TNF) and Th2 cytokines (e.g., IL-4, IL-5, IL-13), with subsets capable of producing IL-9, IL-10, IL-17A, and IL-22 (see the “The many kinds of invariant natural killer T cells” section). This explosive production of cytokines is more similar to innate immune cells or a memory T-cell response, as a conventional naïve T lymphocyte would take days of stimulation to produce these cytokines. In contrast to naïve T cells, iNKT cells are somewhat resistant to cytokine polarization (Matsuda et al., 2003) and the response toward a strong TCR agonist is a mixed IFN $\gamma$ /IL-4 or Th0-response (Sullivan et al., 2010).

Contrary to this manifold array of cytokines following TCR-driven activation, the indirect, cytokine-driven activation, for example, by IL-12 and IL-18, leads exclusively to the production of IFN $\gamma$  by the stimulated iNKT cells (Nagarajan and Kronenberg, 2007; Tyznik et al., 2008). Similarly, IL-1 $\beta$  and IL-23 stimulate the IL-17A producing subset to secrete IL-17A (Doisne et al., 2011; Moreira-Teixeira et al., 2011; Price et al., 2012) and some iNKT cells are stimulated by IL-25 to produce IL-13 (Terashima et al., 2008).

### Down-Stream Effects

Due to their cytokine production, iNKT cells have a pronounced impact on other lymphocytes, amplifying responses of DCs (Chen et al., 2005; Kitamura et al., 1999; Kojo et al., 2005), macrophages (Denney et al., 2012; Flesch et al., 1997), neutrophils (De Santo et al., 2010; Emoto et al., 2010; Li et al., 2007; Michel et al., 2007; Wintermeyer et al., 2009), NK cells (Eberl and MacDonald, 2000; Smyth et al., 2000a,b), and B and T cells. However, in some cases the interaction has been shown to be in part cell–cell contact dependent (Baev et al., 2008; Caielli et al., 2010; Novak et al., 2005; Yang et al., 2011).

Moreover, activated iNKT cells can skew or polarize the character of the entire immune response either toward a Th1- (Cui et al., 1999; Denkers et al., 1996; Gonzalez-Aseguinolaza et al., 2002; Kitamura et al., 1999) or a Th2- (Bendelac et al., 1996; Burdin et al., 1999; Hong et al., 2001; Sharif et al., 2001; Singh et al., 1999; Yoshimoto et al., 1995a, 1995b) direction. This can be promoted by the stimulating antigen utilized, with some synthetic glycolipids, such as C-glycoside (Schmieg et al., 2003), leading to a Th1 bias and others such as OCH (Miyamoto et al., 2001) and C:20 (Yu et al., 2005), leading to a Th2-bias (Birkholz et al., 2015; East et al., 2014). Interestingly, this bias is not reflected in the initial iNKT cell cytokine response, which remains Th0 (Sullivan et al., 2010), but instead reflects the interactions between networks of cells including the presentation of the antigen on antigen-presenting cells (APCs) (Arora et al., 2011; Im et al., 2009). For

example, Th1 skewing of the cytokine response reflects enhanced IFN $\gamma$  production by NK cells (Birkholz et al., 2015b; East et al., 2014).

Consequently, by orchestrating the ensuing immune response, with regard to its strength and properties, iNKT cells can act as a bridge between innate and adaptive immune responses. Therefore it is not surprising that iNKT cells have been reported to be crucially involved in the early phases of a dazzling variety of different immune reactions, ranging from self-tolerance and autoimmunity to include responses to pathogens and tumors.

## The many kinds of Invariant Natural Killer T Cells

There is increasing evidence that the functionally diverse roles of iNKT cells are partly due to functional iNKT cells subsets with distinct homing properties and cytokine profiles. Depending on the subset and the conditions, these may be preprogrammed in the thymus or induced in the periphery under the influence of particular stimulatory conditions. At first, iNKT cells subsets were defined by the expression of surface molecules, such as CD4 (Gumperz et al., 2002; Kim et al., 2002; Lee et al., 2002a), NK1.1 (McNab et al., 2007), IL17RB (Terashima et al., 2008), Ly49 receptors (Hammond et al., 1999; Skold and Cardell, 2000), and CD49b/DX5 (Hammond et al., 1999; Pellicci et al., 2005), among others.

However, with recent advances it is now feasible, at least in the mouse, to attempt to define some iNKT cell subsets based on transcription factor usage (Table 7.1): (1) NKT1 cells are  $Tbet^{high}$ , PLZF $^{low}$ , GATA3 $^{low}$ , and ROR $\gamma t^{neg}$  and are characterized by a Th1–cytokine pattern (IFN $\gamma$  > IL-4) (Lee et al., 2013). (2) NKT2 cells are PLZF $^{high}$ , GATA3 $^{high}$ ,  $Tbet^{low}$ , ROR $\gamma t^{low}$ , and produce cytokines with a Th2–cytokine pattern (IL-4 > IFN $\gamma$ ) (Lee et al., 2013). (3) NKT17 cells are ROR $\gamma t^{pos}$ , GATA3 $^{high}$ , PLZF $^{int}$ , and  $Tbet^{low}$  and are characterized by IL-17A production (Coquet et al., 2008; Doisne et al., 2009, 2011; Lee et al., 2013; Michel et al., 2007, 2008; Milpied et al., 2011; Pichavant et al., 2008). These subsets can be identified in the thymus and, therefore, may be considered preprogrammed, and their transcriptomes differ by hundreds of genes, despite their similar specificities (Engel et al., 2016; Georgiev et al., 2016; Lee et al., 2016). (4) NKT10 cells are defined by their production of IL-10. They too can be detected in the thymus, albeit, at very low frequency. However, NKT10 cells greatly expand after antigenic stimulation with Th1-biasing iNKT cell antigens in vivo, and they are long lived (Birkholz et al., 2015a; Lynch et al., 2015; Sag et al., 2014; Wingender et al., 2015a,b). It was suggested that NKT10 cells are characterized by the transcription factor E4BP4 (Lynch et al., 2015; Vieth et al., 2016). (5) NKT<sub>FH</sub> cells are induced by strong antigenic stimulation, are short-lived, and are characterized by the expression of the transcription factor Bcl6 and the surface markers CD185 (CXCR5) and CD279 (PD-1) (Chang et al., 2012; King et al., 2012; Toni et al., 2012). (6) FoxP3 $^+$  iNKT cells acquire FoxP3 expression following strong antigenic stimulation in the presence of high amounts of TGF $\beta$  (Moreira-Teixeira et al., 2011, 2012). Furthermore, iNKT cells capable of producing IL-9 (Kim and Chung, 2013; Monteiro et al., 2015) or IL-22 (Paget et al., 2012; Raifer et al., 2012) have been described, however, it is not clear to date if they constitute independent iNKT cell subsets.

In contrast, in humans iNKT cell subsets are not yet as well defined. However, expression of CD4 has been correlated with functional differences. Following antigenic stimulation the cytokine production of CD4 $^+$  V $\alpha$ 24*i* NKT cells follows a Th0-pattern, whereas CD4 $^{neg}$  iNKT cells are biased toward a Th1-pattern (Gumperz et al., 2002; Lee et al., 2002a). Furthermore, an IL-17 producing subset of human iNKT cells exists, but unlike in mice, it requires exposure to inflammatory cytokines as well as TCR activation for IL-17 production (Moreira-Teixeira et al., 2011).

Altogether, these data demonstrate that iNKT cells are heterogeneous. Because the prevalence of functional iNKT cell subsets may differ between inbred mouse strains or individuals, some of the current controversies regarding the roles of iNKT cells could depend on subset prevalence or selective activation of subsets under certain conditions.

## TECHNICAL PROBLEMS AND THE SPECIES DIVIDE

Several technical problems complicate the interpretation of the reported human data on iNKT cells and autoimmunity that we summarize below. Human iNKT cells can be identified by CD1d/ $\alpha$ GalCer tetramers, which may be the most inclusive and accurate method. A clonotype specific antibody that recognizes the CDR3 $\alpha$  region formed by the invariant V $\alpha$ 24-J $\alpha$ 18 rearrangement also is available (clone 6B11) (Montoya et al., 2007), but may miss some human  $\alpha$ GalCer and CD1d reactive cells that do not use V $\alpha$ 24 (Brigl et al., 2006; Constantinides et al.,

2011; Gadola et al., 2002; López-Sagasta et al., 2012). Although a large variability in the frequency of such V $\alpha$ 24<sup>neg</sup> CD1d/ $\alpha$ GalCer-reactive T cells was found within in vitro expanded cells lines (Brigl et al., 2006), their frequency in fresh PBMCs was estimated to be around  $1 \times 10^{-5}$  among total CD3<sup>+</sup> cells (Constantinides et al., 2011). Interestingly, the TCRs expressed by these cells are related to the canonical TCR, as they express V $\beta$ 11 and the predominant V $\alpha$ -segments they express (V $\alpha$ 3.1 and V $\alpha$ 10.1) are rearranged to the same J $\alpha$ 18 expressed by V $\alpha$ 24<sup>i</sup> NKT cells (Brigl et al., 2006; Constantinides et al., 2011; Gadola et al., 2002). The combination of V $\alpha$ 24 and V $\beta$ 11 antibodies also is sometimes used, but this might leave out some V $\alpha$ 24-negative *i*NKT cells, as well as including some non-*i*NKT cells. However, frequently less accurate methods to define *i*NKT cells are used, including (1) V $\alpha$ 24-specific antibodies alone, (2)  $\alpha\beta$ TCR and expression of one of several NK cell markers (e.g., CD161, CD56, CD16), (3) CD4<sup>-</sup>CD8<sup>-</sup> (DN)  $\alpha\beta$ T cells, and (4) RT-PCR for the *i*TCR, which does not allow for a direct assessment of cell frequency. Altogether, this means that different human studies are difficult to compare, as different populations may have been investigated. Here we will focus mainly on reports using CD1d/ $\alpha$ GalCer tetramers, the 6B11 antibody, or V $\alpha$ 24<sup>+</sup>V $\beta$ 11<sup>+</sup> double positive cells, which are now the standards. Furthermore, the depths of the characterization of *i*NKT cells in humans remains limited, especially regarding functional subsets, as analysis is usually confined to CD4 expression, one of the NK receptors, IFN $\gamma$  and IL-4. However, a “global” look at *i*NKT cells might miss important phenotypic and functional changes by a so far overlooked subset, which might be relevant in a particular disease. Moreover, most information about human *i*NKT cells is, for apparent reasons, derived from PBMCs. How human *i*NKT cells in peripheral blood relate to tissue *i*NKT cells is largely unknown. For mice it has been reported that *i*NKT cells in blood poorly reflect the cells in other tissues regarding frequency, phenotype, and function (Berzins et al., 2004). Furthermore, when the frequency or function of *i*NKT cells during autoimmune diseases was reported, this was usually done at a single time in an individual, rather than longitudinally, which could be misleading in cases where the importance of *i*NKT cells changes importance at different stages during disease progression. Finally, some problems were noted with one commonly used *i*NKT cell-deficient animals. The J $\alpha$ 18<sup>-/-</sup> (*Traj18*<sup>-/-</sup>) mouse line, originally described by Cui et al. (1999) (called J $\alpha$ 281<sup>-/-</sup> therein) and used since then by many researchers, carries a neomycin-resistance gene and it was shown that this gene suppresses a substantial amount of rearrangements leading to the absence of approximately 60% of the  $\alpha\beta$ TCR diversity in these mice (Bedel et al., 2012). This raised the question if the results obtained with this J $\alpha$ 18<sup>-/-</sup> mouse line were due to the absence of *i*NKT cells or the effects on the TCR repertoire in conventional T cells. Since then, four new J $\alpha$ 18<sup>-/-</sup> mouse lines with an undisturbed  $\alpha\beta$ TCR repertoire have been described (Chandra et al., 2015; Dashtsoodol et al., 2016; Ren et al., 2017; Zhang et al., 2016), and so far, the data obtained with those mice replicated earlier findings on the importance of *i*NKT cells.

## The Species Divide

Most of the work on *i*NKT cells has been done in mouse models. Apart from the quip that “mice are not humans,” and the obvious fact that the genetic background in human subjects is much more varied than in the few inbred mice strains commonly used, there are a few other aspects worth noting that complicate the translation of findings from mice to humans. A striking difference is in the relative distribution of *i*NKT cells in different organs. In mice the highest frequency of *i*NKT cells is found in liver, followed in descending order by adipose tissue, thymus/spleen/bone marrow/PBMCs, and lymph nodes. In humans, *i*NKT cells are abundant in adipose tissue, but not very abundant in liver/peritoneum and generally lower in frequency than in the commonly studied inbred mouse strains. In addition, in humans MAIT and type II NKT cells are more frequent than in mice and they contain additional nonconventional T lymphocytes reactive to CD1a, CD1b, and CD1c (Bendelac et al., 2007; Kronenberg, 2005; Kronenberg and Gapin, 2002). So, whereas in many cases the role of *i*NKT cells in animal models of autoimmunity is well established, controversy to varying degrees remains with regard to their role in human autoimmunity.

## THE JANUS-LIKE CHARACTER OF INVARIANT NATURAL KILLER T CELLS IN AUTOIMMUNITY

In line with the diversity of *i*NKT cell cytokine and effector responses, and their involvement in shaping immune responses, it is not surprising that *i*NKT cells have also been reported to participate in autoimmune disease pathogenesis (for earlier reviews on this topic see: Berzins and Ritchie, 2014; Berzins et al., 2011; Di Pietro

and Falcone, 2014; Novak and Lehuen, 2011; Simoni et al., 2012). Despite conflicting data, here we distinguish those autoimmune diseases in which *i*NKT cells mostly seem to promote pathogenesis in the majority of reports from those in which they tend to prevent it. Given the vast literature in the field, not all details can be described here, but rather we summarize the major findings, emphasizing the underlying mechanisms and focusing on recent developments.

<sup>a</sup>The table only lists reports in which iNKT cells were identified by CD1d/ $\alpha$ GalCer tetramers or 6B11 antibodies or the combination of Vo24 $^+$ V311 $^+$ . Comments: [1] NKT-cell like cells (CD3 $^+$ CD161 $^+$ ) were found in atherosclerotic plaques (Bobryshev and Lord, 2005; Chan et al., 2005). [2] Differing results in Magnan et al. (2000), Prell et al. (2003), and Wu et al. (2010). [3] NKT-like (CD3 $^+$ CD57 $^+$ ) cells accumulated in the bile ducts of PBC patients (Harada et al., 2003). [4] NKT-like cells (Vo24 $^+$  CD56/CD161 $^+$ ) were found in psoriatic plaques and their frequency directly correlated with the length of the rete ridge, a measure of the skin inflammation (Kono et al., 2014).

PBMC, Peripheral blood mononuclear cells; RA, rheumatoid arthritis.

## Too Much of a Good Thing: Detrimental Roles of Invariant Natural Killer T Cells

For diseases in this section, the data are most consistent with roles for iNKT cells in initiating and/or aggravating pathogenesis (Table 7.2).

### Atherosclerosis

Atherosclerosis is a chronic inflammatory disease within the vessels, driven by responses to accumulated lipids in the arterial intima. A contribution of the adaptive as well as the innate immune system, and an autoimmune component, have become apparent (earlier reviews on the role of iNKT cell in atherosclerosis: Braun et al., 2010b; Getz and Reardon, 2017; Grundtman and Wick, 2011; van Puijvelde and Kuiper, 2017).

In PBMCs of human patients, iNKT cell numbers were decreased (Kyriakakis et al., 2010). Furthermore, iNKT (Kyriakakis et al., 2010) and NKT-like cells (CD3 $^+$ CD161 $^+$ ) (Bobryshev and Lord, 2005; Chan et al., 2005) were found in atherosclerotic plaques, where they represented up to 3% of the lymphocytes. Of note, CD1d expression was enhanced in the atherosclerotic plaques (Bobryshev and Lord, 2000, 2005; Chan et al., 2005; Kyriakakis et al., 2010; Melián et al., 1999). iNKT cell lines derived from atherosclerotic plaques produced proinflammatory cytokines following  $\alpha$ GalCer stimulation and did this with an approximately 10-fold higher antigenic sensitivity than PBMC-derived iNKT cell lines (Kyriakakis et al., 2010).

In mouse models of atherosclerosis, iNKT cells also could be found in the atherosclerotic lesions (Aslanian et al., 2005; Nakai, 2004; Tupin et al., 2004), and data with reporter mice suggest that CD186 (CXCR6) signaling might be required for this accumulation (Galkina et al., 2007). Interestingly, when serum lipids from atherosclerosis-prone LDL-receptor deficient mice were fed to DCs, this led to a CD1d-dependent stimulation of iNKT cell hybridoma cells (Vanderlaan et al., 2007), and inhibition of CD1d presentation with DPPE-PEG<sub>350</sub> ameliorated the development of atherosclerosis in vivo (Li et al., 2016). iNKT cell-deficient mice developed a greatly ameliorated disease (Aslanian et al., 2005; Major et al., 2004; Nakai, 2004; Rogers et al., 2008; Ström et al., 2007; To et al., 2009; Tupin et al., 2004) and transfer of CD4<sup>+</sup> iNKT cells could transfer susceptibility (Li et al., 2015; To et al., 2009; Vanderlaan et al., 2007). The reduced plaque formation in iNKT cell-deficient animals correlated with an approximately 90% decrease in IFN $\gamma$  mRNA in the atherosclerotic lesions (Rogers et al., 2008). Consequently, activation of iNKT cells either by antigens (Major et al., 2004; Nakai, 2004; Tupin et al., 2004) or with lipopolysaccharide (LPS) (Andoh et al., 2013; Ostos et al., 2002) aggravated disease, and increased iNKT cell numbers within the atherosclerotic lesions (Nakai, 2004; Tupin et al., 2004). This is in line with the observation that microbial infections enhance the development of atherosclerosis in both human and animal models (Hansson et al., 2006). Importantly, the proatherosclerotic effect of the transferred CD4<sup>+</sup> iNKT cells was independent of T-, B-, and NK cells, as well as independent of IL-4, IL-21, and IFN $\gamma$  (Li et al., 2015), rather the expression of cytotoxic proteins (granzyme B, perforin) by the CD4<sup>+</sup> iNKT cells was required for the proatherosclerotic effect (Li et al., 2015). A similar mechanism has been suggested for NK cells (Selathurai et al., 2014) and CD8<sup>+</sup> T cells (Kyaw et al., 2013). Nonetheless, one study reported a protective effect of iNKT cell stimulation on atherosclerosis (van Puijvelde et al., 2009). Finally, it is important to keep in mind that several proteins involved in lipid metabolism have been shown also to be involved in CD1d lipid antigen loading, including apoE (Elzen et al., 2005), sphingolipid activator protein (Zhou et al., 2004), and microsomal triglyceride transfer protein (Brozovic et al., 2004). For example, apoE can bind  $\alpha$ GalCer and aid in its uptake (Allan et al., 2009; Elzen et al., 2005), and two studies suggested that iNKT cells in apoE-deficient mice were hypo-responsive (Braun et al., 2010a; Soh et al., 2016).

### Asthma

Asthma is multifactorial disease that could in some cases have an autoimmune component. Several studies have implicated V $\alpha$ 24i NKT cells in the pathogenesis of asthma in humans (earlier iNKT cell reviews see: DeKruyff et al., 2014; Rijavec et al., 2011; Thomas et al., 2010; Umetsu and DeKruyff, 2010). A decreased frequency in PBMCs from asthmatic patients, at least in the CD4<sup>+</sup> subset of iNKT cells, has been reported by some (Ikegami et al., 2009; Koh et al., 2010; Yan-ming et al., 2012), but not by others (Akbari et al., 2006; Antunes et al., 2018; Koh and Shim, 2010; Koh et al., 2012; Magnan et al., 2000; Shim and Koh, 2014). Interestingly, upper respiratory tract infections, which often exacerbates asthma, were correlated with a decrease of iNKT cells in PBMC (Koh et al., 2012), suggesting potential recruitment to the lung. In line with this notion, iNKT cells are almost undetectable in the airways of healthy controls, either in lung biopsies (Akbari et al., 2006; Reynolds et al., 2009; Vijayanand et al., 2007) or in the bronchoalveolar lavage fluid (BALF) (Akbari et al., 2006; Matangkasombut et al., 2009; Thomas et al., 2007) but can be detected in samples from asthmatic patients. However, controversy remains about the magnitude of this increase within the lungs of asthmatics. For BALF only two studies reported a frequency of more than 2.5% of iNKT cells within total T cells (Akbari et al., 2006; Matangkasombut et al., 2009), with most studies reporting frequencies between 0.6% and 2.5% (Bratke et al., 2007; Brooks et al., 2010; Heron et al., 2007; Matangkasombut et al., 2009; Mutualithas et al., 2007; Pham-Thi et al., 2006; Thomas et al., 2007, 2006; Vijayanand et al., 2007). For lung biopsies the values ranged from 1.7% (Vijayanand et al., 2007) to 9.8% (Reynolds et al., 2009) to over 50% (Akbari et al., 2006). Importantly, it was noted that the frequency of iNKT cells in the lung increases with the severity of symptoms (Akbari et al., 2006; Hamzaoui et al., 2006; Koh and Shim, 2010; Matangkasombut et al., 2009; Reynolds et al., 2009). A prospective cohort study did not find a correlation between the iNKT cell frequency in PBMCs of children at age 1 and asthma at age 7 (Chandra et al., 2018). However, a correlation with the iNKT cell antigenic content in the house dust was noted. Young children growing up in homes with more iNKT cell antigens were less likely to develop asthma (Chandra et al., 2018), perhaps reflecting increased microbial load in those homes and consistent with the hygiene hypothesis. Most forms of asthma are associated with Th2 cytokine profile, but conflicting data were reported regarding the presence of a Th2 skewed cytokine production by restimulated iNKT cells from PBMC of asthma patients (Th2-bias? Yes: Shim and Koh, 2014; Yan-ming et al., 2012, no: Sen et al., 2005). However, antigen-stimulated iNKT cells from BALF of asthmatic patients produced IL-4 and IL-13, but hardly any IFN $\gamma$  (Akbari et al., 2006), in line with the hypothesized Th2-bias.

In mouse airway inflammation models, the evidence is strong for a major pathogenic role for *i*NKT cells in airway hypersensitivity. The potency of *i*NKT cells in airway inflammation is illustrated by the fact that airway challenge with *i*NKT cell glycolipid antigens alone, such as  $\alpha$ GalCer, induces many of the pathological features of asthma, even in MHC class II-deficient mice that lack conventional CD4 $^{+}$  T cells (Meyer et al., 2006). This suggests that asthma might be induced directly by airway exposures to *i*NKT cell antigens present in inspired air. Clearly, weak environmental *i*NKT cell antigens found in house dust could act as potent adjuvants in the sensitization to a model antigen (Wingender et al., 2011). Even in the absence of known *i*NKT cells antigens, several groups have found that *i*NKT cells are required in mouse models of asthma initiated by ovalbumin sensitization (Akbari et al., 2003; Kim et al., 2009, 2004; Lisbonne et al., 2003), ragweed (Bilenki et al., 2004), or ozone (Pichavant et al., 2008). This is best illustrated by the clearly reduced airway inflammation in *i*NKT cell-deficient animals in several models, and the restoration of susceptibility by *i*NKT cell transfer (Akbari et al., 2003; Cui et al., 1999; He et al., 2017; Kim et al., 2012; Lisbonne et al., 2003; Nie et al., 2015; Pichavant et al., 2008; Scheuplein et al., 2015; Wingender et al., 2011). In the allergen-induced model of airway hypersensitivity, secretion of IL-4 and IL-13 by *i*NKT cells has been implicated (Akbari et al., 2003; Meyer et al., 2006; Terashima et al., 2008), while the ozone-induced model depended upon IL-17A as well as IL-4 and IL-13 (Pichavant et al., 2008). Germ-free mice were reported to have an increased frequency of lung *i*NKT cells and enhanced asthma susceptibility, and both could be reversed by early life exposure to normal microbiota (Olszak et al., 2012). Furthermore, antigenic stimulation of lung *i*NKT cells early in life (2 weeks of age) expanded CD38 $^{+}$  *i*NKT cells that predominantly produced IFN $\gamma$  and were protective against airway hypersensitivity (Chang et al., 2011; Chuang et al., 2018). This suggests that different *i*NKT cell subsets play opposing roles during asthma.

Three studies in macaques were in line with the findings in mouse models in showing that a glycolipid antigen for *i*NKT cells could induce hypersensitivity and that an allergen challenge could lead to *i*NKT cell infiltration into the lung (Ayanoglu et al., 2011; Matangkasombut et al., 2008; Nambiar et al., 2015).

### **Inflammatory Bowel Disease/Colitis**

Inflammatory bowel disease (IBD) denotes a spectrum of chronic disorders of different parts of the gastrointestinal tract. The inflammatory response is triggered by antigens derived from the gut lumen, which may follow a perturbation of the epithelial layer, caused either through genetic alterations or the administration of exogenous agents. Several reviews on the role of *i*NKT cells in colitis models have been published (Liao et al., 2013; Wingender and Kronenberg, 2008; Zeissig and Blumberg, 2014). Some types of intestinal bacteria are probiotic, in that they prevent inflammation of the intestine. It is therefore of note that *i*NKT cells can influence the microbial colonization and the composition of intestinal bacteria (Nieuwenhuis et al., 2009). Furthermore, the activation state of *i*NKT cells, and their influence on the mucosal immune response, is highly altered in germ-free mice (Olszak et al., 2012; Wingender et al., 2012b).

Ulcerative colitis is an inflammation of the superficial layers of the colon that has been attributed in some studies to an exaggerated Th2 response. *i*NKT cells were decreased in the PBMCs of ulcerative colitis patients (Grose et al., 2007b; van der Vliet et al., 2001). In addition, there was a reduction in V $\alpha$ 24 mRNA in the intestine of colitis patients (Grose et al., 2007b), but the majority of these V $\alpha$ 24 $^{+}$  cells might not be *i*NKT cells, as judged by V $\beta$ 11 expression (O'Keeffe et al., 2004). Interestingly, in ulcerative colitis patients, it was found that *v*NKT cells, rather than *i*NKT cells, were the major CD1d-dependent producers of the deleterious IL-13 (Fuss et al., 2004). This is in contrast to results obtained using the oxazolone-induced mouse model of colitis, where it was shown that the pathogenic IL-13 was derived from *i*NKT cells (Heller et al., 2002). In this model, *i*NKT cells from lamina propria had increased CD199/CCR9 expression and chemotaxis to CCL25, which mediate intestinal homing (Zhu et al., 2014). Furthermore, interfering with *i*NKT cell activation prevented disease development (Brozovic et al., 2004; Camelo et al., 2012; Heller et al., 2002; Rosen et al., 2013; Schiechl et al., 2011).

### **Primary Biliary Cirrhosis**

Primary biliary cirrhosis (PBC) is characterized by portal inflammation and immune-mediated chronic destruction of intrahepatic small bile duct epithelial cells (i.e., cholangitis) (for earlier *i*NKT cell reviews see: Camelo et al., 2012; Mattner, 2013; Uibo et al., 2012).

*i*NKT cells are increased in PBMCs as well as in the liver of PBC patients (Kita et al., 2002), and these livers contain higher IFN $\gamma$  levels (Omenetti et al., 2009). The increase of *i*NKT cells in the liver coincided with an increase of CD1d expression levels on epithelial cells of the small bile duct of PBC patients in most studies (yes: Kita et al., 2002; Tsuneyama et al., 1998; no: Schrumpf et al., 2015). The cross-reactivity of antibodies to several

bacteria with the lipidated mitochondrial protein PDC-E2 has been implicated in the genesis of PBC (Bogdanos and Vergani, 2009; Bogdanos et al., 2004; Padgett et al., 2005; Selmi et al., 2003; Yanagisawa et al., 2011).

One bacterium in particular that is the target of these cross-reactive antibodies from PBC patients is *Novosphingobium aromaticivorans* (Olafsson et al., 2004; Padgett et al., 2005; Selmi et al., 2003). This bacterium is of interest because of its relation to Sphingomonas bacteria, which bear known iNKT cell antigens (Kinjo et al., 2005; Mattner et al., 2005). Most importantly, *N. aromaticivorans* can induce a PBC-like disease in a mouse model in an iNKT cell-dependent fashion (Mattner et al., 2008; Mohammed et al., 2011), although other bacteria, without known iNKT cell antigen, could cause inflammation as well (Wang et al., 2014). In line with a crucial role for iNKT cells in initiating PBC-like disease in mice is the observation that stimulation of iNKT cells can exacerbate disease (Chang et al., 2015; Chuang et al., 2008; Wu et al., 2011), whereas in iNKT cell-deficient mice disease was ameliorated (Berntsen et al., 2018; Chang et al., 2015).

### Rheumatoid Arthritis

In rheumatoid arthritis (RA) auto-reactive Th1 and Th17 T cells cause inflammation of small and large synovial joints, leading to joint deformation and loss of movement (for earlier iNKT cell reviews see: Chen et al., 2016; Drennan et al., 2010; Sowden and Ng, 2012).

Human RA patients display reduced iNKT cell frequencies in PBMCs (Kojo et al., 2001; Mansour et al., 2015; Parietti et al., 2010; Tudhope et al., 2010; van der Vliet et al., 2004). Furthermore, iNKT cells were detected in the rheumatoid synovium (Gutowska-Owsiaik et al., 2014; Linsen et al., 2005; Maeda et al., 1999; Zhao et al., 2018), with two studies showing an increased frequency in the synovium compared to the PBMCs (Gutowska-Owsiaik et al., 2014; Zhao et al., 2018). Although the iNKT cell frequency in PBMCs did not correlate with clinical disease severity in most studies (no: Parietti et al., 2010; Tudhope et al., 2010; yes: Mansour et al., 2015), it was noted that the frequency increased following treatment (Parietti et al., 2010; Tudhope et al., 2010). iNKT cell lines derived from RA patient's PBMCs expanded less in vitro following  $\alpha$ GalCer stimulation (Jin et al., 2015; Kojo et al., 2001; Linsen et al., 2005; Mansour et al., 2015; Tudhope et al., 2010) and produced reduced cytokines, although with a Th1 bias (Gutowska-Owsiaik et al., 2014; Jin et al., 2015; Kojo et al., 2001; Linsen et al., 2005; Mansour et al., 2015), when compared to control lines. In contrast to PBMCs, no impairment of iNKT cell expansion and function was observed in synovial derived iNKT cell lines (Linsen et al., 2005). However, when synovial iNKT cells from RA patients were analyzed directly ex vivo they produced less IFN $\gamma$  than the iNKT cells from matched PBMCs (Zhao et al., 2018). Interestingly, the iNKT cell lines derived from patient's PBMCs were particularly depleted of iNKT cells with a high-affinity TCR, and those that remained lost their Th0-cytokine pattern in favor for a Th1- or Th2 pattern (Mansour et al., 2015). Furthermore, even though the expression levels of CD1d on PBMCs might not be altered (no change: Kojo et al., 2003; Mansour et al., 2015; higher on DCs: Jacques et al., 2010), it was reported that RA patients have decreased levels of soluble CD1d in the serum (Kojo et al., 2003; Segawa et al., 2009).

Without delineating the details of the different mouse models for RA that have been studied, the role of iNKT cells appears to depend on the dominant iNKT cell subset: NKT1 cells being protective and NKT17 cells being pathogenic. The frequency of iNKT cells increased with disease progression (Chiba et al., 2005; Postigo et al., 2012; Zhao et al., 2018), they upregulated activation markers (Jung et al., 2009; Kim et al., 2006; Miellot-Gafsou et al., 2010; Zhao et al., 2018), and they were recruited to the joints (Kim et al., 2005; Park et al., 2010; Zhao et al., 2018), where they could be activated directly by aggregated antibodies (Kim et al., 2005). Furthermore, the percentage of IL-17A $^+$  NKT17 cells increased with disease progression (Jung et al., 2009; Zhao et al., 2018) with a concomitant decrease of IFN $\gamma$  + NKT1 cells (Zhao et al., 2018). Injection of blocking  $\alpha$ CD1d-antibodies ameliorated arthritis (Chiba et al., 2005; Miellot-Gafsou et al., 2010) and in iNKT cell-deficient mice the disease was less severe ( $\text{J}\alpha 18^{-/-}$ : Chiba et al., 2005; Ohnishi et al., 2005; Yoshiga et al., 2008; CD1d $^{-/-}$ : Jung et al., 2009; Kim et al., 2006, 2005; Ohnishi et al., 2005; Teige et al., 2010; Zhao et al., 2018). Such diseased iNKT cell-deficient animals had higher IL-10 production by collagen-specific T cells (Chiba et al., 2005; Jung et al., 2009) and the levels of proinflammatory cytokines tended to be lower (Chiba et al., 2005; Jung et al., 2009; Ohnishi et al., 2005; Yoshiga et al., 2008). In addition, they had reduced antigen-specific antibody titers (Jung et al., 2009; Ohnishi et al., 2005), with an elevated IgG1/IgG2a ratio (Chiba et al., 2005), suggesting a Th2 deviation. Furthermore, injection of iNKT cell antigens generally ameliorated disease (Chiba et al., 2004; Coppieters et al., 2007; Jin et al., 2015; Kaieda et al., 2007; Miellot et al., 2005; Oleinika et al., 2018; Takagi et al., 2006; Yoshiga et al., 2008, 2011; Zhao et al., 2018). The disease amelioration could be attributed to the impairment of the pathogenic Th17 response, rather than to a Th2 cytokine deviation (Chiba et al., 2004; Jung et al., 2009; Kaieda et al., 2007; Yoshiga et al., 2011). In line with this, several studies showed that IFN $\gamma$  is protective in different RA mouse models

(Coppieeters et al., 2007; Jin et al., 2015; Kaieda et al., 2007; Kim et al., 2005; Oleinika et al., 2018; Yoshiga et al., 2011; Zhao et al., 2018). Although IL-4 and/or IL-10 were implicated as well by some studies (Chiba et al., 2004; Kaieda et al., 2007; Kim et al., 2005; Miellot et al., 2005), one study reported a pathogenic role of IFN $\gamma$  (Teige et al., 2010). Two studies reported on a required interaction of iNKT cells with other cells for the protective effect of iNKT cells. Both studies showed that CD1d expression by DCs (Jung et al., 2010) or Bregs (Oleinika et al., 2018) is necessary to ameliorate arthritis. Importantly, one study showed that the Th1-biasing iNKT cell antigen 7DW8-5 was therapeutically active and could ameliorate arthritis after the onset of disease (Zhao et al., 2018). This could not be achieved with  $\alpha$ GalCer, which, although highly potent, is a less Th1-biasing antigen (Zhao et al., 2018). Intriguingly, it has been suggested that V $\alpha$ 14i NKT cells might recognize a mouse collagen II-derived peptide (mCII<sub>707–721</sub>) in a CD1d-dependent manner (Liu et al., 2011). This report is one of the very few that indicate that peptides, in addition to lipids, can be presented by CD1d (Castano et al., 1995; Girardi et al., 2016; Lee et al., 1998; Tangri et al., 1998; Zeng et al., 1997). Further studies will be required to understand the mechanism of peptide binding into the hydrophobic CD1d groove and the relevance of such peptides for iNKT cell function.

### **Skin Disorders**

Psoriasis is a local inflammation of the skin driven by a mixed Th1/Th17 T cell response (Lowes et al., 2008; Zaba et al., 2009) leading to abnormal proliferation and differentiation of keratinocytes (for earlier iNKT cell reviews see Balato et al., 2009; Peternel and Kastelan, 2009; Tobin et al., 2011). One report showed a decreased frequency of iNKT cells in PBMCs from psoriasis patients (van der Vliet et al., 2001). For the skin, there are several reports of T cells expressing NK cell markers in the psoriatic skin lesions (Bonish et al., 2000; Cameron et al., 2002; Curry et al., 2003; Gilhar et al., 2002; Koreck et al., 2002; Langewouters et al., 2007; Nickoloff, 2000), but only two studies reported an increase of NKT-like ( $V\alpha 24^+ CD56/CD161^+$ ) (Kono et al., 2014) or iNKT cells (Zhao et al., 2008) in psoriatic plaques. Interestingly, the frequency of these NKT-like cells directly correlated with the length of the rete ridge, a measure of the skin inflammation, and they produced more IFN $\gamma$  than IL-4 (Kono et al., 2014). Furthermore, CD1d expression was upregulated in the inflamed skin (Bonish et al., 2000; Gober et al., 2008; Zhao et al., 2008). Specifically, IFN $\gamma$  pretreated keratinocytes up-regulate CD1d and could induce IFN $\gamma$ , but not IL-4, production by iNKT cell lines (Bonish et al., 2000).

In systemic sclerosis iNKT cells from patient's PBMCs have been reported to be decreased (Kojo et al., 2001) and to display a Th1-bias (Kojo et al., 2001).

Similarly, in contact dermatitis iNKT cells from patient's PBMCs, especially the DN subset, were decreased in most (Gyimesi et al., 2011; Ilhan et al., 2007; Oishi et al., 2000; Takahashi et al., 2003), but not all (Magnan et al., 2000; Prell et al., 2003; Wu et al., 2010) reports. Whereas skin from control subjects did not contain detectable iNKT cells, they could be found in patient skin biopsies (Balato et al., 2012; Gober et al., 2008; Simon et al., 2009; Wu et al., 2010), consistent with a possible migration from the blood to the site of inflammation. iNKT cells, all CD4 $^+$ , were found within the dermal infiltrating cells and made up 6%–9% of the T cells, although none were found in the epidermis (Gober et al., 2008; Simon et al., 2009). After the stimulation of PBMC iNKT cells, two reports noted a Th2-bias (IL-4 > IFN $\gamma$ ) of the cytokine response in patient iNKT cells (Gyimesi et al., 2011; Takahashi et al., 2003), whereas one report observed a Th1 bias (Oishi et al., 2000). Furthermore, production of IFN $\gamma$  and IL-4 by iNKT cells was also detected within the affected skin of patients (Gober et al., 2008; Kono et al., 2014; Simon et al., 2009). Interestingly, thymic stromal lymphopoietin (TSLP), a cytokine that is produced by activated keratinocytes (Soumelis et al., 2002) and is elevated in patient lesions (Nakamura et al., 2008; Wu et al., 2010), can bias cytokine production by activated iNKT cells toward a Th2 pattern (IL-4, IL-13) (Jariwala et al., 2011; Wu et al., 2010).

In animal models of contact hypersensitivity (CHS), the majority of studies demonstrated a pathogenic role for iNKT cells (Askenase et al., 2011; Campos et al., 2003, 2006a,b; Curzytek et al., 2015; Dey et al., 2011; Eguchi et al., 2013; Nieuwenhuis et al., 2005; Shigematsu et al., 2014; Shimizuhira et al., 2014). However, two reports each suggested a beneficial (Fjelbye et al., 2015; Goubier et al., 2013) or no (Elkhal et al., 2006; Majewska-Szczepanik et al., 2013) role. This discrepancy is potentially due to differences in the protocols utilized, the genetic background, or the microbiota of the mice studied. iNKT cells accumulated in the affected skin (Campos et al., 2006a; Eguchi et al., 2013; Shigematsu et al., 2014) and the draining lymph node (Shimizuhira et al., 2014) in some, but not all (Goubier et al., 2013; Nieuwenhuis et al., 2005), studies. Interestingly, topical application of a CD1d-binding nonstimulatory glycolipid reduced the severity of the CHS response, likely by blocking the presentation of antigenic lipids by CD1d (Nieuwenhuis et al., 2005). The pathogenic role of iNKT cells was attributed to their rapid production of IL-4 (Campos et al., 2003, 2006b).

**TABLE 7.3** Beneficial Involvement of Human iNKT Cells in Selected Autoimmune Diseases

<sup>a</sup>The table only lists reports in which iNKT cells were identified by CD1d/αGalCer tetramers or 6B11 antibodies or the combination of Vα24<sup>+</sup>Vβ11<sup>+</sup>. Comments: [1] Differing results by Wither et al. (2008).

PBMC, Peripheral blood mononuclear cells.

## Missed So Sadly: Beneficial Roles of Invariant Natural Killer T Cells

Here we outline cases where the current consensus points to a beneficial role of iNKT cells in preventing disease development (Table 7.3).

### Type 1 Diabetes

Type 1 diabetes (T1D) mellitus, also called insulin-dependent diabetes mellitus, is a Th1 autoimmune disease caused by the selective destruction of insulin-producing  $\beta$ -cells in the islets of Langerhans in the pancreas, leading ultimately to the loss of glucose homeostasis (for earlier *iNKT* cell reviews see [Ghazarian et al., 2014](#); [Magalhaes et al., 2015](#); [Tard et al., 2015](#)).

Conflicting data on the frequency and function of *iNKT* cells from patient's PBMC have been reported. Whereas some reports observed lower *iNKT* cell frequencies, at least of the CD4 $^{+}$  cells ([Kis et al., 2007](#); [Kukreja et al., 2002](#); [Montoya et al., 2007](#); [Wilson et al., 1998](#)), others found equal ([Beristain-Covarrubias et al., 2015](#); [Lee et al., 2002b](#); [Michalek et al., 2006](#); [Oling et al., 2007](#); [Tocheva et al., 2017](#); [Tsutsumi et al., 2006](#); [Zhang et al., 2011](#)) or even more *iNKT* cells ([Oikawa et al., 2002](#)) in patient's PBMCs compared to healthy controls. Furthermore, whereas some authors noted reduced cytokine production of *iNKT* cell (lines) and/or a Th1 bias ([Beristain-Covarrubias et al., 2015](#); [Kis et al., 2007](#); [Kukreja et al., 2002](#); [Li et al., 2014](#); [Wilson et al., 1998, 2000](#)), others did not find such differences ([Lee et al., 2002b](#); [Roman-Gonzalez et al., 2009](#); [Tocheva et al., 2017](#)). Importantly, one study analyzed *iNKT* cell lines derived from the draining pancreatic lymph node and observed reduced IL-4 production following antigen stimulation ([Kent et al., 2005](#)).

Nonobese diabetic (NOD) mice develop spontaneous T1D and have been studied extensively. *iNKT* cells in NOD mice are reduced in frequency ([Berzins et al., 2004](#); [Chen et al., 2011](#)) and produce less cytokines following  $\alpha$ GalCer ([Falcone et al., 1999](#); [Gombert et al., 1996](#); [Hong et al., 2001](#); [Lehuen et al., 1998](#); [Li et al., 2008](#); [Sharif et al., 2001](#)) or stimulation of the innate immune system ([Falcone et al., 1999](#)). Increasing the *iNKT* cell frequency in NOD mice, either by cell transfer ([Baxter et al., 1997](#); [Beaudoin et al., 2002](#); [Cain et al., 2006](#); [Chen et al., 2005](#); [Hammond et al., 1998](#); [Lehuen et al., 1998](#); [Simoni et al., 2011](#)) or by over-expression of the *iTCR* ([Beaudoin et al., 2014](#); [Lehuen et al., 1998](#)) or by over-expression of CD1d on pancreatic island cells ([Falcone et al., 2004](#)), prevented or ameliorated symptoms. Consequently, *iNKT* cell-deficient NOD mice showed increased frequency and earlier onset of disease ([Fletcher and Baxter, 2009](#); [Naumov et al., 2001](#); [Shi et al., 2001](#); [Wang et al., 2001](#)), and similar results were obtained after antibody-mediated depletion of *iNKT* cells ([Scheuplein et al., 2015](#)). Furthermore, the repetitive injection of  $\alpha$ GalCer ameliorated disease progression, even when treatment was started after the onset of insulitis ([Hong et al., 2001](#); [Naumov et al., 2001](#); [Sharif et al., 2001](#); [Wang et al., 2001](#)). Other  $\alpha$ GalCer derivatives were similarly effective ([Forestier et al., 2007](#); [Ly et al., 2009](#); [Mizuno et al., 2004](#)). Such antigenic stimulation led to a significant increase of *iNKT* cells in the pancreatic island ([Beaudoin et al., 2014](#)). The original explanation for the therapeutic effect of  $\alpha$ GalCer was the shift to a Th2 response ([Hong et al., 2001](#); [Naumov et al., 2001](#); [Sharif et al., 2001](#)), but not all studies observed such a shift ([Beaudoin et al., 2002](#); [Shi et al., 2001](#); [Wang et al., 2001](#)), and work with congenic NOD lines demonstrated that such a shift is not required for protection ([Jordan et al., 2007](#); [Rocha-Campos et al., 2006](#)). Furthermore, the results from a number of publications are not in agreement as to which cytokine is essential for the protection from diabetes. IL-10 ([Hammond et al., 1998](#); [Hong et al., 2001](#); [Naumov et al., 2001](#); [Sharif et al., 2001](#)) and/or IL-4 ([Hong et al., 2001](#); [Naumov et al., 2001](#); [Sharif et al., 2001](#)) have been suggested to be important, but not in every case ([Beaudoin et al., 2002](#); [Chen et al., 2006](#); [Mi et al., 2004](#); [Novak et al., 2005](#)), and even IFN $\gamma$  elicited by *iNKT* cell activation was implicated as protective in one study ([Cain et al., 2006](#)). Besides the production of protective cytokines by *iNKT* cells, their lack of production of pathogenic cytokines seems to play a role as well. It was reported that *iNKT* cells in NOD mice, although reduced in total numbers, contained an increased frequency of pathogenic NKT17 cells ([De Giorgi et al., 2018](#); [Di Pietro et al., 2016](#); [Li et al., 2014](#); [Simoni et al., 2011](#)). The repeated injection of  $\alpha$ GalCer suppressed the IL-17A production by *iNKT* cells ([Simoni et al., 2011](#)), and this ([Simoni et al., 2011](#)) or the neutralization of IL-17A in vivo ([Emamaulee et al., 2009](#)) ameliorated the disease in the NOD mice. Besides such direct effects, it was shown that activated *iNKT* cells can also interact and influence T cells and DCs in multiple ways, improving disease progression indirectly. Activated *iNKT* cells were reported to impair the differentiation of pathogenic islet-specific CD4 $^{+}$  T cells, leading to T cell anergy ([Beaudoin et al., 2002](#); [Hugues et al., 2002](#); [Novak et al., 2005](#)). This was dependent on cell-cell contact between the *iNKT* and CD4 $^{+}$  T cells ([Novak et al., 2005](#)) and independent of CD4 $^{+}$  T cell CD1d expression ([Novak et al., 2007](#)). In regard to regulatory T (Treg) cells,  $\alpha$ GalCer injection did not necessarily increase their frequency in the NOD mice (no change: [Forestier et al., 2007](#); [Ly et al., 2006](#); [Sharif et al., 2001](#); increase: [Beaudoin et al., 2014](#); [Li et al., 2008](#)). Nonetheless, a protective role for Tregs activity in this NOD/ $\alpha$ GalCer model has been implicated by some ([Beaudoin et al., 2014](#); [Diana et al., 2011](#); [Ly et al., 2006](#)), but not all ([Beaudoin et al., 2002](#); [Cain et al., 2006](#)) studies. Tolerogenic ([Chuang et al., 2011](#)) or inhibitory ([Beaudoin et al., 2014](#)) effects on CD8 $^{+}$  T cells have been reported too. Furthermore, *iNKT* cells in NOD mice treated with  $\alpha$ GalCer could affect several DC populations leading to a tolerogenic outcome ([Beaudoin](#)

et al., 2014; Chen et al., 2005; Diana et al., 2011; Driver et al., 2010; Naumov et al., 2001; Saxena et al., 2007). Interestingly, this also required both cell–cell contact (Baev et al., 2008; Caielli et al., 2010) and CD1d expression by the DCs (Caielli et al., 2010). These tolerogenic DC were reported to induce Tregs (Beaudoin et al., 2014; Diana et al., 2011) and migrate to the pancreatic lymph node to tolerize T cells locally (Chen et al., 2005). The diverse outcomes in the NOD mouse could reflect the different experimental systems used, or differences in the microbiota associated with the respective animal facilities (De Giorgi et al., 2018; Okada et al., 2010).

### **Inflammatory Bowel Disease/Crohn's Disease**

Crohn's disease is characterized by a chronic and discontinuous inflammation deep in the tissues of both the small and large intestines, with high levels of Th1 cytokines. iNKT cells are reduced in PBMCs of affected patients (Grose et al., 2007b; van der Vliet et al., 2001). In addition, V $\alpha$ 24 mRNA and the numbers of V $\alpha$ 24 $^{+}$  cells were reduced in the intestine (Grose et al., 2007b).

In Th1 cytokine-mediated mouse colitis models (induced by TNBS or DSS), the iNKT cell frequency increased in the colon (Burrello et al., 2018). Stimulation of iNKT cells could ameliorate disease in most studies (yes: Numata et al., 2005; Saubermann et al., 2000; Ueno et al., 2005, no: Selvanantham et al., 2016). Furthermore, iNKT cell-deficient animals showed exacerbated diseases in most studies [yes: Selvanantham et al., 2016 (CD1d $^{-/-}$ ), Kim and Chung, 2013, and Montbarbon et al., 2013 (J $\alpha$ 18 $^{-/-}$ ); no: Huang et al., 2016 (CD1d $^{-/-}$ ), Shen et al., 2018 (J $\alpha$ 18 $^{-/-}$ )]. However, it is important to keep in mind that CD1d-deficient (Nieuwenhuis et al., 2009; Sáez de Guinoa et al., 2018; Selvanantham et al., 2016) and J $\alpha$ 18-deficient (Shen et al., 2018) mice were found to host an altered gut microbiota, which was proinflammatory upon transfer into wild-type animals (Selvanantham et al., 2016), highlighting again the mutual influence of the gut microbiota and iNKT cells (Hapil and Wingender, 2018; Wingender, 2016; Zeissig and Blumberg, 2014). Together, these data are consistent with the conclusion that iNKT cell activation shifted the immune response from the deleterious Th1 cytokine pattern to a protective Th2 response (Numata et al., 2005; Saubermann et al., 2000; Ueno et al., 2005).

### **Multiple Sclerosis/Experimental Autoimmune Encephalomyelitis**

Multiple sclerosis (MS) is a chronic, Th1/Th17 T-cell driven inflammatory disease directed against myelin antigens in the central nervous system (CNS), leading to progressive paralysis (for earlier iNKT cell reviews, see Bianchini et al., 2017; Van Kaer et al., 2015).

The frequency of iNKT cells was reduced in patient's PBMCs in most (Araki et al., 2003; Demoulin et al., 2003; Illés et al., 2000; van der Vliet et al., 2001), but not in all the studies (De Biasi et al., 2016; Gigli et al., 2007; O'Keeffe et al., 2008). This reduction was especially prominent in patients under remission (Araki et al., 2003; Illés et al., 2000). Furthermore, when iNKT cell lines derived from patient's PBMCs were analyzed for IFN $\gamma$  and IL-4 production, no difference (Gately et al., 2013; Gigli et al., 2007), a Th1 bias (Gausling et al., 2001), or a Th2-bias of the iNKT cell lines (Araki et al., 2003; O'Keeffe et al., 2008), was observed. When iNKT cells were stimulated directly ex vivo a mixed Th1/Th17 cytokine bias was observed in MS patients (De Biasi et al., 2016). Interestingly, MS patients under treatment (IFN $\beta$ , Gigli et al., 2007) or patients in remission (Araki et al., 2003) displayed an increased frequency of iNKT cells in PBMCs and increased cytokine production by them. Furthermore, myelin-derived antigens for iNKT cells have been proposed, but not characterized (Gately et al., 2013).

MS-like features can be replicated in mice by immunization with CNS-specific peptides, a model called experimental autoimmune encephalomyelitis (EAE). Most (Denney et al., 2012; Jahng et al., 2001; Oh and Chung, 2011; Teige et al., 2004), but not all studies (Furlan et al., 2003; Singh et al., 2001; Waddell et al., 2015) reported that iNKT cell-deficient animals display exacerbated disease. In addition, an increased iNKT cell frequency, due to expression of a V $\alpha$ 14*i* transgene, ameliorated disease (Mars et al., 2008, 2002). Importantly, activation of iNKT cells with  $\alpha$ GalCer (Denney et al., 2012; Furlan et al., 2003; Jahng et al., 2001; Parekh et al., 2004; Qian et al., 2010; Singh et al., 2001; Waddell et al., 2015) or Th2-biasing glycolipids related to  $\alpha$ GalCer (Miyamoto et al., 2001; Shiozaki et al., 2013; Zhang et al., 2008) protected mice against EAE. Protection correlated with a Th1 to Th2 cytokine diversion (Furlan et al., 2003; Jahng et al., 2001; Miyamoto et al., 2001; Oh and Chung, 2011; Pal et al., 2001; Singh et al., 2001; Zhang et al., 2008) and a reduction of the Th17 T cell response (Mars et al., 2009; Oh and Chung, 2011; Waddell et al., 2015; Yokote et al., 2008). However, which iNKT cell cytokines are important for these changes is not clear. IL-4 and/or IL-10 have been suggested (Jahng et al., 2001; Miyamoto et al., 2001; Oh and Chung, 2011; Sag et al., 2014; Singh et al., 2001), but some data contradict this (Furlan et al., 2003; Mars et al., 2002; Waddell et al., 2015). Similarly, divergent results have been reported a role for IFN $\gamma$  (Pro: Furlan et al., 2003; Mars et al., 2009; Con: Jahng et al., 2001; Oh and Chung, 2011). Although iNKT cells can enter the CNS

(Jahng et al., 2001; Mars et al., 2008; Oh and Chung, 2011), this was not seen in all studies (Denney et al., 2012; Waddell et al., 2015), and it is not certain if this is required for protection. Likewise, the importance of CD1d, beyond the primary iNKT cell stimulation, has been disputed (Mars et al., 2008; Wiethe et al., 2007). Finally, other immune cells were implicated in the  $\alpha$ GalCer-induced protection against EAE, such as M2 macrophages (Denney et al., 2012) or myeloid-derived suppressor cells (MDSC) (Parekh et al., 2013) infiltrating into the CNS, or tolerogenic DCs (Kojo et al., 2005; Wiethe et al., 2007).

### **Systemic Lupus Erythematosus**

Systemic lupus erythematosus (SLE) is characterized by the production and deposition of auto-antibodies against multiple nuclear antigens, leading to chronic inflammation of various tissues. The autoantigens are thought to derive from a defective clearance of apoptotic cells. According to one current hypothesis, iNKT cells suppress auto-reactive B cells in a CD1d-dependent fashion (for earlier iNKT cell reviews see Chen et al., 2015; Chuang et al., 2012).

iNKT cells from patient's PBMCs were reduced in frequency (Bosma et al., 2012; Cho et al., 2014, 2011; Kojo et al., 2001; Parietti et al., 2010; Shen et al., 2014; Smith et al., 2016; Sumida et al., 1998, 1995; van der Vliet et al., 2001; Wither et al., 2008; Wong et al., 2009; Yu and Wang, 2011) and proliferated less after stimulation in vitro with  $\alpha$ GalCer (Cho et al., 2011; Kojo et al., 2001; Yu and Wang, 2011). Furthermore, resulting iNKT cell lines (Bosma et al., 2012; Cho et al., 2011; Kojo et al., 2001; Shen et al., 2014; Yu and Wang, 2011), or fresh iNKT cells from PBMCs (Bosma et al., 2012; Shen et al., 2014), produced fewer cytokines than controls and/or displayed a Th1 bias. The frequency of iNKT cells in PBMCs correlated in most studies with disease severity (yes: Cho et al., 2011; Parietti et al., 2010; no: Wither et al., 2008) and serum levels of auto-reactive IgGs (Green et al., 2007; Wither et al., 2008). Interestingly, the frequency of iNKT cells in peripheral blood increased following therapy (Bosma et al., 2012; Oishi et al., 2001). Whereas CD1d expression levels on APCs from patient's PBMCs and healthy subjects did not differ, a decrease of CD1d surface expression was observed on patient B cells (Cho et al., 2011), and it was suggested that B cells in SLE patients were responsible for most of the iNKT cell defects (Bosma et al., 2012). Interestingly, the incubation of patient iNKT cells with patient B cells from PBMCs augmented the production of auto-antibodies by the B cells in a CD1d- and CD40-dependent fashion (Shen et al., 2014). Similar findings were reported in animal models (Takahashi and Strober, 2008; Zeng et al., 2003).

SLE in mice is studied either with mouse lines genetically prone to develop lupus-like diseases spontaneously or in induced models by injection of either the hydrocarbon oil pristane, LPS, or apoptotic bodies in selected mouse strains. Most data are in line with the idea of a protective role of iNKT cells. Crossing lupus-prone mouse lines onto an iNKT cell-deficient background led to exacerbated disease (Chan et al., 2001; Yang et al., 2004, 2007), although this was more pronounced for some organs than others (Chan et al., 2001; Yang et al., 2004). Interestingly, aged  $J\alpha 18^{-/-}$  mice by themselves have been shown to develop lupus-like symptoms (Sireci et al., 2007). Similarly, in the induced lupus models iNKT cell deficiency exacerbated symptoms (Wermeling et al., 2010; Yang et al., 2011, 2003). However, the effect of antigenic stimulation of iNKT cells led to conflicting outcomes in the different models. In the (NZB/NZW)F1 mouse model of spontaneous SLE, injection of  $\alpha$ GalCer into young mice was beneficial, but detrimental in aged animals (Major et al., 2006; Uchida et al., 2018; Yang et al., 2007; Zeng et al., 2003). In line with a switch to a pathogenic role later in the disease is the observation that iNKT cell numbers increased with lupus progression in these (NZB/NZW)F1 mice (Forestier et al., 2005; Morshed et al., 2002; Yang et al., 2007). Furthermore, in aged mice iNKT cells become hyperactive (Forestier et al., 2005) and interfering with their activation by means of blocking glycolipids (Morshed et al., 2009) or anti-CD1d-antibodies (Takahashi and Strober, 2008; Zeng et al., 2000, 2003) ameliorated disease. However, one study reported a reduced cytokine production by iNKT cells from (NZB/NZW)F1 mice at all ages (Yang et al., 2013). Not surprisingly, strain differences are also important, as the effects of  $\alpha$ GalCer treatment in the spontaneous models affected lupus nephritis in one mouse line, but not the other (Forestier et al., 2005; Zeng et al., 2003), and likewise, a strain dependence was observed for the induced models (Singh et al., 2005).

### **Good or Bad Actors?**

In some autoimmune diseases, iNKT cell number and/or function are altered, but it is much less certain if they play a role in pathogenesis or in regulation/prevention of disease. We consider three examples here.

Sjögren's syndrome is mediated by autoimmune destruction of exocrine glands. iNKT cells in patient's PBMCs were reduced in numbers in most studies (yes: Guggino et al., 2016; Kojo et al., 2001; van der Vliet et al., 2001;

no: Papp et al., 2016), produced less cytokines (Guggino et al., 2016; Kojo et al., 2001), and tended to show a Th1 cytokine bias following antigen stimulation (Kojo et al., 2001) compared to control cells. Interestingly, no *i*NKT cells were detected in the salivary glands of patients (Guggino et al., 2016).

Celiac disease is a chronic inflammation of the small intestine driven by the adaptive immune system and triggered by dietary gluten (Stepniak and Koning, 2006). As there is to date no animal model, data on the role of *i*NKT cells are still very limited. In PBMCs from celiac patients a decrease of *i*NKT cells has been reported in most studies (yes: Bernardo et al., 2008; Cseh et al., 2011; Dunne et al., 2013; Grose et al., 2007a, 2008; no: van der Vliet et al., 2001). In addition, fewer  $V\alpha 24^+$  T cells were found in the intestine (duodenum) of celiac patients (Calleja et al., 2011; Grose et al., 2007a, 2008). However, when the analysis focused on *i*NKT cells, the results were conflicting, with one study finding an increased (Montalvillo et al., 2015) and one a decreased (Dunne et al., 2013) frequency of *i*NKT cells in the duodenum of adult patients. Interestingly, an inverse reduction was observed in patients depending on the age: *i*NKT cells were reduced in the PBMCs of adult but not pediatric patients, whereas they were reduced in the duodenum only in pediatric but not in adult patients (Dunne et al., 2013). Furthermore, it has been suggested that patient *i*NKT cells produced less cytokine following in vitro stimulation (Grose et al., 2007a, 2008). In patients the adherence to a gluten-free diet normalized symptoms, and interestingly, this improvement correlated with a normalization of the *i*NKT cell numbers in PBMCs (Bernardo et al., 2008; Calleja et al., 2011; Cseh et al., 2011).

Experimental autoimmune uveitis (EAU) is a chronic inflammatory eye disease that can be induced in animals by immunization with retinal antigens and which serves as a model for human autoimmune uveitis (Kielczewski and Caspi, 2015). During EAU up to 7% of the eye-infiltrating mouse lymphocytes were *i*NKT cells (Oh et al., 2010) and in most studies *i*NKT cell-deficient mice showed an exacerbated course of disease (protective: Oh et al., 2010; Satoh et al., 2016; no difference: Grajewski et al., 2008). Furthermore, stimulation of *i*NKT cells at the time of the immunization ameliorated the disease (Grajewski et al., 2008; Satoh et al., 2016), presumably due to the action of IFN $\gamma$  (Grajewski et al., 2008; Satoh et al., 2016). In line with the role of IFN $\gamma$  was the observation that a Th1-biasing *i*NKT cell antigen (C-Glycoside) was most potent at protecting mice during EAU (Grajewski et al., 2008), although a Th2-biasing antigen was effective too (Grajewski et al., 2008; Satoh et al., 2016). Interestingly, though, the production of IFN $\gamma$  by *i*NKT cells themselves was not necessary, as *i*NKT cells deficient for IFN $\gamma$ , IL-4, or IL-10 were equally protective (Oh et al., 2010). From a therapeutic viewpoint, however, it is important to note that the stimulation of *i*NKT cells at the onset of the disease exacerbated EAU (Satoh et al., 2016). Together, it suggests that *i*NKT cells are beneficial for EAU early in the disease, but detrimental at later stages.

## THE FAR END OF THE QUESTION?

What emerges from this summary is that unlike some other T lymphocyte subsets, for example, Foxp3 $^+$  Tregs, *i*NKT cells have diverse effects on autoimmune disease pathogenesis. How can we account for this, considering their limited TCR diversity and essentially clonal specificity? Two main questions capture the potential involvement of *i*NKT cells during autoimmune diseases: (1) what draws *i*NKT cells in, and (2) what effects do they initiate?

### What Activates Invariant Natural Killer T Cells During Autoimmune Responses?

It is likely that *i*NKT cells need some form of activation to be involved in disease progression and like conventional T cells this could be modulated by differences in signal 1 (TCR), signal 2 (costimulation), and signal 3 (cytokines).

- Signal 1 (TCR): Beyond the inherent auto-reactivity of *i*NKT cells, CD1d-mediated activation of *i*NKT cells could conceivably be augmented in inflammatory settings by several means: (1) up-regulation of CD1d on APCs; (2) the increased presentation of stimulatory self-antigens, for example, following metabolic changes in activated APCs; (3) the presentation of stimulatory neo-antigen; and (4) so far unknown foreign antigens, for example, from commensals or opportunistic pathogens. Furthermore, heterogeneity in the outcome of *i*NKT cell activation could arise from the fact that different glycolipids can elicit divergent cytokine responses, and also, different *i*NKT cell subsets respond differently to the same antigen.
- Signal 2 (costimulation): Besides the “classical” means of *i*NKT cell activation, additional pathways of activation have been described, some of which are known to be important for T cell costimulation. Well-

known costimulatory molecules such as CD28 (Hayakawa et al., 2001; Kawano et al., 1997; Wang et al., 2009) and CD154 (CD40L) (Hayakawa et al., 2001; Kawano et al., 1997) can affect *i*NKT cell activation but so can other members of the TNF super family such as 4-1BB (Kim et al., 2008) and OX40 (Diana et al., 2009). The Ig superfamily molecule CD279 (PD-1), known as a coinhibitory molecule, plays a role in modulating *i*NKT cells in mouse asthma models (Akbari et al., 2010). In addition, there are other receptors that can modulate *i*NKT cell stimulation, including NK receptors (Arase et al., 1996; Exley et al., 1998; Ortaldo et al., 2006), Fc $\gamma$ RIII during arthritis (Kim et al., 2006), adenosine receptors (Lappas et al., 2006), and  $\beta$ -adrenergic receptors (Wong et al., 2011). Some of these, such as the NK receptors, can act independently of TCR stimulation, while others apparently act in concert with the TCR. Although there is still limited information, one might expect that different *i*NKT cell subsets likely express different sets of these receptors and will, therefore, respond differently. As these effects are cell–cell contact dependent, they are also dependent on the migratory behavior of *i*NKT cells to allow them to interact with a given APC.

- Signal 3 (cytokines): Activation of *i*NKT cells by cytokine combinations, such as IL-12/IL-18, IL-1 $\beta$ /IL-23, IL-25, and TGF $\beta$ , have been outlined above. Additional cytokines have been suggested to modulate *i*NKT cell responses, including IL-2 (Sakuishi et al., 2007), IL-7 (Hameg et al., 1999), IL-15 (Li et al., 2006), IL-33 (Bourgeois et al., 2009; Smithgall et al., 2008), GM-CSF (Crough et al., 2004), the prostaglandin D<sub>2</sub> (PGD2) (Torres et al., 2008), and TSLP (Jariwala et al., 2011; Wu et al., 2010). Many of these cytokines can be secreted in affected tissues during autoimmune-mediated inflammation. Therefore different combinations of local cytokines could induce diverse responses from *i*NKT cell subsets that express the appropriate cytokine receptors.

However, many other signals could be relevant as well, and given the gender-bias for many autoimmune diseases, sex hormones are one important aspect in this context. *i*NKT cells were reported to be more frequent in females than in males in some (Kee et al., 2012; Montoya et al., 2007; Sandberg et al., 2003) but not all (Bernin et al., 2016; Jing et al., 2007; Snyder-Cappione et al., 2010) studies. Furthermore, it was suggested that sex hormones could modulate the cytokine production by *i*NKT cells (Gourdy et al., 2005; Lotter et al., 2013).

Therefore the *i*NKT cell–mediated influence on the immune response depends on the means by which a particular *i*NKT cell gets activated. This reflects a complex “information input” that depends on the subset characteristics of the *i*NKT cell, the particulars of the local cytokine milieu, and the type and activation status of the APC they interact with.

## How Do Invariant Natural Killer T Cells Influence Autoimmune Responses?

The different “inputs” causing the activation of *i*NKT cells lead to different “outputs” or *i*NKT cell responses that will affect autoimmune disease pathogenesis in different ways. Three aspects will be highlighted here.

- Cytokine bias: The bias toward Th2 cytokines and a reduction of Th1/Th17 responses imparted by *i*NKT cells seems to be most often proposed as the mechanism for the effects of *i*NKT cells in autoimmune diseases. This is in line with the observations that *i*NKT cells are an important contributor to early IL-4 production in some contexts and that Th2-biasing antigens can have superior effects than  $\alpha$ GalCer in some cases. *i*NKT cells can impact the Th1/Th2 balance via their cytokine production, whereby IL-4 and IL-13 promote Th2; IFN $\gamma$  and TNF promote a Th1 response; IL-10 and TGF $\beta$  suppress pathogenic Th1 responses; and under some circumstances even IFN $\gamma$  has been shown to contribute to the development of Th2 responses (Bocek et al., 2004). However, newer data paint a more complex picture and the Th2-bias is clearly not sufficient to explain all observations. Importantly, beyond the Th1/2 paradigm Th17 responses can be pathogenic (Weaver and Hatton, 2009; Weaver et al., 2007) and *i*NKT cells have shown to be effective at suppressing Th17 responses. Furthermore, other *i*NKT cell–derived soluble factors can play a role, dependent on the particular disease, its stage, and many other circumstances.
- Direct regulation of cells: Besides a general cytokine bias, more direct *i*NKT cell driven mechanisms have been suggested. NKT10 cell–derived IL-10 is immunoinhibitory (Sag et al., 2014; Lynch et al., 2015). Furthermore, IFN $\gamma$  can aid in the induction of anergy or apoptosis in antigen-specific Th1 T cells and this was suggested to be important in diabetes (Beaudoin et al., 2002; Hugues et al., 2002; Novak et al., 2005). In addition, IL-4, IL-10, or GM-CSF can promote the differentiation/recruitment of myeloid cells with tolerogenic properties, such as DCs (Kojo et al., 2005; Naumov et al., 2001; Wang et al., 2008), MDSCs (Huang et al., 2014; Parekh et al., 2013), macrophages (Denney et al., 2012; Lynch et al., 2015), and neutrophils (De Santo et al., 2010). In addition,

*i*NKT cells can under some circumstances aid in the induction of regulatory T cells, either via tolerogenic DCs, pDCs, or via cytokines such as IL-2, IL-10, and TGF $\beta$  (Beaudoin et al., 2014; Diana et al., 2011; Kojo et al., 2005; La Cava et al., 2006; Liu et al., 2005; Ly et al., 2006; Lynch et al., 2015). Furthermore, cell–cell contact-dependent mechanisms are important, either via costimulatory molecules or via retrograde CD1d-signaling (Olszak et al., 2014; Sáez de Guinoa et al., 2018; Yue et al., 2009).

- *i*NKT cell subsets: Due to the increased awareness of *i*NKT cells subsets, at least in the mice, it becomes increasingly clear that different *i*NKT cell subsets can play different roles during autoimmune responses. NKT1 cells are protective, for example, in asthma (Chuang et al., 2018) and RA (Zhao et al., 2018), whereas NKT17 are pathogenic, for example, in diabetes (Simoni et al., 2011) and RA (Zhao et al., 2018). In addition, the timing of *i*NKT cell action might be critical, as exemplified in RA, where a switch from protective NKT1 cells to pathogenic NKT17 cells is seen with disease progression (Zhao et al., 2018). Therefore the impact of *i*NKT cell subsets can be beneficial or detrimental at different stages of the disease. Furthermore, NKT10 cells have been shown to be beneficial during EAE (Sag et al., 2014) and in the adipose tissue (Lynch et al., 2015; Sag et al., 2014), indicating that organ-specific preferences for *i*NKT cells could play a role as well.

The diverse means by which distinct *i*NKT cell subsets are activated, and the different responses they make, are of course not mutually exclusive. This complexity surely contributes to some of the contradictory results on the role of *i*NKT cells in particular autoimmune diseases.

## CONCLUSION

As outlined here, *i*NKT cells have been shown to be crucially involved in a wide range of autoimmune responses. Whereas it seems at first puzzling that a relatively small population has so many effects, one should keep in mind that even if present at less than a 1% frequency, *i*NKT cells are as abundant as typical CD4 $^+$  T cell memory populations, and they can exert their pivotal role due to their clonal specificity and explosive cytokine production. However, despite the vast literature on the role of *i*NKT cells in autoimmune diseases, much remains to be learned.

One important question, of course, is the extent to which the knowledge gained from animal models can be applied to humans. Although data from human patients are still relatively scarce, in several contexts they do suggest roles for *i*NKT cells that are comparable to the ones observed in mice. This is indeed very promising. Furthermore, we expect that soon functionally distinct *i*NKT cell subsets will be better characterized in humans, which most likely will help to readdress more specifically the role of *i*NKT cells in autoimmune diseases. A related issue is the potential of stimulating or inhibiting *i*NKT cells for therapeutic purposes. Despite the fact that  $\alpha$ GalCer is used already in clinical trials for cancer, and other glycolipids and approaches for manipulating *i*NKT cells are in trial or are being planned, the therapeutic potential of *i*NKT cells remains to be validated. The therapeutic potential is great, however, because basically all individuals have *i*NKT cells that respond to the same antigens in a comparable fashion.

## INTRODUCTION—WHAT HAS TO BE GENERATED IN B-CELL DEVELOPMENT TO MAKE IT TO MATURITY?

One B lymphocyte makes one antibody, which it displays on the cell surface in  $10^4$ – $10^5$  copies as antigen-recognizing B-cell receptors (BCRs). This central dogma of immunology (Jerne, 1955; Burnet, 1959) is observed in 98%–99% of all B cells for the immunoglobulin (Ig) heavy (IgH) chain locus, and in 95%–97% of all Ig light (IgL) chain loci. Hence, in the majority of all B cells only one of the two IgHs, and only one of the four (in the mouse) or six (in humans) IgL loci are expressed. This choice of only one IgH and one IgL allele for the expression of protein is called “allelic exclusion” (for reviews see Melchers and Rolink, 1999, 2006).

The repertoires of different antigen-specific BCRs can maximally contain the number of Ig-producing B lymphocyte-lineage cells that produce one IgH and one IgL chain. From the cellular dynamics of B-cell development one can try to estimate how many B lineage cells are generated in the lifetime of a mouse or a human; how

many of these B lineage cells make it to a successful, Ig-producing B cell; and how many of these Ig<sup>+</sup> B cells make it into the pools of peripheral, mature, antigen-reactive B cells. The antibody repertoire which is generated from progenitor cells by V(D)J rearrangements in the IgH and IgL chain gene loci is so diverse that many of the developing B cells can recognize autoantigens, and some are even polyreactive to several antigens (Zhou et al., 2007). At the first immature stage of B-cell development, these autoreactive B cells are eliminated (Lederberg, 1959) in the primary lymphoid organ in a process termed “negative selection” (during adult life in bone marrow), at cellular sites yet to be discovered, before they can reach the peripheral sites of mature B cells. Pools of mature B lymphocytes are found at different sites in the body in different numbers and at different stages of differentiation from newly generated cells to antigen-experienced memory cells and antibody-secreting plasma cells. In a 6–8-month-old inbred strain of mice, such as C57BL/6, such mature cells are predominantly found at three types of sites of the body that accommodate either B1, marginal zone (MZ) or B2 B cells.

## FOLLICULAR B CELLS

In the follicular regions of spleen and lymph nodes, B cells aggregate in “B cell-rich” areas and find themselves surrounded, in the neighborhood of follicular helper T lymphocytes (King, 2009), ready to react to foreign antigen, but—in the absence of foreign antigen—over 98% are in a nonstimulated, resting, G<sub>0</sub> cell cycle state. Clearly, they are not stimulated by autoantigens present in their neighborhood. Newly generated B cells are short lived, with half-lives of less than a week. Experience by exposure to stimulation (e.g., by antigen) induces a longer half-life, in some cases of weeks and months. T cell-dependent stimulation in expanding germinal centers (Klein and Dalla-Favera 2008) at the interphase between T and B cell-rich regions induces not only longevity, but also hypermutations of V regions of IgH and L chain genes at rates of  $10^{-3}$  per base pair per division of the proliferating B cells, so that every cell division generates a somatic mutant in the variable regions of IgH and IgL chain genes. Hypermutating B cells in the dark zone of germinal centers divide at least once every 18 hours and maybe even more rapidly, for example, with cell cycle times of 6 hours, a finding that is paradoxical if DNA replication during the S phase of the cell cycle takes 8 hours and needs further investigation (Gitlin et al., 2015).

Therefore this proliferative expansion generates at least 1000 V region-mutant B cells from one antigen-stimulated B cell in a week. It is not the subject of this review but should be noted that such hypermutations are likely to generate long-lived, autoantigen-reactive mature B cells that need to be silenced, not to elicit an autoaggressive response. It is also clear that the antigen-driven expansion of mutant B cells increasingly contributes to the total B-cell repertoires as life goes on.

T cell-dependent stimulation of follicular B cells also induces IgH-class switching and B-cell differentiation to Ig-secreting plasma cells, followed by the migration of resting, long-lived, hypermutated, and Ig class-switched “memory” B cells and Ig-secreting plasma cells (Shapiro-Shelef and Calame, 2005) out of the follicular regions of spleen and lymph nodes, maybe even out of the secondary lymphoid organ and into specific sites (“niches”) within spleen and bone marrow (Tokoyoda et al., 2010; Weill et al., 2013). It has been estimated that a 6–8-week-old C57BL/6 mouse has around  $5 \times 10^8$  of these B2 cells, but a more detailed quantitation of the sizes of these different B-cell subpopulations with age is missing for mice and humans.

## INTRAEPITHELIAL B CELLS

In the gut-associated (and lung-associated) epithelia B lymphocytes are located at two distinct sites: in the gut they are found in follicular structures, surrounded by T lymphocytes not unlike in spleen and lymph nodes, near flat epithelial cells which are suspected to allow permeation of food- and commensal bacteria-derived antigens from the lumen into these lymphoid cell aggregations. Separate from these aggregations, single B lymphocytes and Ig (predominantly M and A)-secreting plasma cells are dispersed in the lamina propria of the gut, from where their secreted IgA can traverse the epithelium and the mucous membranes into the lumen to interact with antigens of food and with commensal bacteria. Many of these so-called B1 lymphocytes (Baumgarth, 2011; Montecino-Rodriguez and Dorshkind, 2012) appear somehow activated (as they are slightly larger and, occasionally, enter cell cycle), and it has been suggested that these B cells are reactive, or at least cross reactive, to autoantigens and such “quasi-autoantigens” as food and commensal bacteria. B1 cells need the spleen to develop (Wardemann et al., 2002). It is, therefore, possible that these B1 cells are positively selected by autoantigens by a

low-affinity reaction of their BCRs with these autoantigens present at these sites. Many of them can respond to antigens in the absence of helper T cells and, hence, to T cell-independent antigens. Many of them can activate activation-induced cytidine deaminase (Muramatsu et al., 2000; Revy et al., 2000) for Ig class switch recombination, again apparently without the help of T cells, but this class switch is almost entirely to IgA, and their capacity to hypermutate their V regions is very limited. It is not clear whether both populations of B cells in the gut, those organized in aggregates and surrounded by T cells near flat epithelium, and the others, the single B cells in the lamina propria, are B1-type cells.

Furthermore, and in contrast to conventional, B2-type B cells, B1 cells are able to repopulate their compartments after adoptive transfers and show strong clonal persistence in vivo. Thus they can be considered to have “stem cell”–like properties, for example, the capacity of migration to the right sites (e.g., gut) and the property of long-term (LT) self-renewal. Many of the B lymphocytes at these sites can be characterized as B1-type cells. In a 6–8-week-old C57BL/6 mouse around  $5 \times 10^8$  cells may be found, that is, as many as there are conventional B2-type cells in follicular regions of spleen and lymph nodes, but these numbers vary considerably with the health of the animal. B1 cells are considered to be the main source of so-called natural antibodies (Hooijkaas et al., 1984; Bos et al., 1989). Again, a more precise quantitative analysis of the sizes of these B1 compartments with time is missing.

All these B-cell sites are connected by blood and lymph vessels. Hence, when B lymphocytes are first generated in primary lymphoid organs, they enter the peripheral immune system via the blood, mainly through the central artery in the spleen from where they distribute themselves via the MZ to the different locations. Some MZ B cells probably continue their travel to the gut- and lung-associated lymphoid regions where many of them establish themselves as B1-type B cells. Other MZ B cells begin to migrate continuously from the MZ into the follicular regions of spleen and back (Arnon et al., 2013). Eventually, they also emigrate from the MZ to peripheral lymphoid organs, such as lymph nodes. In the peripheral lymphoid organs, B cells can become experienced by antigenic stimulation, then circulate back, and reappear in the MZ of the spleen. This may, on rare and ill-understood circumstances, even allow them to change their preimposed preference to circulate back to the peripheral lymphoid site from whence they came and redistribute themselves into another site in the system. For a site-specific distribution into B1-, MZ-, or B2-rich areas they need to be directed by specific chemokines, but it remains unclear whether (low affinity) recognition by autoantigens influences their choice of the B1 compartments, and whether ignorance (lack of any affinity) of autoantigens allows their aggregation in follicular B2 zones in spleen and lymph nodes. In addition, autoantigen recognition at nonlymphoid sites (e.g., in the articular synovial fluid of joints during active phases of rheumatoid arthritis) may contribute to the formation of lymphoid follicular structures capable of performing germinal center reactions at unusual, normally nonlymphoid sites in the body.

## TWO TYPES OF MEMORY B CELLS

The distinction between B1 and B2 cells, particularly striking in the way memory, is maintained in antibody-producing B cells. Longevity in the B1 compartment appears to be connected to the continuous presence of the antigen and to its stimulation to maintain an antigen-specific, long-lived, modestly activated state. Whenever such B1 cells show LT repopulation potential upon transplantation, with longevity and persistence in the areas of the gut-associated lymphoid tissues, a continued low-level antigenic stimulation via the BCR is suspected to be the selecting and survival-inducing signaling force. Food- or commensal bacterially derived antigens, maybe with low-level cross-reactivity with autoantigens, could be such BCR-mediated selecting forces. It is suspected that this cross-reactivity to autoantigens is beneficial to positively selecting and expanding the first line of B cells that encounter microbes which colonize the body after birth.

Memory B2 (classical) B cells and long-lived plasma cells have properties of LT repopulating hematopoietic stem cells (LT-phHSCs) (Wagers and Weissman 2004; Luckey et al., 2006; Eliasson and Jönsson, 2010; Lesinski et al., 2012). They can migrate to, and become resident in, “niches” of spleen and bone marrow as LT resting cells for long, in some cases life-long, periods of time. They retain this property when they are transplanted. We expect memory B2 cells not to rely on continuous low-level stimulation via BCRs for survival. Their LT resting persistence should be independent of the presence and continuous stimulation by an antigen. Antigen-dependent restimulation mobilizes these resting B2 cells to leave their “niches,” and it remains to be seen how antigen-specific this mobilization really is, that is, whether memory cells specific for other, unrelated antigens are comobilized. Once the mobilized B2 memory cells have arrived at a peripheral lymphoid organ (e.g., a lymph node), the

rechallenging antigen will activate the antigen-specific memory B2 cells to a memory-type B-cell response, while those mobilized memory cells that are not specific for the challenging antigen may remain resting and may return to their sites of rest in spleen and bone marrow.

Once the peripheral, mature, B lymphoid sites in the body have been formed and filled, a constant number of cells appear to maintain a given size by (largely unknown) mechanisms of homeostasis. Since the large majority of B cells are expected to turn over within days, weeks, or months, it follows that these B-cell populations must be continuously replenished during life. However, the relative, and even the absolute, sizes of different B-cell compartments change with age.

The description of the different B-cell compartments, restricted to a few inbred strains of mice at a restricted time in their life, is far more detailed than that of humans—not to mention other species such as other mammals, fish, or birds. B1, MZ-, and conventional B2 compartments, comparable but not necessarily identical to a mouse, have been found and defined in humans (Descatoire et al., 2011). Very generally summarized, humans with a 1000-fold higher body size than mice have a thousand times more B cells with similar sites of cellular organization of similar subpopulations with similar functions. However, we lack a more systematic comparison with age and immunological experience of the two species, as these are studied for different reasons—mice, because of the tremendous experimental opportunities to study and interfere with its immune system, and humans, often because of self-centered, health-minded interests. The limitations of the description of B-cell development that follows should be seen in this light.

## B LYMPHOPOIESIS BEFORE IG REPERTOIRE GENERATION—DEVELOPMENT OF PROGENITOR AND PRECURSOR CELLS

Lymphocyte development occurs in two phases. In the first phase, cells are developed in sufficient numbers to the stage at which they first express an antigen receptor. Obviously, this phase is independent of any influence by antigen, because the antigen receptors have not yet been made. Developing hematopoietic cells on their way to B lineage cells enter a series of decisions, which are influenced by their interactions with an inductive microenvironment. Once they are committed to the B lineage cells they begin the second phase, when they begin to express BCRs.

## DEVELOPMENT IN WAVES DURING ONTOGENY AND IN NICHES THROUGHOUT LIFE

Three waves of hematopoietic cell developments colonize the mouse embryo (Cumano et al., 2001; Godin and Cumano, 2002; Ling and Dzierzak, 2002). The first wave (primitive hematopoiesis) begins at embryonic day (E) 7.5 in yolk sac, that is, extra embryonically. This wave, initially, does not develop B lymphocytes, but only fetal-type hemoglobin-expressing erythrocytes, megakaryocytes, platelets, and special types of myeloid cells—the latter with unusual longevity (Irion et al., 2010; Schulz et al., 2012). However, they develop B1-type B cells, when they can enter the developing fetal liver from day 12 of embryonic development. The second and third waves of (now definitive) hematopoiesis originate intraembryonically at E10.5 from the aorta-gonad-mesonephros area (Medvinsky and Dzierzak, 1996), from where undifferentiated pHSCs (Ohmura et al., 2001; Cumano and Godin, 2007; Yokomizo et al., 2011) migrate through embryonic blood to developing rudiments of fetal liver, omentum, thymus, and bone marrow. B cells develop in fetal liver, omentum, and bone marrow, probably in a process involving the transmigration of pHSCs from inside the blood vessels through vascular endothelium, to further differentiate on the other side in contact with mesenchymal and epithelial microenvironments (Tsuneto et al., 2013; Kajikhina et al., 2016). Since B1 cell development in fetal liver occurs in one wave between E12.5 and birth of a mouse, this organ never establishes a niche for LT residing pHSCs.

By contrast, bone and its marrow—which generates B1 and B2 cells throughout life—is capable of developing “niches” of LT resting pHSCs in the neighborhood of, and in close contact with, nonhematopoietic stromal cells. It secures a continuous, life-long generation of new hematopoietic cells, hence B lymphocytes also (Lu et al., 2011). The niches for pHSCs appear localized at subendosteal sites near intrabone surfaces that allow the LT residence of pHSCs with the capacity to LT reconstitute a lethally irradiated host with all lineages of hematopoietic cells, including B lymphocytes. LT-pHSCs exist in different states of the cell cycle. In one state, they are activated into the cell cycle, that is, they divide. One of the two asymmetrically dividing daughter pHSCs keep their stem

cell status, hence they self-renew, while the other daughter cell differentiates to short-term (ST) repopulating HSCs that retain hematopoietic pluripotency, that is, capacity to differentiate to multipotent myeloid/lymphoid progenitors (MPP), to common myeloid progenitors, and to common lymphoid progenitors (CLP), from which B lineage cells develop (Akashi et al., 1999).

In the other state, they are resting in a G<sub>0</sub> state of the cell cycle and consume low levels of energy in a subosteal, hypoxic microenvironment. From this resting state, a small number of cells can be mobilized (stem cell mobilization) to enter the cycling state. However, cycling LT-pHSCs might also revert back to a LT resting state. Bone marrow microenvironments appear uniquely specialized to harbor resting, long-time residing cell types, such as LT repopulating pHSCs, memory lymphocytes, and plasma cells. Among all LT-pHSCs in the resting cell population, only a minor subfraction of cells is “mobilized” at any time to enter asymmetric cell divisions and, because of this, only a part of all LT resting pHSCs participate in hematopoiesis at any given time. This might allow the hematopoietic cell system to continuously refresh its pHSC pools by new, unused pHSCs, thereby preserving its genetic integrity and protecting itself from adverse somatic mutations in actively proliferating pHSCs—mutations that could contribute to breaking tolerance to autoantigens. LT-pHSC can also leave the bone marrow, circulate through blood in the periphery (Pierce et al., 2017), maybe pick up bacteria from centers of infections (Tornack et al., 2017), and reenter the bone marrow. On the other hand, if cycling LT-pHSCs can revert back to the G<sub>0</sub> LT resting state, their somatically mutated genetic constitution might increase the chances for abnormal hematopoiesis and B lymphopoiesis with age (Rossi et al., 2007).

## CELLULAR ENVIRONMENTS OF THE FIRST PHASE OF EARLY, ANTIGEN-INDEPENDENT B-CELL DEVELOPMENT

Early embryonic phases of the first wave of B-cell development in the fetal liver of the mouse can be studied *in situ* in histological sections as the organ develops with time. Attracted by the chemokine ligands CXCL10 and CXCL12, produced by nonhematopoietic vascular endothelial cells and mesenchymally derived stromal cells, CXCR3 and CXCR4-expressing pHSCs and other early progenitors transit from embryonic blood through vascular endothelium into the developing fetal liver and migrate inside to mesenchymally derived stromal cells. These nonhematopoietic cells provide the hematopoietic and B-lymphopoietic progenitors with interleukin-7 (IL-7), the cytokine which is mandatory to interact with IL-7 receptors (IL-7 R) on the hematopoietic progenitors to induce the early, antigen-independent stages of B1 cell development (Tsuneto et al., 2013, Kajikhina et al., 2016). Thymic stromal lymphopoietin has been implied as an alternative stimulating cytokine in fetal liver (Montecino-Rodriguez et al., 2006).

Microenvironmental influences of these early phases of B-cell development during the second continuous wave of B-cell development in developing bone are mostly yet to be discovered, but it appears reasonable to expect that, by similar modes, pHSCs will have to transit from embryonic blood into the environment of developing bone and marrow, and that IL-7, again, is the major force that drives the early phases of B-cell development. Notably, the role of IL7 is less clear in human B-cell development. While fetal liver generates almost exclusively B1a cells, bone marrow develops B1- and B2-type B lymphocytes, but the B1 cells, called B1b, differ from the embryonically developed B1a cells. Transplantation of E13.5 fetal liver pHSC-like cells, upon transplantation, repopulate the host preferentially with B1 cells, while transplantations of pHSCs and progenitors from adult mice repopulate the host preferentially with B2 lymphocytes. Bone marrow retains this capacity, though the numbers of pHSCs decrease with increasing age by at least 100-fold in 1 year of the life of a mouse.

B1a cells generated in fetal liver also differ in some properties from B1b and B2 cells generated in bone marrow. Since the enzyme terminal deoxynucleotidyl transferase (TdT)—which inserts N-region nucleotides at VDJ joints during Ig gene rearrangements—is not expressed in fetal liver (but only in bone marrow) the repertoires of newly generated BCRs are less diverse. How much that influences the capacities of these early embryonic repertoires to recognize and distinguish foreign from autoantigens is still not clear. B1a cells from fetal liver express CD5, a cell surface marker indicating cell activation, while most bone marrow-derived B1b cells do not. Furthermore, micro-RNAs play regulatory roles in the development of fetal liver-derived B1a and bone marrow-derived B cells. Thus the gene Lin28b is selectively expressed in hematopoietic progenitors of fetal liver, but not of adult bone marrow. It downregulates the expression of a family of miRNAs, the let7 miRNA cluster. Ectopic expression of Lin28 in bone marrow-derived pHSCs and progenitors reprograms B-cell development, so

that B1a cells are generated. These results argue for the existence of two B-cell lineages, B1a and B2 (including, maybe, B1b), which are developed as two consecutive layers of B-cell repertoires (Tung et al., 2006; Montecino-Rodriguez and Dorshkind, 2012).

## EARLY COMMITMENTS TO ANTIGEN-INDEPENDENT B-CELL DEVELOPMENT

The initiation and maintenance of the development of B lymphoid lineage cells from pHSCs, MPP, CLP, and pro-/pre-B cells to pre-BI cells, before the generation of sIgM + immature and mature B cells, is controlled externally by a microenvironment of nonhematopoietic (and maybe also hematopoietic) cells that provide cell contacts, cytokines, and chemokines for their mutual attraction, proliferation, and differentiation. ST-pHSCs are induced from LT-pHSCs by the action of FLT3 ligand, acting on flt3, to become MPPs, and after IL-7 has induced IL-7R-expressing progenitors to enter the lymphoid pathway of differentiation. Inside the hematopoietic cells signal transducing and gene transcription-controlling factors regulate these processes of proliferation, cell survival, and differentiation. Three transcription factors, that is, E2A, EBF, and Pax5 (Bain et al., 1994; Zhuang et al., 1994; Sigvardsson et al., 1997; Kee and Murre, 1998; Roessler and Grosschedl, 2006; Kwon et al., 2008), control B-cell development from CLP. By contrast, little is known how microenvironments influence the choices of a multipotent progenitor to become myeloid or lymphoid and how an oligopotent common lymphoid progenitor is influenced to become either a natural killer (NK) lineage, T lineage, or B lineage cell. While these decisions should have no influence on the repertoires of IgH and IgL chains that are generated, they may well be important for the efficiencies with which B cells are provided among the mature pools of cells. Over- or underproduction of B lineage cells could well have an influence on the functions of these B-cell pools.

The molecular details of the transcriptional activation of B-cell development have been clarified in remarkable detail (Decker et al., 2009; Ebert et al., 2011; Medvedovic et al., 2011; Revilla-I-Domingo et al., 2012; Vilagos et al., 2012). First, E2A begins to be transcribed as early in hematopoiesis as in pHSCs. In these cells the promotor of Pax5 remains silenced while its enhancer is activated. One developmental stage later, in MPP, E2A directly activates the expression of early B-cell factor (EBF). This remains the pattern of gene activation, until the Pax5 promoter is activated in pro-/pre-B cells. This allows EBF to bind to the Pax5 promoter, and PU.1, IRF-4, IRF-8, and nFkB to bind to the activated Pax5 enhancer. EBF-complexed promoter and PU.1/IRF-4/IRF-8/nFkB-complexed enhancer form a supercomplex that allows the expression of Pax5. Pax5 then induces a large number of genes involved in the early and late steps of B-cell development, while downregulating the expression of genes involved in myelopoiesis (Schebesta et al., 2007). Finally, Pax5 expression is terminated when differentiation to Ig-secreting plasma cells is induced (Shapiro-Shelef and Calame, 2005; Delogu et al., 2006; Ochiai et al., 2013).

Targeted deletions of the genes encoding these transcription factors result in blocking of B-cell development at different developmental stages. E2A-deficient progenitor B cells have not yet entered DH to JH rearrangements at the IgH chain locus (Ikawa et al., 2004), whereas EBF-deficient and Pax5-deficient progenitors have done so, the latter on both alleles (Rolink et al., 1999). Both EBF- and Pax5-deficient CLP-like pro-/pre-B cells from bone marrow can be established as stable cell lines proliferating for long periods of time, such as pre-BI cell lines (Rolink et al., 1991), identifiable as clones of cells by their individual sets of DHJH-rearranged IgH chain alleles on stromal cells (providing stem cell factor, the ligand of c-kit, and IL-7), added in sufficient quantities *in vitro* by the recombinant cytokine.

The Pax5-deficient progenitors are remarkably flexible cells. Clones of these cells, genetically marked by individual sets of DHJH/DHJH rearrangements at their IgH chain alleles, respond to different cell contacts and cytokines by different differentiation programs. Thus *in vitro* they can be induced to macrophages by macrophage colony-stimulating factor (M-CSF), to dendritic cells by granulocyte-M-CSF (GM-CSF) and M-CSF, to granulocytes by GM-CSF and G-CSF, to NK cells by IL-2 and IL-15, to osteoclasts by TRANCE expressed on mesenchymally derived stromal cells, and to thymocytes by mesenchymally derived stromal cells expressing the NOTCH ligand DELTA-1 in the presence of FLT3 ligand and IL-7, while their development to B cells—which is induced by stromal cells in the presence of FLT3 ligand and IL-7 in Pax5<sup>+/+</sup> cells—is blocked by the Pax5 deficiency (Nutt et al., 1999; Rolink et al., 1999; Höflinger et al., 2004; Radtke et al., 2004).

Removal of the cytokine IL-7 *in vitro*, or transplantation into suitable recipient mice *in vivo*, induces the differentiation to VHDJH/VLJL-rearranged, sIgM + immature B cells—however only of wild-type—but not of EBF- or Pax5-deficient cells. *In vivo* mature B1 cells (Hayakawa et al., 1985) develop from fetal liver as well as bone marrow-derived wild-type cell lines, detectable in spleen and peritoneum of recombination activating gene

(RAG)-deficient recipient mice. From fetal liver cell lines, B1a cells develop, while bone marrow-derived cells generate B1b cells (Hayakawa et al., 1985; Végh et al., 2010).

In the presence of T cells, as in JH-T mice, or in RAG-deficient mice cotransplanted with CD4<sup>+</sup> (and CD4<sup>+</sup>25<sup>+</sup>) T cells), B2-type follicular B cells are also formed, mainly in the spleen. These wild type-, fetal liver-, or bone marrow-derived Pax5-expressing cells do not repopulate the bone marrow. By contrast, Pax5-deficient pro-/pre-B cells do migrate and reside after transplantation to bone marrow (Schaniel et al., 2002a,b), and this homing to bone marrow, also a characteristic of earlier cellular stages of hematopoiesis (including pHSCs), is controlled by miR221 (Knoll et al., 2013). The expression of externally added, that is, retrovirally transduced Pax5 induces B-cell differentiation to CD19<sup>+</sup> pre-BI cells, but not beyond, since the Pax5-deficient pro-/pre-B-cell lines express an endogenously VH(7183)DHJH-rearranged IgH chain that apparently affects allelic exclusion (Simmons et al., 2012). It is still not clear whether such premature IgH chain rearrangements also occur during normal B-cell development *in vivo*, and, if so, how such cells overcome the arrest due to allelic exclusion—maybe by VH gene replacements.

The LT proliferating pro-/pre-B and pre-BI cell lines have been successfully used in experiments which have investigated the transgenic expression of genes active in B-cell development and their functions *in vivo*, such as graded Pax5 expression in Pax5<sup>2/2</sup> cells to biphenotypic myeloid/lymphoid cells, or miR221 expression in pre-BI cells, inducing cell migration to bone marrow, or the synergistic transforming activities of two oncogenes, one, pim-1, inhibiting apoptosis and the other, c-myc, inducing proliferation of pre-B cells to form pre-B lymphomas (Bouquet and Melchers, 2012; Wolf et al., 2016, 2017). Unfortunately, such transduced expression of individual antibody genes has not yet been achieved, because the IgH chain gene cannot be expressed at the appropriate stage of B-cell development but is induced too early, blocking normal B-cell development due to allelic exclusion.

## THE SECOND, EVENTUALLY AUTOANTIGEN-SENSITIVE, PHASE OF B-CELL DEVELOPMENT TO SIGM<sup>+</sup> IMMATURE B CELLS

In the second phase of B-cell development, Ig genes are rearranged, Ig H and L chains are made, deposited as pre-BCRs and BCRs on the cell surface and molecularly linked to intracellular signaling pathways. V(D)J rearrangements at the Ig loci occur stepwise at different cellular stages of B-cell development. The emerging repertoires of IgH and L chains are screened successively at two checkpoints, at the first for their fitness by pre-BCR formation and at the second for autoantigen recognition after BCR formation.

After IL-7 has induced IL-7R-expressing lymphoid/myeloid progenitors to enter the lymphoid pathway of differentiation, the rearrangement-active genes RAG1 and 2 and TdT (the latter only in bone marrow, not in fetal liver), as well as the genes encoding the Ig membrane anchoring molecules Ig alpha and beta, and the components of the surrogate light chain (SLC), Vpre-B, and lambda5, become expressed in CLPs. Vpre-B and lambda5 associate noncovalently to form an IgL chain-like structure in pro-/pre-B cells.

As soon as IgH chains become expressed, this SLC can form, between the IgL chain constant region domain-like lambda5 and the first cμH domain, S–S-bonded Ig (BCR)-like structures, called pre-BCRs (Melchers, 2005).

In SLC a carboxy-terminal peptide of Vpre-B and an amino-terminal peptide of lambda5 protrude at the location of the third complementarity-determining region (CDR) of a normal VL domain. These non-Ig parts control the turnover of pre-BCRs with opposite effects on the cell surface: Vpre-B stabilizes surface deposition, while lambda5 downregulates pre-BCR by internalization. As pre-BCR signaling depends on the quantity of molecules on the surface, they appear to modulate pre-BCR signaling in opposite ways (Knoll et al., 2012).

When CLPs enter the B lymphoid pathway they open the IgH chain loci for DH to JH rearrangements and become c-kit flt31CD19-pro-/pre-B cells, not yet expressing Pax5. Pax5<sup>-/-</sup> pro-/pre-B cells appear arrested in B-cell development at that stage.

In pro-/pre-B cells of mice, but not of humans, B-cell development with DHJH rearrangements in reading frame 2 results in the expression of a DJ-cμ protein that can assemble with SLC to form a VH-deficient pre-BCR-like molecule on the surface of such cells. This appears to result in negative signaling to induce the deletion of these pre-BCR-like expressing cells (Haasner et al., 1994). This state of negative selection may extend into that phase of development when VH to DHJH rearrangements are initiated. In Pax5<sup>-/-</sup> pro-/pre-B-cell lines we have found VHDHJH-rearranged IgH loci, expressing IgH chains containing VH segments within the 7183-VH cluster (most frequently the VH81X segment), which are located at the 3' end of the clusters of VH segments in the IgH locus, but which cannot pair with SLC, thereby apparently evading this negative signaling by a pre-BRR (Wolf, I. and Melchers, F., unpublished). If IgH chains were made that could pair with SLC, such IgH chain loci might

enter VH replacement reactions to generate an SLC nonpairing H chain to evade this negative selection (Nakajima et al., 2009). It has been estimated that, in the mouse, between 1% and 7% of all VHDHJH-rearranged IgH loci result from such editing of VH replacements (Davila et al., 2007). It is not known whether a possible specificity of the VH to autoantigens influences this negative selection, but an autoreactive (transgenic) IgH chain has been shown to induce VH editing in pro-/pre-B cells without having to form a functional pre-BCR (Nakajima et al., 2009).

At the chromosomal level of organization the IgH locus is controlled by contractions of large regions (Feeney et al., 2011; Guo et al., 2011a,b). In cells not yet expressing Pax5 the parts of the regions of the IgH locus containing DH segments are brought into proximity to the JH region for rearrangements.

Once these Pax5-negative cells have undergone DH to JH rearrangements, DH proximal VH regions (VH7183 and Q52) can also be brought near to the DHJH-rearranged regions, and rearranged, even before Pax5 is expressed. Strikingly, one VH segment, VH81x, is rearranged as the first VH segment most frequently. When  $\mu$ -chain gene rearrangements are made in bone marrow with N-region insertions, the vast majority of these  $\mu$ H chains cannot pair with SLC. Hence, in the adult, the B2 repertoire is selected against the inclusion of these VH81x-expressing pre-B and B cells. By contrast, VH81x-containing  $\mu$ H chains, produced in the fetal liver without N-region insertions, can pair with SLC and appear in the peripheral, mature B1a cell repertoire. This “useless” function of the earliest VDJ rearrangements for the developing adult B-cell repertoire in bone marrow has long been an enigma. However, the recent discovery, the IgH locus is further subdivided for additional control of VH rearrangements, suggests a more differential usage of VH segments for the total process of VDJ rearrangements at the IgH locus. In the chromosomal region of the IgH locus between the DH and the JH segments, a CTCF-cohesin binding site is located that further regulates the order of VH to DHJH rearrangements. Deletion of this site on the IgH locus increases proximal (VH7183, especially VH81x) over distal (VH J558) rearrangements (Giallourakis et al., 2010). As the 3'-located VH segments have been found to be used preferentially, as B cells begin VHDHJH rearrangements, we can speculate that the VH regions of the IgH locus are opened in a stepwise fashion. In the first step, accessibility of the locus may be more important than productivity for  $\mu$ H chains.

## THE FIRST CHECKPOINT FOR THE EMERGING B-CELL REPERTOIRE—PROBING THE FITNESS FOR A GOOD BCR

Once the locus is open at all VH regions, distal VH rearrangements induced by Pax5 can be made. They are induced when Pax5-negative flt3<sup>+</sup>CD19-pro-/pre-B cells differentiate to Pax5-expressing flt3<sup>-</sup>CD19<sup>+</sup> pre-BI cells (Ebert et al., 2011). At this first checkpoint the emerging repertoire of  $\mu$ H chains is probed for fitness of pairing with SLC. Pre-B cells expressing an SLC-fitting  $\mu$ H chain can display the resulting pre-BCR on the surface. Cross-linking of the pre-BCRs by ligands provided either by the microenvironment or by the pre-B cells themselves induce proliferation of large pre-BII cells, signal downregulation of the rearrangement machinery (RAG1 and 2) and of SLC expression, thereby limiting the supply of SLCs for pre-BCR formation and, hence, limiting pre-BCR-induced proliferation. The VH repertoires of early pre-B cells before SLC-mediated proliferative expansion and of large pre-BII cells during proliferative expansion have been found to use VH segments at different frequencies, suggesting that the fitness for SLC pairing may be different for different VH families. This VH repertoire shift is delayed in SLC-deficient bone marrow (ten Boekel et al., 1997).

Only between 20% and 50% of all IgH chains can pair to form a pre-BCR on the surface of pre-BII cells, and they do so with varying degrees of fitness (ten Boekel et al., 1997, 1998; Kawano et al., 2006). The better they fit, the longer they proliferate. Cross-linking of pre-BCRs through positively charged arginine residues in the non-Ig portion of  $\lambda$ 5, possibly mediated by repetitive negative charges on molecules such as nucleic acids and other molecules on stromal cells, or by molecules expressed in pre-B cells themselves (Bradl et al., 2003; Ohnishi and Melchers, 2003), initiates pre-BCR signaling. Some  $\mu$ H chains have been found that enter proliferation as large pre-BII cells even in the absence of a functional SLC. They carry charged amino acids (arginines, lysines) in the CDR3 regions of their VH domains, not unlike the carriage of non-Ig parts of SLC. It suggests that the charged amino acids in CDR3s can function in place of SLC to signal the proliferative expansion of pre-BII cells. It remains to be seen what terminates this proliferation that is normally limited by SLC expression.

Pre-BII cells also close the second, often DHJH-rearranged IgH allele for further rearrangements, thereby securing allelic exclusion at the IgH locus. Since triple-deficient V<sub>pre-B1</sub><sup>-/-</sup>, V<sub>pre-B2</sub><sup>-/-</sup>,  $\lambda$ 5<sup>-/-</sup> B lineage cells still show allelic exclusion of the expression of their IgH loci, pre-BCRs cannot be involved in signaling for allelic exclusion, leaving it open just how the successful expression of an IgH chain mediates allelic exclusion in such

situations (Shimizu et al., 2002). Since double productively VHDHJH-rearranged B lineage cells have been found in numbers expected from a random process of in- and out-of-frame rearrangements at the IgH alleles, and since in all these cases only one of the two productively rearranged alleles could form a pairing IgH chain (ten Boekel et al., 1998), it remains to be seen just which is the SLC analogous partner to sense the pairing capacity of a newly made IgH chain.

Those heavy chains unfit to pair with SLCs do not induce proliferation of pre-BII cells through pre-BCRs. In situations where pre-BCRs cannot be formed, such nonproliferating pre-BII cells nevertheless proceed toward differentiation (Grawunder et al., 1993, 1995; Rolink et al., 1996). However, because such pre-BCR-defective pre-B cells do not proliferate, their contribution to the developing B-cell compartment should be at least 20- to 40-fold lower than that of their pre-BCR-expressing counterparts (Rolink et al., 1993).

In conclusion, the pre-BCRs do not use the classical CDRs of the VH domain of their IgH chains to bind ligands that could induce proliferation. Therefore the newly generated VH domain repertoire is not screened for antigen, that is, autoantigen binding, but merely for fitness to pair, first with SLC and eventually with conventional IgL chains. In this way, there is an exclusion of unfit H chains that may have other unwanted deleterious properties, such as the formation of self-aggregating immune complexes that might confer the danger of glomerulonephritis and vasculitis (Melchers, 2005).

## EXPRESSION OF IGL CHAINS

When large pre-BII cells have terminated their proliferative expansion, they become resting, small pre-BII cells, just as the SLC nonpairing, nonproliferating pre-BII cells do. The IgL loci are opened, RAG1 and 2 become reexpressed, and VL-to-JL rearrangements are initiated, in the mouse five times more frequently at the kL locus than the  $\lambda$ L loci, whereas in the human equally frequently at the kL and  $\lambda$ L loci. Only 10% of all potentially rearrangeable Vk segments, spread over the entire Vk region, are used in these first rearrangements, and they use the most 5'-located Jk most frequently. Vk segments, which are located in both orientations in the locus, are equally frequently rearranged by deletions and inversions. Two-thirds of the emerging in-frame rearranged immature sIgM<sup>+</sup> B cells are immediately selected, such that further IgL loci rearrangements are terminated by downregulation of the RAG genes, the second kL allele remains in germline, nonrearranged form, and all  $\lambda$ L loci remain nonrearranged (Melchers et al., 2007). The immature B-cell is likely to sense the production and surface deposition of a BCR, probably by "tonic" signaling and without recognition by an autoantigen binding to the VH/VL domains of the BCRs.

In the remaining pre-BII cells secondary and even subsequent rearrangements occur, probably for two reasons. One reason is that two of three VL-to-JL rearrangements end up out of frame, and hence do not allow translation into IgL chains. Hence, the cell remains in the pre-BII stage, does not express BCRs, keeps the RAG genes expressed, and all IgL alleles open for secondary and subsequent rearrangements, until it either manages a productive rearrangement to produce an IgL chain and, therefore, a BCR and becomes an immature sIgM<sup>+</sup> B cell, or until it runs out of opportunities to rearrange, when all JL segments have been used up.

The other reason is that either after the first or after any subsequent productive VL-to-JL rearrangement, the resulting BCR is autoantigen reactive. This immature autoreactive B-cell is then recognized at the second checkpoint by autoantigens existing in bone marrow and presented by a specialized microenvironment. It has been found that such autoantigen recognition keeps RAG expression upregulated, giving the immature B-cell the opportunity to "edit" its BCR by secondary and subsequent VL-to-JL rearrangements, in an attempt to abrogate the recognition of autoantigen and enter the resting, immature sIgM<sup>+</sup> B-cell compartment, ready for exit from the bone marrow to the periphery, through blood via the central artery into the spleen. Hence, "edited" B cells contain signs of secondary rearrangements, as circles of DNA containing the excised intervening sequences between the VL and the JL segment used in the rearrangement, and by an increased frequency of V $\lambda$  to J $\lambda$ -rearranged alleles.

In human B-cell development, most of the polyreactive cells (Wardemann and Nussenzweig, 2007) and some, but not all, autoreactive cells are lost during the transition from pre-B2 to immature B cells. In patients with systemic lupus erythematosus (SLE) and rheumatoid arthritis, however, these autoreactive and polyreactive BCRs are not lost at this checkpoint (Witsch et al., 2006), pointing to a role of this checkpoint in preventing autoimmune disease. By contrast, Köhler et al. (2008) found a subset of polyreactive pre-BCRs, expressed in pre-B2-like cells, to induce proliferation in vitro, suggesting positive selection by polyreactive pre-BCRs. However, other

experiments indicate that pre-BCR cross-linking in fetal liver organ culture does not boost pre-B-cell proliferation ([Ceredig et al., 1998](#)).

During the process of light chain editing, evolutionarily selected “editor” Ig light chains with low iso-electric points can “neutralize” the DNA-binding properties of certain heavy chains. Such IgL chains may preclude diseases, for example, SLE that is mediated by antibody–DNA complexes ([Li et al., 2001](#)). Continued VL-to-JL rearrangement can also lead to the expression of two or even more different light chains in a single immature B cell ([Doyle et al., 2006; Khan et al., 2008](#)). Immature B cells with one autoreactive and one nonautoreactive BCR can become unreactive to autoantigen because of dilution of the autoreactive with the nonautoreactive BCR. Dual-IgL-expressing B cells can enter the mature B-cell pool while remaining potentially autoreactive. Light chain replacement can also lead to polyreactivity ([Witsch et al., 2006](#)). Interestingly, some human B cells coexpress Vpre-B and conventional light chains together with  $\mu$  chains containing CDR3 regions enriched in positively charged and/or aromatic amino acids. Two-thirds of these cells are autoreactive and appear to have escaped central tolerance. Although human Vpre-B, which has an isoelectric point of 5.67, may act as an “editor” by neutralizing positively charged CDR3 regions, mouse Vpre-B proteins have an isoelectric point of 9.37 and thus may not be able to perform this function ([Meffre et al., 2004](#)).

## THE SECOND CHECKPOINT: SITES AND MECHANISMS OF SELECTION OF NEWLY GENERATED SIGM<sup>+</sup> B CELLS

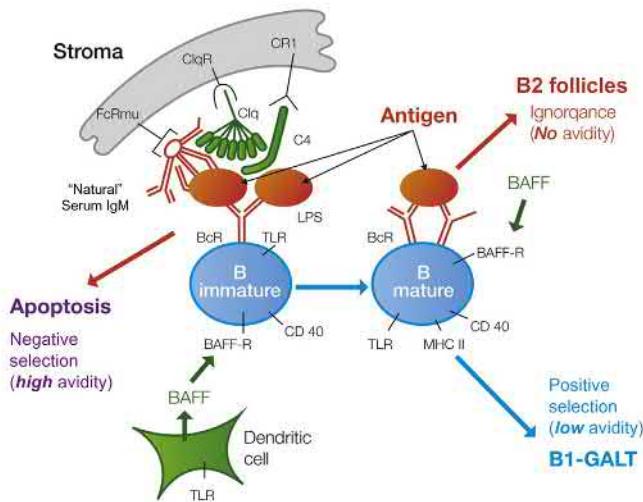

While VH repertoires expressed in immature B cells in the bone marrow and in immature and mature B cells in the spleen are not significantly different, almost 90% of the newly formed immature B cells never leave the bone marrow ([Rolink et al., 1999](#)). They have half-lives of less than a week, probably for two reasons: (1) they might have an intrinsic cellular program to enter apoptosis, unless selected to transit out of bone marrow into the periphery, (2) and they might be subject to autoantigen-induced mechanisms of cellular deletion. In essence, a 6–8-week-old mouse continuously generates from around 10<sup>4</sup> pHSCs over  $2.5 \times 10^6$  pre-BI cells, and  $5 \times 10^7$  small pre-BII  $2 \times 10^7$  immature sIgM<sup>+</sup> B cells, into a pool of around  $10^8$  such immature B cells, only to discard  $9 \times 10^7$ , that is, the vast majority of them, mostly in fear of autoreactivity. The invention of nature to generate a diversity of recognition by V(D)J rearrangements must have been an accident in evolution that was developed as the adaptive branch of the immune system to be advantageous for the defense of the individual against unexpected aggressors, yet a dangerous weapon that could destroy this individual. No wonder, then, that most of the BCRs on immature B cells ever made have to be eliminated.

In this establishment of “central” tolerance in B-cell repertoires by negative selection, neither the cellular microenvironments in the bone marrow nor the molecular mechanisms of deletion are well known. This is all the more remarkable since the processes of negative selection to establish central tolerance for the T-cell repertoires in the thymus have been so well investigated. While the studies in the thymus have been aided by the realization that autoantigens should be presented by major histocompatibility complex (MHC) I and II molecules, nothing comparable is evident from the genetics of B-cell development that would guide the search for the autoantigen-presenting modes that establish central B-cell tolerance. However, the rapidly expanding cases of genetically identified immunodeficiencies leading to early blockages of B-cell development should help to clarify the means whereby central B-cell tolerance is established. Thus it has been realized for some time that the complement components C1q, C4, serum amyloid protein, complement receptor-2, or secreted natural serum IgM could be involved, as deficiencies of any one of these lead to SLE.

Two models for the selection of the emerging B-cell repertoires have been proposed. In one model ([Carroll, 2004](#)), the maturing B cells are protected from the stimulatory influence of autoantigens released from apoptosing, blebbing cells in the primary lymphoid organ because macrophages expressing complement receptors (CIqR for CIq, CRI for C4) efficiently take up and, thereby, remove apoptosing cells bound by natural serum IgM and complexed with CIq and C4b. This model, however, does not explain how the developing repertoire of immature B cells is purged of autoreactive cells, nor does it take into account that immature B cells are sensitive to induction of apoptosis rather than to proliferation and development of Ig-secreting plasma cells and memory B cells.

In contrast, the second model ([Melchers and Rolink, 2006](#)) ([Fig. 8.1](#), redrawn from Figure 2 in [von Boehmer and Melchers, 2010](#)) proposes that autoantigens from dying cells are presented to the emerging repertoire of B cells by stromal cells in the primary lymphoid organ, that is, bone marrow. The presenting cells are expected to express receptors for natural serum IgM that can bind via its Fc to IgM-Fc receptors. IgM via its variable regions could bind to autoantigens, possibly even in solution, then fix CIq and create a bridge between the CIqR, CRI,

### Selection of the primary B cell repertoires in bone marrow

**FIGURE 8.1** Proposed site for autoantigen-mediated selection of immature B cells. A hypothetical microenvironmental cell, nonhematopoietic?, follicular dendritic?, expresses Fc-μ-receptors, Clq receptors, and CR1. Note that several cells close to each other could also express these different receptors. Fc-μ-R bind natural IgM antibodies, which bind Clq when complexed with autoantigen. That allows binding of Clq to ClqR. C4 bridges the immune complexes with CR1. Newly generated immature sIgM<sup>+</sup> B cells bind autoantigens with different avidities. High avidity binding induces apoptosis (negative selection), possibly aided by signaling from unknown cytokines. Low avidity binding induces survival and selection into B1 pools (not aided by BAFF). No avidity (ignorance) induces BAFF-mediated transfer into the periphery of mature follicular B2 cell pools (via T1 and T2 intermediates) expressing MHC II and CD40. CR1, Complement receptor 1. Source: Adapted from von Boehmer, H., Melchers, F., 2010. Checkpoints in lymphocyte development and autoimmune disease. *Nat. Immunol.* 11, 14–20, and redrawn by Justin Hewlett, MNHS Multimedia Unit, Monash University.

and FcR on the presenting cells. In this way autoreactive BCR on the immature B cell would then be brought together by Clq, C4, serum IgM, and autoantigens. Depending on the strength of the interaction of the BCRs with autoantigens, and possibly also on the nature of the presenting stromal cell, this autoantigen-induced signaling can have different outcomes. It can lead to apoptosis of the B cell, if the avidity of autoantigen-BCR binding is high, leading to a negative selection of the B-cell repertoire. Such negative selection has been documented in a variety of experimental settings. If BCR downregulation and reexpression of a secondary BCR due to editing of a new L chain, thus leading to a new, nonautoreactive BCR, occurs fast enough, this apoptosis may be avoided. Since approximately 90% of the  $2 \times 10^7$  sIgM<sup>+</sup> immature B cells that are made each day in the bone marrow of a mouse never arrive at the immature sIgM<sup>+</sup> B-cell pool of the spleen, it is likely that this negative selection engages the vast majority of the newly generated immature sIgM<sup>+</sup> B-cell repertoires in bone marrow, and before their transit to spleen (Rolink et al., 1999).

Alternatively, the interaction of the newly generated immature B cells can lead to positive selection, maybe into the B1b compartment, if the avidity of BCR-mediated interaction is low. Those B cells expressing BCRs with no avidity to autoantigens present in bone marrow will be “ignored” and will be allowed to exit to the periphery, as long as they show their “passport” specifying an unrecognized BCR on their surface. It is truly remarkable that despite this extensive effort to avoid autoimmunity, the peripheral, mature B cells continue to be an autoimmune threat. Needless to point out, we still do not know how the adaptive immune system “tolerates” BCRs, TCRs, and Igs, when they are first made.

Further, it remains equally remarkable just how many cells are made, and then discarded, to generate the few that are finally allowed to leave the bone marrow to face the world of foreign antigens. This fate of the majority of all newly generated B cells reminds me of a fable, told by France (1893), of a young Persian king, who asked his academicians to write the history of mankind—as this article is written to describe the history of B cells. Their initial rendition was carried to the king on 20 camels with 500 books each. The king complained that he would not have the time to read it all and asked for a shorter version. Even the shorter versions were always too long to be read by the king in his remaining lifetime. Finally, a lone academician arrived with only one book, but the king responded by saying: “So I will die without knowing human history.” To which the academician replied, “I can summarize it for you in three words: ‘ils naquinent, ils souffrent, ils moururent’ (They are born, they suffer, they die).”

## FUTURE APPROACHES TO UNDERSTANDING CENTRAL B-CELL TOLERANCE

A better understanding of the modes of central tolerance induced by apoptosis, editing, anergy, and ignorance still requires an identification of all of the relevant antigen-presenting cell populations. A strikingly similar model has been proposed for the establishment of peripheral B-cell tolerance, that is, negative selection of autoreactive B cells, which are randomly, hence accidentally, generated by somatic hypermutation and class switching of a follicular helper T cell–driven immune response within germinal centers (Vinuesa et al., 2010). In this model the hypermutated, autoantigen-recognizing IgG takes the role of the natural IgM antibody proposed in our model (above) for the establishment of central tolerance of B cells.

In contrast to T-cell development, in which only MHC-restricted, that is, self MHC-I- or II-plus autoantigen peptide-recognizing, T cells that recognize self MHC-I or MHC-II are allowed to exit the thymus and enter the periphery, B cells just need to show surface-bound IgM that does not recognize any autoantigen in bone marrow and which has been “ignored” by the selecting environment to gain exit from the bone marrow. Once in the periphery, particularly the spleen, hardly any further cell loss is detected during the transition from immature (including transitional T1 and T2 B cells) to mature B cells in the spleen. In humans there is a further reduction of the percentage of autoreactive cells (from 40% to 20%) across this transition, whereas the percentage of poly-reactive cells remains at the low level (6%) already achieved during the transition from pre-B to immature B cells (Wardemann and Nussenzweig, 2007). Patients with, say, SLE or rheumatoid arthritis fail to establish recessive tolerance even at this second checkpoint, indicating that failure of several mechanisms for establishing tolerance likely contributes to these diseases (Yurasov et al., 2005). The genetics of autoimmune diseases and immunodeficiencies are now investigated by full genome analyses (Mackay et al., 1999; Rolink et al., 2002; Kumar et al., 2006; Deane et al., 2007; Liu et al., 2007; Xie et al., 2007; Shlomchik, 2008). It is predictable that an ever-increasing number of mutant molecules involved in (often also epigenetic) regulation of gene expression, of signal transductions from a variety of receptors involved in the interactions of B lineage cells with their inducing microenvironments, controlling proliferation, differentiation, migration, and survival on their way to mature B cells will be found to change the normal course of B-cell development.

Finally, it is unclear how the affinity for antigen of a BCR decides what it signals to either the immature or later the mature B cell. Of relevance here, a monoclonal, autoreactive, dsDNA-binding, SLE-propagating, hypermutated IgG autoantibody was isolated from an SLE patient. The corresponding VH and VL domains of the IgH and IgL chain genes were then “back-mutated” to the germline-encoded VH/VL sequence and expressed as an antibody (Schroeder et al., 2013). In this back-mutated form, the antibody remarkably failed to bind to dsDNA any longer. The corresponding immature B-cell expressing this antibody as a BCR was evidently not negatively selected by dsDNA, which is abundantly present in bone marrow throughout life. How, then, did the mature BCR1 B-cell ever become autoreactive? Possibly the cell entered a germinal center reaction, hypermutated, and that a dsDNA-binding somatic mutant B-cell then evaded negative selection in the process of peripheral tolerance induction—but who or what triggered it?

It is fully possible that we do not understand how a cell surface-bound BCR establishes contact with the autoantigen (in bone marrow) or antigen (in the periphery), possibly presented (as occurs for T cells in thymus and periphery) by antigen-presenting cells. To quote Huppa and Davis (Huppa et al., 2010; Huppa and Davis, 2013) on their studies of the interaction of T cells with antigen-presenting cells in immunological synapses, “There is increasing evidence that the molecular dynamics of receptor-ligand interactions are not only dependent on the intrinsic properties of the binding partners but also become transformed by cell biological parameters such as the geometrical constraints within the immune synapse, mechanical forces, and local molecular crowding. To appreciate the complete picture, we think a multidisciplinary approach is imperative, which includes genetics, biochemistry, and structure determination and also biophysical analyses and the latest molecular imaging techniques.” It, therefore, seems not unreasonable to expect that similar dynamics of antigen recognition by BCRs on immature and on mature B cells, and of costimulatory or coinhibitory surface-bound ligands and receptors will become evident, which will lead to redefinitions of the distinction between “self” and “nonsel” in B-cell repertoires at different stages of development.

All these examples should make it clear that we are merely at the very beginning of a vision of the control of autoimmunity, or better, the lack of it, in the genetic variants of nearly  $7 \times 10^9$  human individuals with a functional immune system. Moreover, it will not only be the genetics of B cells, but also their environment, that will be found to exert control. Kurt Tucholsky (1890–1935), a German journalist and satirical writer, unwillingly but farsightedly defined what appears to become so important to understand about the functioning of the immune

system of lymphocytes in their environments: "Ein Loch ist da, wo etwas nicht ist. Das Merkwürdigste an einem Loch ist der Rand. Er gehört noch zum Etwas, sieht aber beständig in das Nichts, eine Grenzwache der Materie. Das Nichts hat keine Grenzwache: während den Molekülen am Rande schwindlig wird, weil sie das Loch sehen, wird den Molekülen des Lochs 'fest-lig'?" (Zur soziologischen Psychologie der Löcher, 1931). [Translated: "A hole is there where something is not. The most remarkable thing about the hole is its rim. It belongs to the something, but looks into the nothing, as a border control of the material. The nothing has no border control, while the molecules at the rim of the hole get dizzy, because they see the hole, do the molecules of the hole get 'stabilized'?" (The Sociological Psychology of the Holes, 1931)].

## Acknowledgments

It should be clear to the reader that my description of B-cell development is highly personal, often biased, and incomplete in the quotation of relevant literature, particularly of opposing views. I apologize to all those whom I might have disappointed or even offended. During my attempts to assemble it, I was often ready to give up. Only the patient persistence of the editors has brought this chapter to its present status. To once more quote Anatole France (as I was alerted to him by one of the editors, I.M.), "My article is less than 500 books in size, and more than the final format of the one sentence quoted above, in the hope that the king does have the time to read it." I thank my long-time scientific friends, especially Jan Andersson and Ton Rolink at the no-longer-existing Basel Institute for Immunology, for the never-ending discussions of the scientific subject that has united us for so many years. Finally, I thank the Max Planck Society and its Institute for Infection Biology in Berlin for the many years of support as a Max Planck Fellow, well beyond the limits of my official retirement from the Basel Institute for Immunology.

The second edition is left largely unchanged.

## B CELL ACTIVATION

B cells form an important part of the immune system by helping the host to fight pathogens or their products, and most successful vaccination strategies rely on an antibody response by B lymphocytes (Plotkin, 2010). Surveillance for foreign antigens requires B cells to (1) gain access to areas where antigen is available (migration); (2) recognize and bind to antigen (antigen specificity); (3) increase antigen-specific cell numbers (proliferation); and (4) give rise to *plasma cells* that secrete antibodies to neutralize or opsonize antigen and *memory cells* that “remember” previous antigen encounter and aid rapid and robust recognition of the same antigen during future infections (differentiation).

The process controlling this series of events is referred to as B cell activation. T cell–dependent (TD) activation of B cells occurs in two distinct phases. First, B cells are triggered by antigen and, second, antigen-specific B cells interact with activated T helper (Th) cells with the same antigen specificity.

## Antigen-Driven B Cell Activation

Like T cells, B cells express an antigen receptor, the B cell receptor (BCR), that is highly variable between different B cells (basic features of the BCR are given in [Box 9.1](#)). Engagement of the BCR by antigen initiates two interdependent processes, signaling and internalization of the antigen-receptor complex. Mature B cells that have not been previously activated by their specific antigen are referred to as “naïve” and express surface immunoglobulin (Ig) D and IgM (Ig isotypes are discussed further below). Nanoclusters of BCRs comprising IgD and IgM molecules are organized in regions of the cell membrane with distinct lipid and protein compositions ([Mattila et al., 2013](#)). Three alternative models have been proposed for how antigen-binding results in the initial signaling events downstream of the BCR. First, the conformational change model, which proposes that an antigen-induced change in the shape of the Ig is transmitted across the membrane allowing access to molecules that initiate BCR signaling ([Harwood and Batista, 2010](#)). Second, the dissociation model, which proposes that in naïve B cells, BCRs exist in inhibitory nanoclusters, which prevent access to the signaling molecules, and that antigen binding leads to the reorganization of these domains in such a way that the BCRs are dissociated, allowing signaling to occur. Third, the kinetic segregation/collision coupling model proposes that BCRs in resting B cells are associated with inhibitory coreceptors and segregated from activating coreceptors. Upon the binding and close contact with membrane-associated antigen, bulky inhibitory receptors are excluded from the close contact sites between the BCR and membrane, allowing signaling to occur. To date, there is evidence for the involvement of all three models in BCR signaling. All three models rely on the signal transduction ability of CD79a(Ig $\alpha$ )/CD79b(Ig $\beta$ ) dimers, which are molecules that are noncovalently linked to the membrane-bound Ig molecules. Membrane-bound Ig molecules contain no intrinsic signaling capability, which is provided by CD79 dimers. The conserved signaling motifs [immunoreceptor tyrosine-based activation motifs (ITAM)] contained within the cytosolic tails of CD79a/CD79b are tyrosine phosphorylated by Src-family tyrosine kinases (importantly, Lyn and Syk). These events cause further activation of intracellular signaling molecules and transcription of genes involved in the regulation of B cell activation ([Harwood and Batista, 2010](#)).

### BOX 9.1

#### BASIC FEATURES OF THE B CELL RECEPTOR

- B cells recognize specific antigens through antigen receptors, B cell receptors (BCRs), that are expressed early in B cell development following the rearrangement of immunoglobulin (Ig) genes.
- The BCR is a membrane-bound version of monomeric Ig (antibody) and comprises two identical heavy chains and light chains that are noncovalently associated with CD79 dimers that provide the signaling capacity of the BCR.
- In health, B cells should only express one copy of heavy and light chain variable region genes, and thus one specificity of BCRs.
- The BCR recognizes unprocessed antigen based on the complementarity of shape and charge between the antigen and the variable, antigen-binding domains of the BCR.
- Diversity in BCR specificities is achieved through the stochastic recombination of the genes that encode the highly variable antigen-binding domains of Ig heavy and light chains.
- Rearrangement of Ig genes to bring heavy chain variable region genes into proximity with different heavy chain constant region genes determines the isotype of antibodies the B cells produce. These can be either IgM, IgG, IgA, or IgE.
- The nature of the constant region of the BCR, and the isotype of the antibody produced, can change over the course of an immune response, allowing the B cell to make the appropriate antibody response for the particular invading pathogen.

## Amplification and Modulation of B Cell Activation Signals

A number of B cell surface coreceptors are involved in amplification and modulation of BCR-mediated signals. These fine-tune the threshold for B cell triggering and thus balance activation and tolerance. Among these molecules are CD19, CD81, and CD21, which comprise the BCR-coreceptor complex. CD19 is the only molecule with a signal transduction domain in this coreceptor complex. CD81 immobilizes CD19 in nanoclusters at the plasma membrane (Mattila et al., 2013). CD21 (also referred to as complement receptor 2) binds to iC3b, C3dg, or C3d, which are components of the complement pathway (Carroll, 1998; Harwood and Batista, 2010). Via CD21, the BCR-coreceptor complex can bind to complement components deposited on microbial antigens at the same time as the BCR binds to epitopes on the antigen. Thus CD21 allows the cross-linking of the BCR and CD19 and enhances BCR activation and subsequent signal transduction in response to antigen. In support of their importance to BCR signaling, CD19 or CD21 deficiency leads to an inability to mount responses to TD antigens (Ahearn et al., 1996). The importance of complement-mediated activation of B cells is shown in mice with a disrupted CD21 gene, these mice display a reduced number of B cells in the spleen, a defect that is reversed upon reconstitution with bone marrow from CD21-expressing wild-type mice (Ahearn et al., 1996). Similarly, mice lacking CD21 expression are unable to generate antigen-specific plasma cells or to maintain antibody production in response to viral infection, as CD21-mediated costimulation is required to induce the transcriptional regulators Blimp-1 and XBP-1, molecules driving plasma cell differentiation (Gatto et al., 2005).

B cells also express a variety of surface molecules containing immunoreceptor tyrosine-based inhibitory motifs (ITIM). For example, the ligation of the inhibitory coreceptor CD22 causes phosphorylation of the ITIM and, subsequently, recruitment of the SH2 domain-containing phosphatase 1 (SHP-1), which negatively regulates signaling through the BCR (Doody et al., 1995) by dephosphorylating BCR-activated protein tyrosine kinases and their downstream targets. In addition to SHP-1, ITIMs recruit such regulators as SH2 domain-containing inositol 5'-phosphatase 1 (SHIP-1) and phosphatase and tensin homolog (PTEN). These are particularly important in establishing thresholds for B cell activation and maintenance of anergy, a state of antigen-specific hyporesponsiveness. Indeed, a number of studies have shown that aberrant negative circuits can lead to a breach in tolerance and, consequently, autoimmunity (discussed further below).

## Antigen Processing Following B Cell Activation

B cells process antigen through a series of orderly steps. BCR-mediated antigen capture and internalization is the initial event in the process that culminates in antigen presentation to T cells. Internalized antigens are directed to the endo/lysosomes, where the antigen is degraded. Importantly, these are sites of proteolysis that generate peptide fragments to be loaded onto major histocompatibility complex (MHC) class II molecules and transported to the cell membrane for presentation to Th cells. The intracellular trafficking of BCR–antigen complexes is mediated via the reorganization of actin cytoskeleton and involves the synergistic action of small proteins that promote cell contraction, for example, myosin II and chaperone molecules that guide the BCR–antigen complexes to lysosomes (Vascotto et al., 2007). BCR-mediated endocytosis initiates signaling cascades that enhance the synthesis of molecules involved in B–T cell interaction. Among these are MHC class II molecules and increased expression of the costimulatory molecule 86 (B7–2) (Rodriguez-Pinto and Moreno, 2005). CD86 binds CD28 on T cells and is critical for their activation. Any defects in the molecules or mechanisms involved in the transport of antigen or its degradation, or in the loading onto MHC class II, result in impaired antigen presentation to T cells and consequently abnormal B cell activation.

## OPTIMAL B CELL ACTIVATION REQUIRES INTERACTION WITH T HELPER CELLS

T cell help for B cells manifests through both cognate interactions and secretion of cytokines (Guy and Hodes, 1989). During cognate interactions, B cells present peptides in MHC class II–antigen complexes for T cell recognition, and both cells provide reciprocal activating signals in a process known as costimulation. Of note, this interaction requires specificity of B and T cells for the same, or linked, antigen, but each cell may recognize a different epitope of those antigens. For example, the BCR can recognize an exposed structure on a pathogen surface in its native conformation, while the T cell can respond to a processed peptide fragment of internal pathogen molecule that is internalized along with the molecule recognized by the BCR. In addition, the BCR can recognize multiple

types of molecules, for instance, proteins, lipids, and carbohydrates in their native structure, while the T cell receptor can only recognize processed peptides presented by MHC molecules. This ability to recognize different, but associated, parts of the same pathogen is referred to as linked recognition.

## Surface Molecules in B Cell–T Cell Interactions

CD40, which is constitutively expressed on the surface of B cells, has a critical role in sustaining B cell activation and enhancement of their antigen-presenting capacity. CD40 interacts with CD154, which is expressed on activated T cells. The engagement of CD40 by CD154 leads to a further upregulation of CD86 on B cells, which in turn binds to CD28 on T cells, resulting in feed-forward activation of T cells.

The interaction between CD40 and CD154 is also important for class-switch recombination (CSR) (discussed later), the clinical relevance of which became apparent when defects in the CD154 gene were found to be associated with the development of X-linked hyper IgM syndrome. These patients are unable to switch the isotype of secreted antibodies, resulting in a higher proportion of IgM production at the expense of IgG, IgA, and IgE. As a result of the inability to produce class-switched antibodies, patients with X-linked hyper IgM syndrome also have increased susceptibility to common infections, in particular to opportunistic pathogens (Noelle, 1996). Blocking the CD40–CD154 pathway, and thus immune activation, using an anti-CD154 monoclonal antibody has been shown to be effective in reducing the severity of autoimmune responses, such as experimental collagen-induced arthritis in rodents (Durie et al., 1993) and immune thrombocytopenia in humans (Kuwana et al., 2004), further reinforcing the importance of this pathway in B cell activation. More recently it has also been shown that a CD40 blocking antibody (CFZ533, in phase II clinical trials), which inhibits activation through CD40/CD154 interactions, has beneficial effects for patients with primary Sjögren's syndrome (NCT02291029).

## Cytokines Involved in B Cell–T Cell Interactions

Activation of costimulatory pathways not only stabilizes and strengthens the communication between B and T cells but also leads to the transcription of several genes by both B and T cells, including the upregulation of cytokine receptors on the surface of B lymphocytes. A number of cytokines produced by activated T cells are important in guiding B cell activation. For example, T cell IL-2 promotes B cell proliferation, while IL-4 and IL-10 are known to drive B cell differentiation (Mingari et al., 1984; Rush and Hodgkin, 2001). Cytokines also instruct the isotype of Ig in CSR. For example, IL-4 drives IgG1 and IgE production, while TGF- $\beta$  drives IgG2b and IgA and IFN- $\gamma$  drives IgG2a and IgG3 in mice (McHeyzer-Williams and McHeyzer-Williams, 2005).

Understanding the costimulation pathways involved in the activation of B cells and their further maturation to antibody-producing plasma cells has led to the development of therapeutic agents to prevent the development of autoreactive antibodies and to treat autoimmune diseases. For example, abatacept, a CTLA4-Ig fusion protein, was developed to block costimulation of T cells by B cells, and other antigen-presenting cells, and its safety and therapeutic efficacy have been demonstrated in the treatment of rheumatoid arthritis (Genovese et al., 2012).

## MATURATION AND ACTIVATION OF B CELLS OCCUR IN LYMPHOID ORGANS

The previous section described how activation of B cells requires highly synchronized processes initiated by the recognition of antigen and by the interaction with T cells. But where do these interactions take place? In the bone marrow, B cells carrying an antigen receptor develop from pluripotent hematopoietic stem cells. B cells that have successfully expressed a functional BCR and that have passed central tolerance checkpoints (discussed next) migrate to the periphery where they progress through distinct developmental stages. Finally, upon antigen-driven activation, they can differentiate into long-lived plasma cells and memory B cells.

## Location of B Cell Activation

Mature naïve B cells reside mainly in primary lymphoid follicles in lymph nodes, spleen, and mucosa-associated lymphoid tissue. In addition to B cells, these areas are enriched with follicular dendritic cells (FDC), which are cells of mesenchymal origin that help organize the lymphoid architecture and play critical roles in B cell activation and affinity maturation. FDCs express a variety of cell surface receptors, including Fc receptors

CD23 and CD32, which bind the constant (nonvariable) region of IgS and complement receptors CD21 and CD35. These cells can, therefore, capture and retain antigen in native conformation on their surface, generating what are referred to as antigen depots. These antigen deposits are important in the development of an already initiated immune response; however, initial B cell encounter with antigen may rely on several methods. First, small soluble antigens may gain access to the follicles directly from afferent lymph vessels and be accessible to B cells as free diffusing antigen. Second, particulate opsonized antigen can be presented to B cells as they migrate through the follicles, either on the surface of specialized macrophages located in the subcapsular sinus of lymph nodes or on the surfaces of FDCs. Third, dendritic cells may migrate into lymph nodes carrying unprocessed intact antigen that antigen-specific B cells are able to remove from their cell surface (Cyster, 2010, 135).

B cell migration through the lymph nodes is guided by the release of chemokines by FDCs, and marginal and fibroblastic reticular cells (Cyster, 2010). Mature B cells express the chemokine receptors CXCR5, CCR7, and Epstein–Barr virus-induced gene 2 (EBI2), which is a G protein-coupled receptor that binds oxysterols (Hannedouche et al., 2011). Integration of signals from CXCR5 and CCR7 allows B cells to navigate the lymphoid structures guided by stromal cell chemokine gradients of CXCL13 in the B cell follicle and CCL19/21 in the T cell zone, respectively. Importantly, CCR7 and EBI2 are upregulated upon B cell activation. The upregulation of CCR7 expression causes increased responsiveness to CC19/21, enabling the B cells to migrate to the B–T cell border where they interact with cognate T cells. B cell migration is a dynamic process and B cells that have not been primed (not encountered their specific antigen) within around 24 hours of arriving in the lymphoid tissue recirculate back to the blood in search of cognate antigen in other peripheral lymphoid tissues (Gonzalez et al., 2011).

## B Cell Activation and the Germinal Center Response

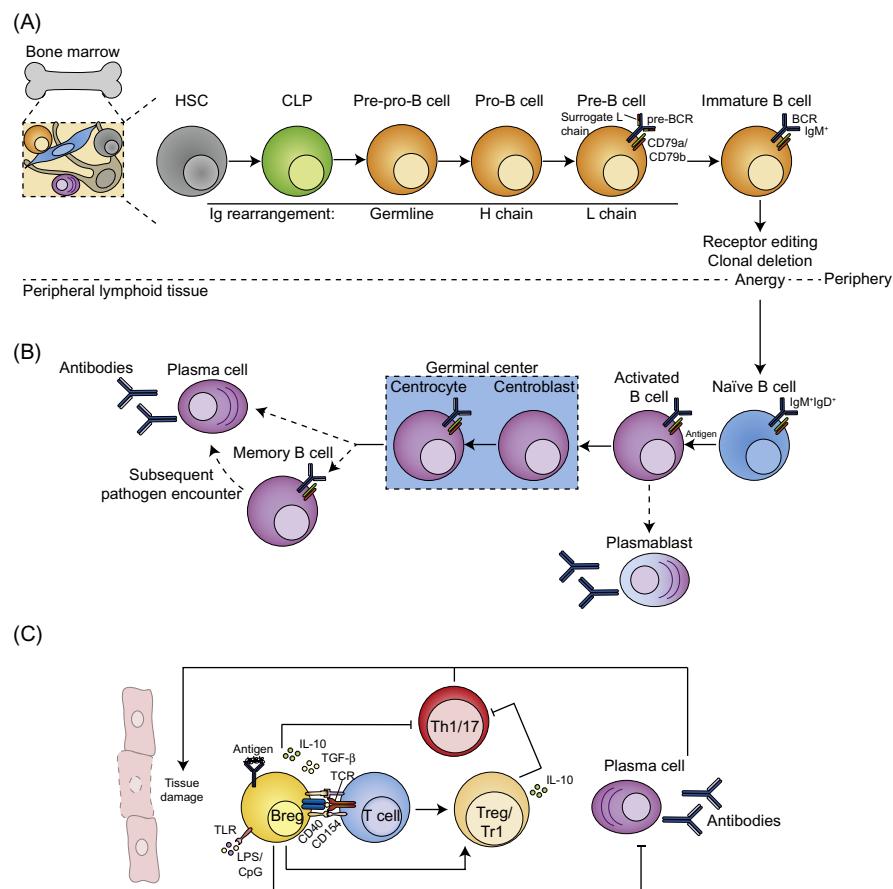

The initial interaction with T cells at the B–T cell border can result in two alternative outcomes for B cells. First, B cells can differentiate into short-lived antibody-secreting cells, known as plasmablasts, which provide an immediate IgM antibody response to control the spread of infection. Second, some of the antigen-activated B cells migrate into the primary lymphoid follicle and form germinal centers. Germinal centers comprise dividing B cells, FDCs, and a small proportion of antigen-specific T cells that provide help to B cells (Cyster, 2010). Several important events related to activation occur in germinal centers, including *somatic hypermutation* (SHM), a process altering the sequences of the variable (V)-regions of Ig genes; *affinity maturation*, the selection of the B cells with high antigen specificity; and CSR, whereby the selected B cells change the class of antibodies they secrete to exert their distinct functions.

During SHM, site-directed point mutations are induced in the V regions of the Ig genes of activated B cells, resulting in the expression of BCRs with potentially altered specificities. This process is facilitated by the enzyme activation-induced cytidine deaminase (AID). The affinity of the newly generated BCRs is then tested by competition with other B cells for the ability to bind and remove antigens held by FDCs. If SHM results in a BCR with an increased affinity for the original antigen, the B cell expressing this BCR will outcompete antigen-specific B cells with lower BCR–antigen affinities to bind antigen held by FDCs, which it can subsequently present to in cognate interactions to Tfh cells. Tfh then provides survival signals to these B cells, through both CD154–CD40 interactions and by provision of IL-21, a cytokine that drives B cell proliferation and retention in the germinal centers. This process, called affinity maturation, will lead to a pool of antigen-specific B cells secreting higher affinity antibodies than those secreted by the initial antigen-specific B-cell pool and will thus result in the generation of B cells better equipped to combat the infection (Di Noia and Neuberger, 2007).

CSR refers to the irreversible recombination events that change the class of the BCR and antibody expressed by the B cell from IgM/IgD initially to IgG, IgA, or IgE (Muramatsu et al., 2000). Each of these classes of the antibody has distinct effector functions and the particular class of antibody that results will be driven by the nature of the immune response and resultant cytokine microenvironment. Intrachromosomal recombination of the Ig genes causes IgM and IgD heavy chain genes to be excised from the Ig locus and the constant region for another Ig heavy chain to be joined to the heavy chain Ig variable region. The variable region of the Ig heavy chain remains unchanged. Thus in the germinal center reaction, B lymphocytes can alter their IgS from low-affinity IgM/IgD to a high-affinity IgG/IgA/IgE/IgM class (Di Noia and Neuberger, 2007). Like SHM, CSR requires AID, and AID deficiency results in the development of hyper IgM syndrome type 2. These immunodeficient patients are characterized by the absence of Ig CSR, the lack of Ig SHM, and lymph node hyperplasia caused by the presence of enlarged germinal centers (Revy et al., 2000). The germinal center reaction prepares the B cell for production of a long-term targeted response to a foreign antigen.

## The Germinal Center

Histologically, the germinal centers can be divided into two main zones: the dark zone and the light zone. Within the dark zone of the germinal centers, antigen-activated B cells mature to form large rapidly proliferating cells called centroblasts (Fig. 9.1B). It is at this stage and in this location that centroblasts diversify their IgV genes by SHM. Centroblasts move out from the densely packed dark zone and enter the light zone (FDC area) where they differentiate into noncycling centrocytes. Although most centrocytes die in situ, those receiving appropriate help from surrounding T cells will survive and can either undergo further rounds of SHM or differentiate into memory B cells or plasma cells. The outcome of the germinal center reaction is the production of (1) plasma cells

**FIGURE 9.1** Following the journey of B cells from the bone marrow to the periphery. (A) B cell development and tolerance. In the bone marrow, B cells develop from common lymphoid progenitors that originate from HSC. The stochastic rearrangement of Ig genes results in expression of the BCR. In the bone marrow, the B cell is tested for self-reactivity. If the B cell recognizes self-antigen, its developmental progress can be halted and the BCR may be edited to produce a nonself-reactive version, this is known as receptor editing. If receptor editing cannot remove the autoreactivity, then the B cell will generally either apoptose (clonal deletion) or enter a hyporesponsive state (anergy). B cells exit the bone marrow as immature transitional cells and complete their maturation to IgM<sup>+</sup>IgD<sup>+</sup> mature naive B cells in peripheral lymphoid organs, in particular the spleen. B cells may also enter a state of anergy after they leave the bone marrow if they are subject to prolonged exposure to soluble antigen exposure in the absence of costimulation by cognate T cells. (B) B cell activation. Mature naive B cells recirculate around the peripheral lymphoid tissues (lymph nodes and spleen) via the blood and lymphatic systems. In peripheral lymphoid tissues, B cells follow chemoattractant gradients to migrate to areas of these tissues where they can interact with antigen-bearing cells and T cells. Interaction with antigen results in B cell activation. If the antigen-activated B cell receives T cell help, or sufficient T cell-independent stimulation, the B cell will begin the process of differentiation into terminal effector cells such as plasmablasts, plasma cells, and memory B cells. Some B cells will give rise to short-lived plasmablasts initially largely producing IgM, while others will enter germinal centers in an attempt to refine specificity and affinity of their BCRs for the activating antigen. These B cells will differentiate into long-lived memory B cells and plasma cells. (C) Suppression of an autoreactive response. Additional regulatory systems exist to control the potential damage that maturation of autoreactive B cells may have on the immune system. In response to activation, some B cells may differentiate into Bregs. Bregs limit tissue damage in certain autoimmune conditions by dampening inflammatory responses. This is achieved by the secretion of antiinflammatory cytokines, such as IL-10 and TGF- $\beta$ , and/or via inhibition of the development of proinflammatory T cells (T helper 1/T helper 17), and/or by promoting the development of Tregs, which in turn inhibit the production of autoantibody. HSC, Hematopoietic stem cells; Ig, immunoglobulin; BCR, B cell receptor; Bregs, regulatory B cells; IL, interleukin; TGF, transforming growth factor; Tregs, regulatory T cells.

that secrete high-affinity antigen-specific IgGs and (2) memory B cells that protect against any subsequent encounter with the same antigen. Memory B cells and plasma cells are long-lived cells, surviving for many years or potentially for the lifetime of the host (Klein and Dalla-Favera, 2008). The potential of B cells to differentiate from naïve B cells into plasma cells, memory, and germinal center B cells was addressed by Taylor et al. They showed that while some naïve B cells only gave rise to one of these effector cell types, others, through clonal expansion, were able to differentiate into all three. This ability to acquire all three fates is dependent on the B cell's ability to resist apoptosis and affinity for antigen in the germinal center reaction (Taylor et al., 2015).

## T CELL-INDEPENDENT ANTIBODY RESPONSES

B cell activation and antibody production that require T cell help, as described above, are known as TD responses. An Ig response that occurs in the absence of T cell help is referred to as T cell independent (TI). TI responses can be induced by structures shared by many common pathogens, for instance, lipopolysaccharides that form the outer surface membrane of Gram-negative bacteria or repetitive polysaccharides of bacterial cell wall of Gram-positive bacteria. TI responses can be further classified into types 1 and 2. Type 1 responses (TI-1) are elicited by the antigen engaging both the BCR and pattern-sensing Toll-like receptors (TLRs), which are molecules involved in innate immune recognition and regulation. TLRs recognize highly conserved molecular patterns on microorganisms. B cells can express multiple TLRs, and while in naïve B cells TLR expression is low, it is enhanced in response to BCR engagement. In humans, for example, naïve B cells express low levels of TLR7 and TLR9, but these receptors are upregulated in memory B cells (Bernasconi, 2003, 133). Thus optimal response to TI type 1 antigens requires concomitant engagement of the BCR and TLR. Type 2 responses (TI-2) are initiated by BCR engagement by multivalent ligands that are able to simultaneously cross-link multiple BCRs and deliver sufficiently strong signals in the absence of coreceptor engagement. An example of a multivalent ligand is the repetitive structures of the streptococcal cell wall. In both cases, the cumulative signal strength resulting from either engagement of BCR and TLR, or BCR cross-linking, is sufficient to overcome the requirement for T cell help. Nevertheless, in general in the absence of T cell help, there is a lack of memory, SHM, and CSR.

## B CELL TOLERANCE: TRADITIONAL AND NEW CONCEPTS

The immune system is highly efficient at defending the host against continuous exposure to diverse foreign antigens whilst halting the maturation or activation of B cells that recognize self-antigens—autoreactive B cells. This phenomenon is known as B cell tolerance. Defects in tolerance contribute to the development of autoimmune diseases wherein various organs in the body come under misguided attack from its own defense system. The profound discrepancy between the frequency of autoreactive cells generated in the thymus or bone marrow, and the rarity of autoimmune diseases, highlights the efficacy of tolerance mechanisms for purging or controlling autoreactive lymphocytes. Tolerance acquired during the development of B cells in the bone marrow constitutes “central tolerance,” whereas mechanisms halting the maturation or activation of autoreactive B cells in the peripheral lymphoid tissues constitute “peripheral tolerance.” In humans it is estimated that 55%–75% of the IgGs expressed by early immature B cells are autoreactive (Wardemann et al., 2003); however, multiple checkpoints throughout B cell development usually prevent mature B cells from producing autoantibodies.

The number of mechanisms described to contribute to tolerance is expanding, but classically, central tolerance comprises BCR editing, clonal deletion, and anergy (Nemazee, 2017). More recently, sialic acid-binding Ig-like lectin (Siglec)-dependent induction of tolerance has been described to be important (Duong et al., 2010), as has the induction of regulatory B cells (Bregs) as active suppressors of immune responses (Mauri and Bosma, 2012).

### Mechanisms of B Cell Central Tolerance

First, if a B cell expresses an autoreactive BCR, particularly at an early stage of development, it can alter its BCR genes in order to express a nonautoreactive version, a process called “receptor editing.” Second, if receptor editing fails, autoreactive B cells can be removed while still in the bone marrow by a process termed “clonal deletion.” Third, autoreactive B cells that nevertheless escape to the periphery may acquire tolerance by entering a state of specific hyporesponsiveness to antigen, termed “anergy” (Fig. 9.1A).

## Receptor Editing and Clonal Deletion

The generation of adaptive immune responses relies on the stochastic rearrangement of antigen receptor genes to produce a diverse repertoire of antigen receptor specificities. Successful in frame V, diversity (D), and joining (J) gene segment, recombination leads to the expression of a BCR, followed by suppression of RAG 1 and 2 expression to prevent further rearrangements (Nussenzweig et al., 1987). Following the productive rearrangement of the Ig genes on one allele, the Ig genes on the other allele are silenced and thus not expressed. This phenomenon is called allelic exclusion.

However, if these rearrangements produce an autoreactive BCR, the B cells may undergo receptor editing. Receptor editing is the continued rearrangement of the V–J genes encoding the variable regions of Ig light chains, or less commonly the V–(D)J genes encoding the heavy chain variable loci, which results in the expression of a BCR with a new specificity (Gay et al., 1993). This has been reported to be the main mechanism of B cell central tolerance toward high avidity membrane-bound antigens (Halverson et al., 2004). If the rearrangement of the light chain genes results in the expression of a functional BCR that does not bind self-antigen present in the bone marrow, then B cells survive and leave for the periphery. Receptor editing usually occurs early during B cell development and predominantly, although not exclusively, in the bone marrow. Secondary rearrangements may also occur in the periphery, although their importance in maintaining tolerance remains to be fully defined. RAG genes are reexpressed in germinal centers, and it has been demonstrated in mice that mature follicular B cells that are autoreactive/anti-dsDNA specific can undergo receptor editing in germinal centers, following antigen activation, which removes dsDNA specificity (Rice et al., 2005).

Receptor editing allows for several attempts at altering the specificity of the Ig; however, if receptor editing in the bone marrow fails to produce B cells with functional BCRs that are not autoreactive, then the B cells may be eliminated by apoptosis, a process termed “clonal deletion” (Nemazee and Burki, 1989; Hartley et al., 1993). Immature B cells are susceptible to apoptosis by surface Ig cross-linking. Clonal deletion was originally thought to be the major mechanism of B cell central tolerance to high avidity membrane-bound or multivalent self-antigens. However, later studies have suggested that receptor editing is the primary mechanism for removing autoreactive B cells and clonal deletion acts to maintain tolerance when receptor editing fails (Pelanda and Torres, 2012). For instance, Gay et al. generated mice that were transgenic for Ig heavy and light chain genes that encoded a BCR that was specific for dsDNA, an autoantigen in murine and human lupus. As these genes were already rearranged, they would be the first heavy and light chains to be transcribed and, in the absence of receptor editing, all B cells should have been clonally deleted due to their autoreactive BCRs. However, the adult mice had a normal number of mature B cells due to the fact that, while all their B cells expressed the heavy chain transgene, all mature B cells expressed an endogenous light chain, demonstrating that receptor editing had taken place to produce a nonautoreactive BCR (Gay et al., 1993).

## Defective Receptor Editing and Clonal Deletion Can Promote Autoimmunity

Although receptor editing is the main process contributing to the removal of autoreactive B cells, this system is not perfect, and both insufficient and excessive editing can have potentially adverse consequences on autoreactivity (Verkoczy et al., 2004; Yachimovich-Cohen et al., 2003). The Ig heavy chain often has the dominant contribution to BCR specificity and if the heavy chain is autoreactive, the rearrangement of the light chain may not fully remove the autoreactivity (Luning Prak et al., 2011). In addition, light chain rearrangement does not always lead to the abrogation of expression of the initial light chain and when the B cells reach the periphery, the initial autoreactive light chain may be reexpressed (Li et al., 2002b).

Defective receptor editing has been associated with autoimmunity in both mice and humans. In models of SLE (Clark et al., 2013; Lamoureux et al., 2007), type 1 diabetes mellitus (Henry-Bonami et al., 2013) and Sjögren's syndrome (Meng et al., 2012) as well as in patients with SLE (Yurasov et al., 2005) defects in receptor editing and early B cell tolerance have been reported. It has been hypothesized that inefficient receptor editing in autoimmune-prone mice might allow the escape to the periphery of B cells with two types of Ig heavy or light chains. These dual-reactive B cells are rare in healthy mice but present at increased levels in autoimmune strains and are frequently more autoreactive than B cells expressing only one heavy and light chain (Fournier et al., 2012). Excessive receptor editing may also contribute to pathogenesis through the generation of B cells with autoreactive BCRs. For example, lupus-prone NZB/NZW F1 mice that develop disease utilize secondary receptor arrangements to generate high-affinity antibodies from low-affinity precursor clones (Yachimovich-Cohen et al., 2003). In addition, lupus-prone MRL/lpr.56R mice that are transgenic for an

autoreactive Ig heavy chain have increased production of autoantibodies compared to nontransgenic MRL/lpr mice. However, the majority of the autoantibodies in the transgenic mouse do not use the transgenic Ig heavy chain, suggesting that excessive receptor editing has led to the generation of autoreactive BCRs (Li et al., 2002a). These findings indicate that even small perturbations in the efficacy of selection mechanisms could potentially result in the breach of tolerance.

## B Cell Anergy

Despite the general efficiency of receptor editing and clonal deletion, B cells carrying self-reactive BCRs may still escape central tolerance and reach the periphery. Here, elimination of autoreactive B lymphocytes can be achieved by inducing a state of specific hyporesponsiveness to antigen, known as anergy, in the autoreactive B cells. Typically, anergy is a consequence of prolonged exposure to antigen and is achieved through B cell functional inactivation (Cambier et al., 2007). Anergic B cells are unable to interact effectively with helper T cells and do not participate in immune responses against their cognate antigen. It was initially demonstrated that B cell tolerance to antigens could arise through anergy rather than clonal deletion (Nossal and Pike, 1980), as follows. Treatment of newborn mice with a soluble molecule that would generate an immune response in adult mice, fluorescein-human gamma globulin (Flu-HGG), resulted in tolerance to this molecule when the mice reached maturity, even though they maintained normal numbers of Flu-HGG-specific B cells. Subsequently, Hartley et al. (1991) demonstrated that it is the nature of the antigen, rather than the affinity of BCR–antigen interactions, that is responsible for whether tolerance comes from clonal deletion or anergy. Hartley et al. generated two transgenic mouse models both carrying BCRs that were specific for hen egg lysozyme (HEL); the first expressed membrane-bound HEL as well as the transgenic BCR, and the second expressed soluble HEL as well as the transgenic BCR. The results demonstrated that clonal deletion of the HEL-specific transgenic B cells occurred when mice expressed membrane-bound HEL, whereas clonal anergy occurred in mice expressing soluble HEL. Thus in immature B cells, binding to high avidity multivalent membrane-bound antigen predominantly leads to receptor editing, or clonal deletion, while binding to low avidity monovalent, or oligovalent, soluble antigen mainly leads to anergy. More recently, it has been demonstrated that there is a spectrum of B cell hyporesponsiveness following B cell encounter with self-antigen; the signal strength of the interaction with self-antigen directs the degree of B cell responsiveness to subsequent antigen encounter. Thus an anergic B cell can exist somewhere along a continuum of possible anergy states (Zilberman et al., 2012).

## Characteristics of Anergic B Cells

Anergic B cells are characterized by reduced expression of BCR on their surface. This low expression of the BCR is an important feature of anergic B cells as the impaired transduction of positive signals via CD79 prevents autoreactive B cell signaling and activation. If B cells are unable to downregulate their BCR in response to self-antigen, autoimmunity may develop. For instance, double deficiency in the E3 ubiquitin ligases Cbl and Cblb leads to the inability to downregulate surface BCR and development of lupus-like disease (Kitaura et al., 2007). Anti-CD79 antibody has been shown to ameliorate disease in lupus-prone MRL/lpr mice (Li et al., 2008) as well as in a murine model of rheumatoid arthritis (Hardy et al., 2014). The latter study demonstrated that anti-CD79 antibody treatment modulated BCR signal strength and induced an anergic state in B cells, suggesting induction of anergy as an alternative strategy to B cell–depletion therapy in the treatment of autoimmune diseases (Hardy et al., 2014). Another characteristic of anergic B cells is the increased recruitment of negative signaling regulators, including the SHP-1 and SHIP-1, to the BCR complex. Increased SHP-1 and SHIP-1 expression can inhibit BCR-mediated B-cell activation by the dephosphorylation of signaling molecules downstream of the BCR and CD79. Defects in SHP-1 or SHIP-1 are associated with increased autoantibody production (Huang et al., 2003). B cell–specific deletion of SHIP-1 causes loss of anergy and lupus-like disease in mice (O'Neill et al., 2011). Resistance to apoptotic stimuli and increased autoantibody production in the absence of B cell PTEN have also been demonstrated (Suzuki et al., 2003). The short half-life of anergic B cells is a further characteristic that adds an additional brake to B cell autoreactivity. Anergic B cells have an estimated half-life of 3–4 days in contrast to nonanergic naïve B cells with a half-life of around 4–5 weeks (Fulcher and Basten, 1994).

## B CELL–ACTIVATING FACTOR AND TONIC SIGNALS MODULATE B CELL TOLERANCE

### B Cell–Activating Factor in B Cell Development and Survival

B cell development, survival, and differentiation depend on the presence of several key chemical mediators, among which B cell–activating factor (BAFF), also known as B lymphocyte stimulator, is critical. The importance of BAFF in B cell maturation was demonstrated by work from the Mackay group, they showed that B cells in BAFF- and BAFF-receptor (BAFF-R)-deficient mice were developmentally arrested at the immature stage of B cell development (Mackay et al., 2002). BAFF is a trimeric member of the tumor necrosis factor (TNF) family and it signals through BAFF-R, B cell maturation antigen (BCMA), and transmembrane activator and calcium modulator and cyclophilin-ligand interactor (TACI) (Mackay and Schneider, 2009). These receptors are differentially expressed at each stage of B cell development and differentiation. For example, BAFF-R is expressed from the immature B cell stage and increases in expression as they mature; however, it is absent on germinal center B cells and long-lived plasma cells in the bone marrow. Antibody-producing cells express BCMA, while TACI is expressed on switched memory B cells amongst others. BAFF itself is produced by stromal and myeloid lineage cells, as well as lymphocytes under certain conditions (Mackay and Schneider, 2009).

### Tonic Signaling in B Cell Development and Survival

Tonic signaling is important for the development of immature B cells in the bone marrow and for the maintenance and survival of mature B cells in the periphery. Tonic signaling refers to the process of low-level constitutive signaling in the resting state in the absence of full and robust B cell activation. In B cells, this basal signaling is thought to occur through the BCR. Whether endogenous ligand expression plays a role in tonic signaling, or whether BCR expression without ligation is sufficient for tonic signaling, remains unclear (Cariappa and Pillai, 2002; Cancro and Kearney, 2004; Su et al., 2004). Nevertheless, evidence suggests that while early in B cell development, tonic signaling may be antigen independent, mature B cell survival in the periphery may require low-level antigen stimulation. In mature naïve B lymphocytes, cells with low-level self-reactivity have a competitive survival advantage over B cell clones that do not (Rosado and Freitas, 1998).

In the steady state, the stochastic phosphorylation of ITAMs in CD79 is held in dynamic equilibrium with negative signals through the phosphatase activity of CD45 and inhibitory receptors such as CD5, CD22, and CD72. Src kinases that are activated by tonic BCR signals also phosphorylate inhibitory ITIMs on molecules such as CD22. These, in turn, recruit protein tyrosine phosphatases that dephosphorylate the ITAMs on CD79 to inhibit BCR signals.

A failure of tonic signaling at an immature B cell stage can lead to a developmental regression that can restart the process of Ig gene recombination (Tze et al., 2005). Indeed, during development in the bone marrow, the inability to express BCR or its signaling components leads to ongoing light chain rearrangement (Pelanda, 2014). Thus the tonic signaling that results from successful BCR expression is needed for the B cell to move on to the next developmental stage. The requirement for tonic signaling in mature B cell peripheral persistence is demonstrated by the rapid loss of mature B cells upon inducible BCR ablation (Lam et al., 1997; Kraus et al., 2004). It has been subsequently demonstrated that mature naïve B cell survival in the absence of BCR expression can be rescued through the expression of PI3K, which makes up for the lack of tonic signaling through the BCR (Srinivasan et al., 2009).

Tonic signaling positively regulates the expression of BAFF-R, and the combination of tonic signaling and BAFF/BAFF-R signaling drives B cell maturation (Rowland et al., 2013). The requirement for both BAFF-R expression and tonic signaling for B cell maturation provides a checkpoint for preventing the escape of autoreactive B cells into the periphery as binding of autoantigen by autoreactive B cells leads to the internalization of the BCR and thus a loss of both tonic signaling and BAFF-R expression (Pelanda and Torres, 2012; Rowland et al., 2010).

### B Cell–Activating Factor, Tonic Signaling, and Autoimmunity

A role of BAFF in autoimmunity was observed in BAFF-transgenic mice that developed an autoimmune-like syndrome, where the B cells from BAFF-transgenic mice secreted unusually high amounts of rheumatoid factor

antibodies and the mice developed lupus-like disease (Mackay et al., 1999). BAFF overexpression rescued autoreactive B cells from deletion in the periphery, but not in the bone marrow, and favored their migration to secondary lymphoid tissues for maturation (Thien et al., 2004). Patients with autoimmune diseases such as Sjögren's syndrome and SLE have high levels of BAFF, which may contribute to altered differentiation of B cells (Pillai et al., 2011), and this was the rationale for clinical application of the anti-BAFF antibody belimumab in the treatment of SLE (Navarra et al., 2011). It is currently the only biologic treatment approved for SLE. Thus whereas BAFF signaling is critical in normal B cell development, when dysregulated, it can provoke a breakdown in B-cell tolerance leading to systemic autoimmunity.

Defects or deficiencies in tonic signaling can lead to autoimmunity. A breach of tolerance can occur due to incomplete allelic exclusion of light chain genes, whereby dual-specificity BCRs are expressed, that is, development of B cells that express both autoreactive and nonautoreactive BCRs. If the ratio of autoreactive to nonautoreactive BCRs is such that the majority of signaling is tonic signaling from the nonautoreactive BCR, rather than stronger self-antigen-mediated signaling through the autoreactive BCR, this may allow the maturation of these bispecific B cells (Pelanda and Torres, 2012). In such cases, the autoreactive BCR is generally expressed first, and allelic inclusion occurs as a consequence of incomplete silencing.

Deficiencies in the molecules that negatively regulate tonic, and antigen-dependent, BCR signaling can also lead to autoimmunity. CD22-deficient mice produce high-affinity anti-dsDNA antibodies suggesting that defects in CD22 function may support B cell–mediated autoimmunity (O'Keefe et al., 1999). The combined deficiency of CD22 and its ligand Siglec-G causes spontaneous autoimmunity in mice and thus targeting this pathway could be useful in the treatment of autoimmunity (Muller and Nitschke, 2014).

Fc $\gamma$ RIIb, an inhibitory Fc receptor, which also contains an ITIM on its intracellular domain, plays a role in regulating BCR signals, through the recruitment of tyrosine phosphatases. Mice deficient in this receptor develop a spontaneous autoimmune disease characterized by fatal glomerulonephritis and accumulation of anti-dsDNA-producing plasma cells (Fukuyama et al., 2005). In humans, polymorphisms in the Fc $\gamma$ RIIb gene, which encode receptors with reduced regulatory activity, have been associated with SLE (Niederer et al., 2010). In lupus-prone mice, overexpression of Fc $\gamma$ RIIb restored B cell tolerance (McGaha et al., 2005).

## REGULATORY T CELLS

B cell peripheral tolerance is also maintained by regulatory T cell (Treg) suppression of autoantibody production by B cells. Tregs can suppress maturation of the humoral response either indirectly by suppressing the activation of Tfh cells that would support B cell autoantibody production (Fields et al., 2005) or directly by physically removing cognate Tfh help (Sage et al., 2016). Direct induction of B cell apoptosis by Tregs in a B cell PD-1-dependent manner has also been described (Gotot et al., 2012). It is likely that additional checkpoints for Tregs in the suppression of B cell responses are yet to be uncovered.

## ANTIBODY-INDEPENDENT ACTIVITY OF B CELLS IN TOLERANCE

As discussed earlier, B cell tolerance is shaped during the development of B lymphocytes, by receptor editing, clonal deletion, and anergy. However, evidence is mounting for an antibody-independent role for B cells in the maintenance and breakdown of tolerance. In part driven by the success of B cell–depletion therapies even in cases where autoantibody levels remain unaffected, it is now recognized that B cells have antibody-independent effects on disease. Other B cell roles in the maintenance and breakdown of tolerance include the antigen-presenting role of B cells and their production of both pro- and antiinflammatory cytokines.

### Antigen Presentation by B Cells

B cells act as antigen-presenting cells, priming T cells and enhancing their activation. It has been demonstrated that B cell expression of MHC class II is required for the development of autoimmunity in a murine model of multiple sclerosis, and this occurs in an antibody-independent manner (Molnarfi et al., 2013). In a small cohort of patients with the autoimmune disease pemphigus vulgaris who had been treated with rituximab, the depletion of B cells was accompanied not only by the reduction in autoantibody levels but also a

decline in the autoantigen desmoglein 3-specific Th1 and Th2 cell frequencies. At the same time, the total CD4+ T cell count as well as irrelevant antigen-specific T cell frequencies were maintained (Eming et al., 2008). Similar observations have been made in rheumatoid arthritis patients, where the synovial tissue following rituximab treatment was shown to have reduced numbers of Th17 cells, as well as reduced expression of the associated transcription factor ROR- $\gamma$ t and the cytokine IL-22. These reductions correlated with better clinical outcome (van de Veerdonk et al., 2011).

## Cytokine Production by B Cells

Most of our knowledge about B cell cytokine production in the regulation of immune responses come from animal models (Shen and Fillatreau, 2015). It is now recognized that B cells can produce a polarized array of cytokines depending on their primary encounter with antigen and T cells. Therefore, similar to T cells, B cells can be categorized based on the cytokines that they produce.

It was first recognized in mice that under certain conditions, B cells could be polarized to secrete IFN- $\gamma$  or IL-4 (Harris et al., 2000). Naive B cells differentiated in the presence of Th1 cells release IFN- $\gamma$  and IL-12. In contrast, naïve B cells that differentiate in the presence of Th2 cells predominantly produce IL-2, IL-4, and IL-6 (Harris et al., 2000). IL-17-producing B cells have been reported to have a physiological role in response to *Trypanosoma cruzi* infection (Bermejo et al., 2013). Using both murine and human primary B cells, Rawlings et al. demonstrated that B cell–specific IL-17 deficiency led to inability to control infection, increased liver damage, and reduced survival compared to control animals (Bermejo et al., 2013). Murine B cells have also been shown to contribute to protective immunity in *Salmonella enterica* serovar *Typhimurium* infection through IL-6- and IFN- $\gamma$ -mediated Th1 programming (Barr et al., 2010), as well as to enhance Th1 responses to *Toxoplasma gondii* through the provision of TNF- $\alpha$  (Menard et al., 2007). Thus B cells can produce a variety of cytokines and contribute to the protective immunity during infection. The contribution of the cytokines released by B cells in the pathogenesis of autoimmune disease is yet to be clearly defined, but recent findings have shown that IL-6-producing B cells promote Th17 responses and contribute to the pathogenesis of experimental autoimmune encephalomyelitis and to multiple sclerosis (Barr et al., 2012). Further, proinflammatory GM-CSF-producing memory B cells are enriched in multiple sclerosis patients compared to healthy controls, which was normalized following B cell–depletion therapy (Li et al., 2015).

## Regulatory B Cells

B cells can also produce antiinflammatory cytokines IL-10 and TGF- $\beta$ , known to restrain the excessive inflammation associated with autoimmunity. Over the last decade, numerous studies have confirmed the importance of IL-10-producing Bregs in the maintenance of tolerance (Mauri and Bosma, 2012). Studies utilizing chimeric mice, whose B cells alone are IL-10 deficient, have revealed that B cell–derived IL-10 limits the severity of inflammation in several autoimmune disorders (Carter et al., 2011; Fillatreau et al., 2002). In the absence of IL-10-producing B cells, chimeric mice present a reduction in the number of T regulatory 1 and Foxp3 $^{+}$  Tregs, and an increase in inflammatory Th1 and Th17 cells compared to mice with IL-10 sufficient B cells. In mice, TGF- $\beta$ -mediated inhibition of CD8 $^{+}$  T cell responses by lipopolysaccharide (LPS)-activated B cells has also been demonstrated (Parekh et al., 2003). Thus Bregs contribute to the maintenance of peripheral tolerance by the production of the potent antiinflammatory cytokines IL-10 and/or TGF $\beta$ , directly by inhibiting the differentiation of Th1, Th17, and CD8 $^{+}$  T cells and indirectly by converting targeted effector T cells into Tregs (Carter et al., 2011).

BCR activation, which is crucial in dictating the specificity of antibody responses and the function of B cells as antigen-presenting cells, has been shown to play a role in Breg function. Research has revealed that exposure to an autoantigen leads to an increased IL-10 production by Bregs and an enhanced ability to suppress autoimmune responses (Mauri et al., 2003). Similarly, in the field of transplantation, it has been reported that TIM-1 $^{+}$  Bregs prolonged pancreatic islet allograft survival, but only when the TIM-1 $^{+}$  B cells are specific for the MHC expressed by the transplanted islet cells, suggesting a role for specific BCR signaling (Ding et al., 2011). Other signals that induce IL-10-producing Bregs have also been uncovered, including CD40 ligation and cytokines including IL-1 and IL-6 (Rosser et al., 2014), IL-21 (Yoshizaki et al., 2012), and IL-35 (Wang et al., 2014).

Bregs also play a role in the maintenance of tolerance in healthy individuals. While murine Bregs are functionally better characterized, human IL-10-producing B cells have been postulated to arise at multiple stages of B cell development and can be detected within populations that phenotypically resemble CD24<sup>hi</sup>CD38<sup>hi</sup> immature B cells, CD24<sup>+</sup>CD27<sup>+</sup> memory B cells, and CD24<sup>-</sup>CD38<sup>hi</sup>CD27<sup>+</sup> plasmablasts. Immature B cells isolated from healthy volunteers produce a higher amount of IL-10 than any other human peripheral blood B cell subset and can suppress proinflammatory cytokine production by anti-CD3-activated CD4<sup>+</sup> T cells in vitro. Interestingly, in patients with SLE, isolated Bregs failed to upregulate IL-10 in response to CD40 engagement and failed to suppress the production of proinflammatory cytokines by T cells (Blair et al., 2010). Accordingly rituximab, a B cell-depleting anti-CD20 monoclonal antibody, which has proved successful for treating some autoimmune conditions, may function not only by depleting autoantibody-producing B cells but also by resetting the balance between pathogenic and Bregs following B cell repopulation (Bosma et al., 2012; Manjarrez-Orduno et al., 2009). Interestingly, while CD24<sup>hi</sup>CD38<sup>hi</sup> Bregs are either numerically or functionally deficient in autoimmunity, CD24<sup>hi</sup>CD27<sup>+</sup> Bregs are expanded in patients with autoimmune disease (Iwata et al., 2011).

The immune system, thus, has several checkpoints to curtail the escape of autoreactive B cells to the periphery, as well as their activation, and hence to prevent autoimmunity. Among these checkpoints, as described earlier, are receptor editing, clonal deletion, and anergy. However, it is becoming clearer that in the periphery, tolerance is maintained also by regulatory subsets of cells, including Bregs and Tregs, that control the production of inflammatory cytokines and limit autoreactive responses (Fig. 9.1C).

## Future Directions

Although there are a number of potential models for the first steps of B cell activation, it is still unclear how antigen binding to the BCR initiates activation. Better understanding this process may lead to the development of therapies that would be beneficial for the treatment of autoimmunity. For example antigen-specific immobilization of BCR or its signaling components within certain cell surface domains, or inhibiting the segregation of stimulatory and inhibitory coreceptors, could prevent the activation of autoreactive B cells. Since B cell role in antigen presentation requires antigen internalization via BCR following binding, this may also lead to down-modulation of B cell antigen presentation to autoreactive T cells.

Whether defects in particular mechanisms of B cell tolerance result in clinically different autoimmune diseases remains unanswered. In particular, it is yet to be determined exactly how B cells bearing two different BCRs are both generated and able to escape central tolerance and whether the persistence of these cells does actually contribute to the development of autoimmunity. For instance, could defects in receptor editing that lead to the expression of two distinct BCRs by mature B cells, one autoreactive and one reactive to a microbial antigen, be important in generating autoantibody to autoantigens that the B cells might otherwise not see in the bone marrow? Thus B cells expressing dual BCRs may be activated by the microbial antigen to produce autoreactive antibody and contribute to the pathogenesis of autoimmune diseases, even though the relevant autoantigen would not generally be subject to immune surveillance (i.e., nuclear antigens following microbe-induced inflammatory response)? Or will dual-specific B cells only be generated to self-antigen available in the early stages of development?

Do evolutionary pressures to maintain diversity in B cell specificity have the consequence of also maintaining some autoreactivity within the mature B cell compartment? It has been recently demonstrated that self-reactive B-cell clones participate in responses to foreign antigens that are structurally similar to self-antigens. In this case, self-reactive clone anergy was reversed through a challenge with high-density foreign antigen, but the BCR hypermutation that occurred resulted in increased recognition of the foreign antigen and decreased self-reactivity (Burnett et al., 2018). Thus perhaps maintaining a degree of autoreactivity allows for a larger diversity in B cell antigen reactivity and is of benefit to the host as it allows defense against a wider array of pathogens.

Similarly, it is not currently clear what effect the presence of a constantly renewing niche of anergic B cells in healthy humans has on B cell–driven immune responses (Palanichamy et al., 2009). Assuming a large proportion of these anergic B cells are autoreactive, they may compete with nonanergic B cells for autoantigen, and thus their presence could act as a sink for autoantigen, sequestering it from nonanergic autoreactive B cells and preventing the activation of autoreactive T cells. Defects in the generation of anergic B cells may thus lead to autoreactive T cell–mediated autoimmunity. Or conversely, an excessively large anergic B cell pool containing polyreactive as well as autoreactive B cell specificities may prevent nonanergic pathogen-specific B cells from activating T cells.

## INTRODUCTION

Macrophages are part of the innate immune system and play an important role in the maintenance of tissue homeostasis as well as initiation and regulation of inflammation. The versatility of these cells is linked to their ability to sample and react to their environment in a tissue-dependent manner, exploit their arsenal of degrading enzymes to effectively eliminate endocytic and phagocytic cargo, and secrete a wide range of mediators that influence the behavior of immune and nonimmune cells in a paracrine and endocrine manner (Taylor et al., 2005).

The strong link between particular human leukocyte antigen (HLA) haplotypes and autoimmune diseases highlights the important role of adaptive immunity in autoimmune diseases (Gough and Simmonds, 2007). Dendritic cells instruct T and B lymphocytes to undergo specific activation profiles in the context of selected cytokine environments by displaying at the cell-surface antigens in the form of major histocompatibility complex (MHC)-peptide complexes alongside costimulatory signals (Audiger et al., 2017). Thus dendritic cells enjoy central stage in autoimmunity research aiming to understand how self-antigens are presented in an immunogenic fashion to autoreactive T cells that escape negative selection in the thymus (Audiger et al., 2017). Dendritic cells and macrophages are both mononuclear myeloid cells and share numerous characteristics including a highly developed endocytic compartment, expression of a wide range of sensing receptors termed pattern recognition receptors (PRRs), and ability to migrate and respond to their environment. Both cells are professional antigen presenting cells but, from a functional point of view, dendritic cells are endowed with the capacity to activate

naïve T cells (Guerder et al., 2013). Macrophages, in contrast, interact with activated T cells during inflammation and, as such, act as effector and regulatory cells during T cell–mediated inflammatory responses. The contribution of macrophages to T cell–mediated immunity in autoimmunity can be further shaped through interaction with self-reactive antibodies recognized by receptors for their Fc portion (Fc receptors, FcRs) (Clynes et al., 1999; Swanson and Hoppe, 2004; Takai, 2002).

Distinction between autoimmune and autoinflammatory diseases is based on the identification of self-reactive T and B cells, which are lacking in autoinflammatory diseases (Manthiram et al., 2017). Nevertheless, it is plausible that dysregulated antigen presentation takes place in the context of genetic abnormalities in intracellular sensing pathways of macrophages linked to autoinflammatory diseases. In this context, the lower threshold of macrophage activation and associated inflammation could provide the setting for the release and modification of self-antigens that can then be internalized and presented by activated dendritic cells.

This chapter will first provide a general overview of macrophage biology focusing on macrophage heterogeneity, receptors used by macrophages to survey their environment, and the phagocytic process. Because of the importance of self-recognition in the induction of autoimmune diseases, special mention will be made of endogenous activators and inhibitors of macrophage receptors and the process of apoptotic cell clearance.

## GENERAL CHARACTERISTICS OF MACROPHAGES

Macrophages are cells of hematopoietic origin first identified by Élie Metchnikoff more than a century ago as mediators of cell-mediated immunity in the form of phagocytosis (Gordon, 2016). Macrophages reside in all tissues under steady-state conditions and adopt tissue-specific characteristics. Tissue adaptation is underpinned by epigenetic modifications and translates into distinct transcriptome profiles (Davies et al., 2013). Macrophages display a highly developed endosomal compartment which enables effective endocytosis and phagocytosis. In addition, macrophages secrete a wide array of soluble molecules encompassing cytokines and chemokines, complement components, lipids, and growth factors. Macrophages can also control amino acid availability through the action of indoleamine 2,3-dioxygenase (Munn et al., 1998, 1999; Ravishankar et al., 2012) and arginase (Pesce et al., 2009) that degrades tryptophan and L-arginine, respectively, with important consequences on dampening T cell proliferation, and contributes to bone remodeling, erythropoiesis, brain development, lung homeostasis, iron recycling (Soares and Hamza, 2016), and thermogenesis (Gordon and Martinez-Pomares, 2017).

## HETEROGENEITY OF TISSUE MACROPHAGES UNDER STEADY-STATE CONDITIONS

Macrophages are intrinsic components of all organs where they contribute to tissue homeostasis and surveillance (Okabe and Medzhitov, 2016). Macrophage phenotype in tissues is associated with distinct gene expression patterns controlled epigenetically and largely dictated by the tissue environment rather than ontogeny (Lavin et al., 2014). Hence, under steady-state conditions, tissue macrophages display a variety of phenotypic adaptations linked to their anatomical location and contribution to tissue function. For instance, alveolar macrophages contribute to surfactant homeostasis (Gordon and Martinez-Pomares, 2017), while splenic red pulp macrophages eliminate old erythrocytes and degrade heme groups, hence contributing to iron recycling (Gordon and Martinez-Pomares, 2017). Microglia in the central nervous system promote neuronal development and are involved in synaptic remodeling, and bone-marrow macrophages support hematopoiesis (Gordon and Martinez-Pomares, 2017). Phagocytosis of circulating blood cells further increases the heterogeneity of macrophages within tissues (Noelia et al., 2017). In spite of these differences, all tissue macrophages share an important role in immuno-surveillance which places them as central initiators of inflammation (Haldar and Murphy, 2014). The threshold of activation and sensing mechanisms can vary substantially amongst different macrophage populations (Gordon and Martinez-Pomares, 2017).

The model proposing a monocyte-derived origin of tissue macrophages (van Furth et al., 1972) dominated the field of macrophage differentiation for decades. In 2011 a seminal work by Jenkins et al. (2011) demonstrated that in the context of T helper (Th)2-dominated inflammation, numbers of macrophages increased through cellular replication rather than monocyte recruitment. These findings challenged the idea of macrophages as long lived, terminally differentiated cells with limited ability for self-replication; self-replication has been observed in tissue macrophages under steady-state conditions and additional populations of inflammatory macrophages

(Amano et al., 2014) with early reports showing replication of human alveolar macrophages under inflammatory conditions (Bitterman et al., 1984).

Fate-mapping techniques have enabled the establishment of the embryonic origin of most tissue macrophages. Tissue macrophages are seeded during embryonic development and derived from the yolk sac and/or fetal liver. Once definitive hematopoiesis initiates in the bone marrow, hematopoietic stem cells (HSC) contribute to the replenishment of tissue macrophages through their differentiation into circulating monocytes (Epelman et al., 2014; Ginhoux and Guilliams, 2016; Haldar and Murphy, 2014; Sieweke and Allen, 2013; Wynn et al., 2013). The contribution of monocytes to the maintenance of tissue macrophage populations varies among organs and depends on the self-renewal capacity of resident macrophages and accessibility to blood of the particular organ. Tissues with rapid macrophage turnover that rely on monocyte recruitment and differentiation to maintain tissue macrophage numbers include skin dermis and intestine; macrophages in both locations have an estimated half-life of 4–6 weeks and are not capable of self-maintenance (Ginhoux and Guilliams, 2016). Tissues with low access to blood such as epidermis, lung, and brain (Langerhans cells, alveolar macrophages, and microglia, respectively) depend on self-renewal of resident macrophages. In between these extremes, organs, such as spleen and kidney, contain variable percentages of fetal- and monocyte-derived macrophages. Guilliams and Scott (Guilliams and Scott, 2017; van de Laar et al., 2016) recently proposed that niche availability determines the contribution of recruited monocytes to the maintenance of macrophages in tissues and suggests a mechanism of “quorum sensing” by tissue macrophages based on availability of macrophage colony stimulating factor (M-CSF, CSF-1). Under-stated conditions where there is a drastic reduction in the number of tissue macrophages, these will be replenished through an increased replication of resident macrophages, as well as increased recruitment of monocytes that differentiate into macrophages. The population of “monocyte-derived tissue macrophages” will be maintained through self-renewal alongside their fetal-origin counterparts.

In adulthood, all monocytes are generated from definitive HSC from monocyte–macrophage–dendritic cell progenitors, and their production is completely M-CSF-dependent (Ginhoux and Jung, 2014). Two populations of monocytes have been described in mouse, LY6C<sup>hi</sup>CX<sub>3</sub>CR1<sup>mid</sup>CCR2<sup>+</sup>CD62L<sup>+</sup>CD43<sup>low</sup> and LY6C<sup>low</sup>CX3CR1<sup>hi</sup>CCR2<sup>-</sup>CD62L<sup>-</sup>CD43<sup>hi</sup>, which broadly correspond to the CD14<sup>+</sup> and CD14<sup>low</sup> CD16<sup>+</sup> monocyte populations found in humans (Epelman et al., 2014; Halder and Murphy, 2014). LyC6<sup>high</sup> monocytes constitutively migrate into tissues in a CD62L-dependent manner without undergoing differentiation. After antigen acquisition in the peripheral tissue, LyC6<sup>high</sup> monocytes migrate through lymphatic vessels to draining lymph nodes (Jakubzick et al., 2013). The LyC6<sup>-</sup> monocytes (CD14<sup>low</sup> CD16<sup>+</sup> in humans) probably derive from the LyC6<sup>high</sup> cells and likely represent terminally differentiated “blood-resident macrophages.” LyC6<sup>-</sup> monocytes survey the vasculature and contribute to the maintenance of endothelial integrity.

## MACROPHAGE HETEROGENEITY DURING INFLAMMATION

Macrophages exemplify the “modus operandi” of the innate immune system—they display a wide range of systems to sense their environment and respond fast to disturbance(s) of the homeostatic status, while using their substantial endocytic and phagocytic capabilities to contain the damage. The range of “sensing systems” expressed, the threshold of activation, and the type of effector functions can vary dramatically among different macrophage populations. These variations occur among macrophages in different tissues under steady-state conditions, as discussed above, as well as among macrophages within the same organ but exposed to different inflammatory environments. The stage of the inflammatory process (initiation vs resolution) and the predominant cytokine milieu—proinflammatory (Th1-, Th2-, or Th17-dominated) or antiinflammatory (Treg-dominated)—will have major consequences on macrophage phenotype. This heterogeneity described as a “spectrum of macrophage activation” encompasses both proinflammatory (M1-like) and proresolving (M2-like) macrophages which are considered the extremes of a continuum of macrophage phenotypes (Mosser and Edwards, 2008; Murray et al., 2014).

The macrophage polarization concept was originally developed based on the distinct effects of the prototypical Th1 and Th2 cytokines, IFN- $\gamma$ /TNF- $\alpha$  and IL-4/IL-13, respectively, on the phenotype of cultured macrophages (Gordon, 2003; Gordon and Martinez, 2010; Murray, 2017; Murray et al., 2014; Stein et al., 1992). IFN- $\gamma$ -treated macrophages are microbicidal for intracellular pathogens and produce high levels of radical oxygen species (ROS) and, particularly in mice, nitrogen oxide (NO). ROS are generated through the action of the NADPH oxidase NOX2 and NO through the action of iNOS that processes L-arginine into NO and citrulline. M1 macrophages also produce proinflammatory cytokines such as IL-12, IL-6, and TNF- $\alpha$  alongside low IL-10 and the chemokines CXCL9, 10, and 11 and CCL2, 3, 4, and 5. IL-4/IL-13-treated macrophages display high expression of selected

surface markers such as lectin [mannose receptor (MR)], CD163 and scavenger receptors, and process L-arginine through the action of arginase into ornithine and urea. Ornithine can be further processed into proline which is thought to promote collagen synthesis and, in turn, fibrosis. Cytokines produced by M2-like macrophages include IL-1Ra, IL-10, and chemokines CCL17, 18, 22, and CCL24 (Biswas et al., 2013; Mantovani et al., 2004).

Metabolic changes are also characteristic of macrophage polarization (Langston et al., 2017; O'Neill and Pearce, 2016). M1 macrophages change their metabolism toward aerobic glycolysis, termed “the Warburg effect,” and fatty acid synthesis. In M1 macrophages, the Krebs cycle is broken at two places, one after citrate and the other after succinate. Citrate accumulation promotes the synthesis of NO, ROS, and prostaglandins as well as itaconic acid which has antibacterial properties and has been shown to limit the viability of *Salmonella typhimurium* and *Mycobacterium tuberculosis*. Succinate accumulation promotes the synthesis of IL-1 $\beta$  through activation of the transcription factor HIF1 $\alpha$ , which leads to sustained transcription of pro-IL-1 $\beta$ . It has also been shown that glycolysis is required for the activation of the NLRP3 inflammasome which will further promote IL-1 $\beta$  synthesis.

In contrast, the metabolism of M2 macrophages is based on oxidative phosphorylation. The Krebs cycle is intact, and there is an increased amino sugar and nucleotide sugar metabolism leading to high levels of UDP-GlcNAc, UDP-glucose, and UDP-glucuronate (Jha et al., 2015), as well as transcriptional upregulation of steps in the N-glycan pathway (Jha et al., 2015) which suggest the importance of protein glycosylation in these cells. Liu et al. recently showed that  $\alpha$ -ketoglutarate produced through glutaminolysis promotes M2 activation while restricting M1 activation. Interestingly,  $\alpha$ -ketoglutarate also promotes endotoxin tolerance after M1 activation (Liu et al., 2017).

The antiinflammatory cytokine IL-10 has been shown to counteract the switch to glycolysis and glucose consumption induced by lipopolysaccharide (LPS) in macrophages (Ip et al., 2017). IL-10 promotes the induction of autophagy and inhibits the master regulator of metabolism mTOR through the action of the negative regulator DDIT4. Importantly, IL-10 appears to work in an autocrine manner, since IL-10 deficient macrophages displayed an altered metabolic profile after LPS activation (Ip et al., 2017) supporting a self-regulatory circuit during macrophage activation.

Metabolic differences between M1 and M2 macrophages could be related to their different involvement during immune responses. M1 macrophages are required in an acute fashion, and their energy needs are provided by a poorly efficient but fast metabolic setting. M2 macrophage metabolism would be better suited for long-term responses such as those taking place during parasitic infections which are dominated by Th2 immunity (Gause et al., 2013). Iron metabolism is also affected by M1/M2 polarization with M1 shown to sequester iron, an important determinant of microbial growth, while an M2 phenotype has been shown to increase iron availability (Cairo et al., 2011; Soares and Hamza, 2016).

Additional changes associated with macrophage polarization include alterations in the endocytic compartment (Montaner et al., 1999). Phagocytosis in macrophages, unlike neutrophils, follows the endocytic pathway, and differences between M1 and M2 phagolysosomes have been identified (Levin et al., 2016). In M1 macrophages, as in neutrophils, there is a production of large quantities of ROS because of high activity of the NADPH oxidase NOX2, and the luminal pH remains neutral or alkaline because of reduced activity of the V-ATPase (a proton pump) and a large rate of proton consumption through dismutation of superoxide to H<sub>2</sub>O<sub>2</sub>. M2 phagosomes, in contrast, generate less ROS because of reduced NOX2 activity and reach lower pH values. The lower pH provides the optimal environment for the activation of hydrolases present in the lysosomes improving the degradative capacity of the phagosomal compartment.

Although it is relatively safe to link “proinflammatory phenotype” and “M1 activation,” the M2 phenotype is broader and encompasses cells that contribute to Th2-mediated inflammation, such as those induced in response to allergens and parasites (Gause et al., 2013) as well as fibrotic diseases (Vannella and Wynn, 2017). In addition, the term M2 also includes cells with immunosuppressive characteristics that promote resolution of inflammation. Some authors distinguish three types of M2 macrophages: M2a (IL-4/IL-13 induced), M2b (induced by immunocomplexes and LPS), and M2c macrophages (induced by IL-10, TGF- $\beta$ , and/or glucocorticoids) (Roszer, 2015). The existence of M2d macrophages, obtained in response to IL-6 and adenosine (Roszer, 2015), has also been described. Means used by macrophages to inhibit immune responses include sequestration of essential amino acids such as L-arginine and tryptophan (see above), expression of PD-L1 (Fangchao et al., 2017), as well as the production of the antiinflammatory cytokines IL-10 and TGF- $\beta$ . Macrophages also contribute to the synthesis of proresolving lipids (Basil and Levy, 2016; Serhan, 2014) which could contribute to the resolution phase of inflammation (Freire-de-Lima et al., 2006). The acquisition of an M2-like phenotype (M2b) in mouse macrophages upon treatment with endotoxin and immunocomplexes (Edwards et al., 2006) was unexpected as both stimuli in separation are considered proinflammatory. Thus a better understanding of the “decision-making process”

undertaken by macrophages exposed to independent signals is essential to better design tools for the manipulation of macrophages in the context of autoimmune diseases. Members of the collectin family surfactant protein A and C1q have been identified as local tissue amplifiers of IL-4R $\alpha$ -mediated macrophage activation in lung and liver, respectively, through engagement of their receptor myosin 18A (Minutti et al., 2017).

Environmental factors shown to reduce the effector functions of macrophages include the expression of CD200 (Minas and Liversidge, 2006) or CD47 (Sosale et al., 2015) by surrounding cells. CD200 interacts with the inhibitory CD200R receptor expressed by macrophages, resulting in an increased cellular activation threshold. The inhibitory receptor SIRP-1 $\alpha$  inhibits phagocytic uptake upon engagement of the “don’t eat me” signal CD47.

Inflammatory processes differ substantially depending on the target organ and nature and extent of the stimulatory agent(s), but a shared feature is the activation of the vascular endothelium. Endothelial cells respond to the presence of proinflammatory cytokines such as TNF- $\alpha$  and IL-1 $\beta$  produced by resident macrophages upon engagement of PRRs, by sequentially upregulating expression of P and E-selectins and adhesion molecules that facilitate the recruitment of neutrophils and inflammatory monocytes (Soehnlein and Lindbom, 2010). Macrophages also produce eicosanoids derived from the processing of arachidonic acid through the action of cyclooxygenases (to generate prostaglandins) or lipoxygenase (to produce leukotrienes) (Funk, 2001). LyC6<sup>high</sup> monocytes migrate into tissues during inflammation and readily differentiate to macrophages (Epelman et al., 2014). Activation of endothelium increases vascular permeability leading to edema and early recruitment of neutrophils. Granule contents in neutrophils (cathepsin G, LL-37, and azurocidin) engage formyl-peptide receptors in monocytes and favor recruitment of lyC6<sup>high</sup> monocytes (Soehnlein and Lindbom, 2010; Soehnlein et al., 2008). Increase in the number and activation of macrophages in inflamed tissue is probably due to the recruitment and differentiation of LyC6<sup>high</sup> monocytes as well as replication and activation of resident macrophages.

Cross talk between neutrophils and macrophages has important consequences for the outcome of the inflammatory process. The arsenal of degradative products encapsulated within neutrophil granules, if released, has the potential to liquefy tissues, and timely removal of these cells by macrophages is essential for successful resolution. Furthermore, neutrophils when highly activated are capable of releasing their nuclear content to form extracellular neutrophil extracellular traps (NETs) (Papayannopoulos and Zychlinsky, 2009) that contribute to pathogen trapping and killing. Of note, two of the best characterized autoantigens targeted by antineutrophil cytoplasmic antibodies (ANCA) are the neutrophil products myeloperoxidase and the serine protease protease-3 (Thieblemont et al., 2016) which highlights the importance of reducing the availability of these products to minimize self-recognition. In addition, myeloperoxidase can be internalized by macrophages through the MR (CD206) (Shepherd and Hoidal, 1990) and trigger their activation leading to increased inflammation in the context of autoimmunity (Lefkowitz et al., 1999). Similarly, the antimicrobial peptide LL-37 has been proposed as an autoantigen in psoriasis (Lande et al., 2014) and neutrophil proteases that have been shown to mediate IL-1 $\beta$  processing independently of caspase 1 (Guma et al., 2009; Karmakar et al., 2012; Schreiber et al., 2012). More recently, monocytes, which also contain myeloperoxidase and protease-3 within lysosomes and at the plasma membrane after activation, have also been implicated in the pathogenesis of ANCA-associated vasculitides (Brunini et al., 2016).

The specific aspects of the interaction between macrophages and neutrophils determine the extent of neutrophil activation and neutrophil half-life. Although, in general, neutrophils are considered short lived, a concept recently challenged (Kolaczkowska and Kubes, 2013), their viability can be extended during inflammation (Soehnlein and Lindbom, 2010). Similarly, production of granulocyte-macrophage (GM)-CSF by natural killer cells in response to IL-15, produced by inflammatory LyC6<sup>high</sup> monocytes, improves neutrophil activation and their effectiveness in controlling *Candida albicans* infection (Dominguez-Andres et al., 2017). These findings further highlight the important cross talk between monocytes/macrophages and neutrophils during inflammation.

Th17 responses have taken a center stage in multiple autoimmune diseases (Bedoya et al., 2013; Bettelli et al., 2007). The paradigm of Th17-driven inflammation implicates high neutrophil involvement and, accordingly, Th17 cells are essential for the control of infections by extracellular bacteria and fungi (Bedoya et al., 2013; Bettelli et al., 2007). Th17 cells produce IL-17A and IL-17F together with GM-CSF and IL-22, among others, and are considered as the third type of effector T cells (Annunziato et al., 2015). Similarly to M1 and M2 macrophages, respectively, associated with Th1- and Th2-dominated immunity, macrophages also contribute to IL-17-mediated inflammation (Barin et al., 2012) with “M17 macrophages” displaying a proinflammatory phenotype including increased transcription of chemokines CCL2, CCL8, CCL20, CXCL1, CXCL2, and CXCL6 and cell-surface receptors CD14 and CD163 with substantial overlap with M1 cells (Erbel et al., 2014). The paradigm of a simple Th cell expressing a particular subset of signature cytokines and master regulators does not conform to the reality of T cells retaining a high degree of plasticity after differentiation (Hirahara et al., 2013; Nakayamada et al., 2012). Thus a “Th17-component” has been found in Th2-dominated inflammatory responses with negative

consequences on disease severity (Akdis et al., 2012; Bedoya et al., 2013), and Th17 cells expressing both IL-17A and IFN- $\gamma$  have been described in several autoimmune diseases (Boniface et al., 2010; Duhen et al., 2013; Kebir et al., 2009). Conditions leading to Th17 differentiation closely resemble those described for Treg cells (Diller et al., 2016), and IL-17A and IL-10 coproducing Th17 cells have been observed (McGeachy et al., 2007). Conversion of Th17 cells into Treg cells during inflammation (Gagliani et al., 2015) has been described which suggests that this conversion and the associated changes in cytokine environment will contribute to the resolution of inflammation. Consequently, processes hampering this shift in phenotype could lead to chronicity.

Timely uptake of apoptotic neutrophils by macrophages is essential for the resolution of inflammation because (1) it minimizes the potential for secondary neutrophil necrosis which will cause tissue damage and (2) it promotes production of proresolving lipid mediators as part of the lipid switch that takes place (Basil and Levy, 2016; Serhan and Savill, 2005) and the acquisition by macrophages of a “wound healing” phenotype characterized by production of IL-10 and TGF- $\beta$  (see below). The presence of both IL-10 and IL-17A at the site of inflammation could promote resolution with one process involving the improved uptake of apoptotic neutrophils by macrophages. IL-17A in combination with IL-10 improves uptake of apoptotic neutrophils through the apoptotic cell receptor MerTK and acquisition of an immunosuppressive phenotype by macrophages (Zizzo and Cohen, 2013). IFN- $\gamma$ , on the other hand, inhibits this process and promotes upregulation of CD95, FASL, which would make them more susceptible to apoptosis (Zizzo and Cohen, 2013) hampering resolution.

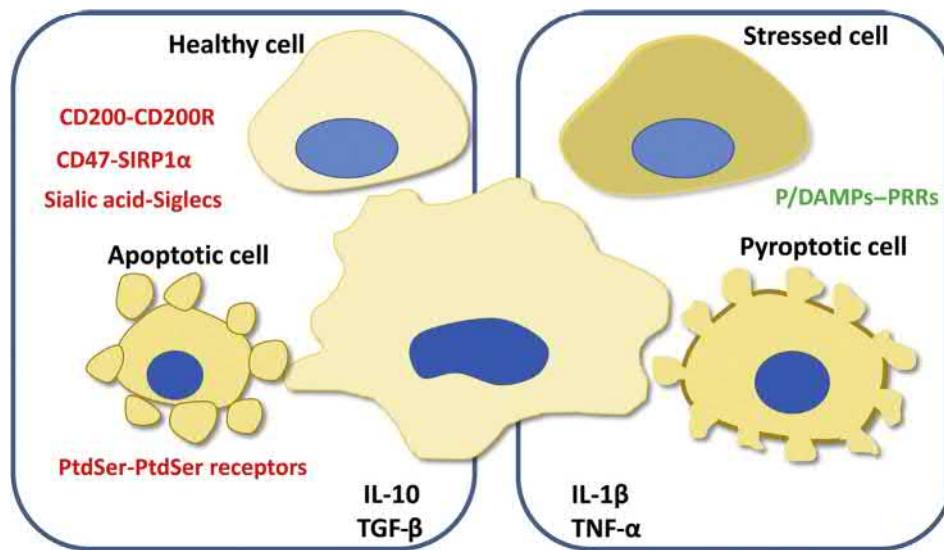

Thus even though macrophage heterogeneity represents a major challenge for researchers trying to understand the contribution of these cells to autoimmune diseases, it also provides the opportunity to harness macrophage malleability through macrophage-targeted therapeutics directed toward pathways that control their regulatory potential.

## OPSONIC AND NONOPSONIC RECEPTORS IN MACROPHAGES

The soluble and cellular arms of the innate immune system intertwine during an immune response through the action of opsonic receptors. Opsonic recognition refers to the ability of myeloid cells to display enhanced recognition of antibody and/or complement-coated material through the action of opsonic receptors. Opsonic receptors include receptors for the constant portion of antibodies and protein fragments derived from active C3. Vignesh et al. (2017) provide a recent overview of the contribution of complement to autoimmune diseases. Nonopsonic recognition refers to the ability of myeloid cells to directly detect and, in some instances, internalize a range of ligands through the action of PRRs (Boller and Felix, 2009; Vance et al., 2009). Recognition ascertains the physiological status of tissues by detecting the presence in the extracellular milieu of endogenous molecules normally sequestered within cells that are released through tissue damage or cellular activation (damage-associated molecular patterns, DAMPs). In addition, PRRs detect the presence of microbial compounds, such as endotoxin, peptidoglycan, and flagellin. In most cases, these microbial molecules are shared between pathogens and commensals, and thus the term microbe-associated molecular patterns, MAMPs, instead of pathogen-associated molecular patterns, PAMPs, has also been proposed (Boller and Felix, 2009). Activation of antimicrobial immunity relies on the detection of MAMPs in the context of DAMPs, that is, an induction of an immune response requires the presence of virulence factors that compromise cell viability alongside MAMPs (Blader and Sander, 2012; Nathan and Ding, 2010; Vance et al., 2009) (Fig. 10.1).

### Fc Receptors

Receptors for the constant region of antibodies (FcR) enable macrophages to bind and internalize antigen-antibody complexes and are also responsible for antibody-dependent cell-mediated cytotoxicity and release of cytokines and cytotoxic molecules (Nimmerjahn and Ravetch, 2008; Takai, 2002). Receptors specific for the IgG Fc fragment are termed Fc $\gamma$ Rs. Many laboratories have shown that Fc $\gamma$ Rs are responsible for IgG effector function with lack of these receptors leading to protection against the development of autoimmune diseases. Intriguingly, although Fc $\gamma$ Rs are widely expressed in phagocytes, the activity of IgG in vivo in a model of IgG-dependent platelet removal and B cell depletion appears to depend on the presence of the Ly6C<sup>lo</sup>CX<sub>3</sub>CR1<sup>high</sup>CD11c<sup>int</sup> monocyte subset (Biburger et al., 2011) which suggests that the cell population responsible for antibody-mediated pathology might be disease dependent.

**FIGURE 10.1** Macrophages as sensors of the health status of tissues. Environmental factors in addition to cellular origin drive tissue specialization of macrophages. Within tissues, in addition to contributing to organ function, macrophages ascertain the health status of surrounding cells with different set of receptors dominating interactions in healthy and pathological conditions. Healthy/apoptotic cells will minimize macrophage activation through the action of inhibitory receptor such as CD200R and SIRP-1 $\alpha$ , and the presence of antiinflammatory cytokines produced upon uptake of apoptotic cells. Under pathological conditions, cells-stressed/damaged by infection, injury or metabolic dysfunction will trigger PRRs in macrophages leading to activation and production of proinflammatory cytokines. Ligands for PRRs can be of self (DAMPs) and microbial origin (M/PAMPs). DAMPs, Damage-associated molecular patterns; M/PAMPs, microbe/pathogen-associated molecular patterns; PRRs, pattern recognition receptors.

Two major types of Fc $\gamma$ Rs have been described, type I and type II. Engagement to each type and, in turn, effector function depends on the glycosylation of the IgG molecule (Biermann et al., 2016; Bournazos et al., 2016). N-linked glycosylation at the Fc portion of the IgG antibody occurs at Asn297 which is located in a hydrophobic cleft formed by the two CH2-proximal hinge regions. Glycosylation at Asn297 is required for maintenance of a conformation permissive for interaction of the IgG molecule with Fc $\gamma$ Rs. Binding to type I Fc $\gamma$ Rs is favored by the presence of the heptasaccharide (GlcNAc2-Man3-GlcNAc2); the addition of branched fucose, and/or galactose, and sialic acid, in particular, promotes binding to the type II FcRs by exposing a region at the CH2–CH3 interface that represents the binding site for these receptors. Type II FcRs belong to the C-type lectins and Siglec families of lectin receptors (see next). The presence of sialic acid induces a closed conformation within the Fc region that inhibits binding to the type I Fc $\gamma$ Rs and promotes lectin-mediated binding (Biermann et al., 2016; Bournazos et al., 2016). IgG, modified by glycans with  $\alpha$ 2,6-linked terminal sialic acid, displays immunosuppressive properties and is responsible for the therapeutic effect of intravenous immunoglobulin therapy (Schwab et al., 2014; Schwab and Nimmerjahn, 2014). There is substantial heterogeneity in Fc glycosylation under steady-state conditions and differential IgG glycosylation; in particular, increased agalactosyl IgG-G0 is associated with disease activity in patients suffering from rheumatoid arthritis, Crohn's disease, juvenile onset arthritis, and systemic lupus erythematosus (SLE) complicated by Sjogren's syndrome. In IgA nephropathy, lack of terminal galactose reduces uptake by the asialoglycoprotein receptor in the liver, which results in its deposition in the kidney (Biermann et al., 2016). Type II Fc $\gamma$ Rs will be discussed below.

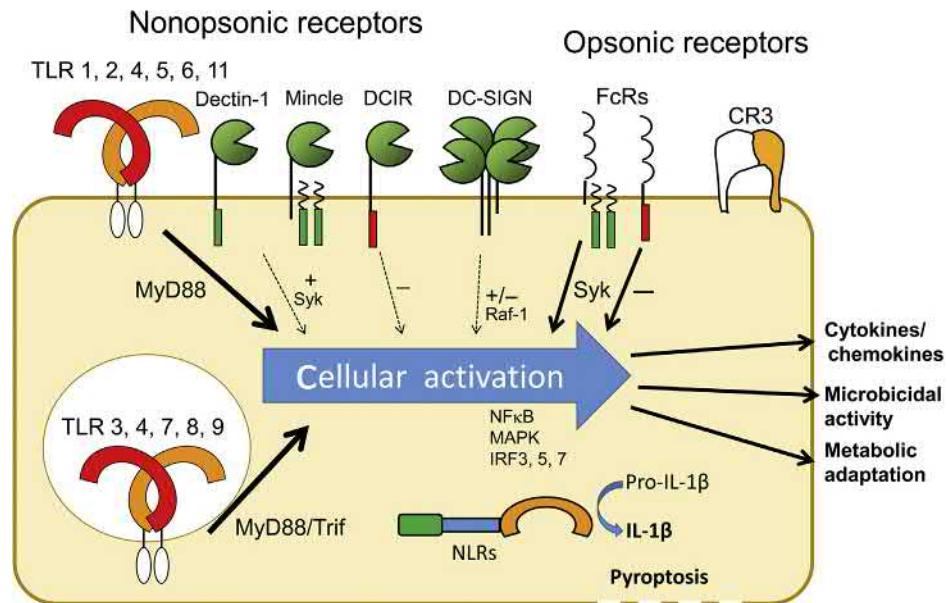

Type I Fc $\gamma$ Rs belong to the Ig superfamily and can act as activating or inhibitory receptors based on the presence of immunoreceptor tyrosine-based activation motif (ITAM) or immunoreceptor tyrosine-based inhibitory motif (ITIM) motifs that transduce activating or inhibitory signals, respectively (Bournazos et al., 2016). In humans, activating Fc $\gamma$ Rs include Fc $\gamma$ RI, Fc $\gamma$ RIIa, Fc $\gamma$ RIIc, and Fc $\gamma$ RIIIa; Fc $\gamma$ RIIb is an inhibitory receptor, and Fc $\gamma$ RIIb is glycosylphosphatidylinositol (GPI)-linked and abundantly expressed by neutrophils. With the exception of the Fc $\gamma$ RI, which binds IgG with high affinity, the rest of the Fc $\gamma$ R receptors display low affinity for monomeric IgG and preferentially recognize antibody-coated targets or immunocomplexes because of an increased avidity. Activating Fc $\gamma$ Rs trigger responses through phosphorylation of ITAM motifs in the common Fc $\gamma$  chain associated with Fc $\gamma$ RI and Fc $\gamma$ RIIIa or located at the C-terminus of Fc $\gamma$ RIIA and Fc $\gamma$ RIIC by Src kinases and recruitment and activation of Syk kinase (Mocsai et al., 2010). NK cells only express low-affinity activating Fc $\gamma$ Rs, and B cells only express inhibitory Fc $\gamma$ R. In contrast, macrophages and dendritic cells express multiple Fc $\gamma$ Rs per

cell, and the balance between responses originated by the activating and inhibitory Fc $\gamma$ Rs will determine the biological outcome (Boruchov et al., 2005). Fc $\gamma$ R activation will lead to endocytosis and phagocytosis of the antibody-antigen complex (Swanson and Hoppe, 2004) and cellular activation. As mentioned above, coengagement of FcR using immunocomplexes and Toll-like receptor (TLR)-4 using endotoxin in nonpolarized macrophages induces a M2-like phenotype referred to as M2b characterized by the production of IL-10, IL-6, and IL-1 and increased phagocytosis and migratory capacity (Edwards et al., 2006). Fc $\gamma$ RIIb-deficient mice are more susceptible to immune-complex-induced shock and arthritis, and this phenotype correlates with a lower activation threshold in macrophages when stimulated with immune complexes (Clynes et al., 1999). On the other hand, these animals are more resistant to pneumococcal peritonitis which emphasizes the important balance set by activating and inhibitory signals in antibody-mediated processes (Clatworthy and Smith, 2004).

## PATTERN RECOGNITION RECEPTORS

PRRs can be broadly classified into “canonical” PRRs, mostly involved in triggering signaling events such as TLRs and nucleotide binding and oligomerization domain (NOD)-like receptors (NLRs), as well as “noncanonical” PRRs, such as scavenger receptors and lectin receptors (Takeuchi and Akira, 2010), which mediate cellular uptake through promotion of endocytosis and phagocytosis. “Noncanonical” PRRs, in general, do not transduce signaling events in isolation but can modulate the signaling triggered by opsonic receptors and canonical PRRs. Macrophages, together with dendritic cells, display a wide range of PRRs and cellular responses result from the integration of the multiple signals triggered through simultaneous or sequential engagement of different PRRs (Fig. 10.2).

Recognition of DAMPs and MAMPs by PRRs takes place at the cell surface, endosomes, and cytoplasm. A vast array of molecular structures including lipids, proteins, lipoproteins, carbohydrates, and nucleic acids is sensed by these receptors. Interestingly, nucleic acid recognition is restricted to the endosomal compartment and cytosol, and this is considered a safeguard mechanism to minimize recognition of self (Crowl et al., 2017; Schlee and Hartmann, 2016). Macrophages respond to PRR engagement by internalizing the triggering agent through

**FIGURE 10.2** Signal integration during macrophage activation. The engagement of opsonic and nonopsonic receptors in macrophages will substantially affect their phenotype leading to changes in their microbicidal and metabolic activity and production of inflammatory mediators. Dominating activating responses such as those triggered by acute engagement of TLRs and activating Fc receptors can be modulated through coengagement of additional PRRs such as lectin receptors that can be activating or inhibitory. Cellular activation can also be influenced by the length and level of stimulation and can lead to tolerance (lack of response) (Collins and Carmody, 2015; Rajaiah et al., 2015) or “training” (primed for enhanced response) (Netea et al., 2011, 2016; van der Meer et al., 2015). PRRs, pattern recognition receptors; TLRs, Toll-like receptors.

endocytosis or phagocytosis and producing immune mediators, growth factors, and complement components. PRRs engagement in macrophages can contribute to the induction and perpetuation of inflammation in the context of autoimmunity.

## Toll-Like Receptors

The family of TLRs (Kawai and Akira, 2010; O'Neill et al., 2013) possess an N-terminal leucine-rich domain (LRR) shaped as a solenoid that mediates ligand binding, a transmembrane domain, and a cytosolic region containing a Toll/interleukin-1 receptor (TIR) domain that in most cases (TLR1, TLR2, TLR4, TLR5, and TLR6) engages the MyD88-mediated signaling machinery shared with the receptors for IL-1 and IL-18 (Gay et al., 2014; O'Neill and Bowie, 2007). In addition, two TLRs (TLR3 and TLR4) trigger MyD88-independent signaling through the adaptor Toll–IL-1 receptor domain-containing adaptor inducing IFN- $\beta$  (TRIF) (O'Neill and Bowie, 2007). TLR4, the TLR responsible for LPS sensing in combination with MD2 and CD14 (Bryant et al., 2010), signals through both MyD88 and TRIF. Unlike MyD88-mediated signaling which promotes the release of proinflammatory cytokines through the action of the transcription factor NF $\kappa$ B and activation of MAP kinases, the TRIF-mediated pathway triggers delayed NF $\kappa$ B activation and, most importantly, production of type I interferons (Kawai and Akira, 2010; O'Neill and Bowie, 2007). Type 1 interferons act in an autocrine and paracrine fashion and induce the synthesis of interferon stimulating genes through binding to their receptor (Novick et al., 1994). TLRs transduce signals through the formation of homo- (TLR3, TLR4, TLR5, TLR7, TLR8, and TLR9) or heterodimers (TLR1/TLR2 and TLR2/TLR6) which bring two TIR domains into proximity providing a functional platform for the formation of the relevant signalosome. The GPI-linked protein CD14 was originally recognized as an important adaptor for the recognition of endotoxin by TLR4 (Fitzgerald et al., 2004) but is now acknowledged as a facilitator of ligand recognition by several TLRs (Finberg and Kurt-Jones, 2006). CD14 has been shown to promote endocytosis of TLR4 after LPS recognition (Zanoni et al., 2011) with this involvement in TLR4-endocytosis being ligand dependent (Rajaiah et al., 2015). Traffic of TLR4 to endosomes recruits TRIF and leads to activation of interferon-regulatory factor (IRF)3. The endosome is considered a unique site for IFN-induction due to the intracellular localization of TRAF-3 which is restricted to the intracellular compartment (Barton and Kagan, 2009).

In the context of autoimmune diseases, TLRs have been linked to the pathogenesis of rheumatoid arthritis, SLE, inflammatory bowel disease, type I diabetes, and multiple sclerosis. TLR dysregulation could act by lowering the threshold of activation of macrophages which will have consequences both during the initiation and progression of disease by generating a positive feedback loop. TLR activation is tightly controlled by negative regulators, including inhibitors of the NF $\kappa$ B pathway (Afonina et al., 2017), and there are strong links between variants in these molecules and autoimmunity. Mice with deficiency in some of these constitutive inhibitors develop spontaneous autoimmune and inflammatory diseases which suggest that they are important for controlling TLR activation in response to endogenous ligands or microbiota (Hamerman et al., 2016). For instance, A20 is a deubiquitinase that cleaves K63-linked ubiquitin from TRAF6 which impairs, among others, TLR-mediated NF $\kappa$ B signaling. Polymorphisms in A20 have been associated with increased risk of autoimmune and inflammatory diseases including RA, SLE, psoriasis, Crohn's disease, and type 1 diabetes (Vereecke et al., 2009). A20 is widely expressed in multiple cell types, but conditional deletion of A20 in macrophages and neutrophils causes the development of spontaneous polyarticular arthritis that resembles RA indicating that A20 in these cells is important for the control of disease (Matmati et al., 2011). TLR10 which is exclusively expressed in humans has been recently characterized as a negative regulator of TLR signaling (Jiang et al., 2016). Thus TLR10 can be added to the extensive list of inhibitors of TLR signaling (Liew et al., 2005).

TLRs are best known for their ability to interact with MAMPs/PAMPs, but substantial evidence supports their involvement in the recognition of DAMPs (Piccinini and Midwood, 2010). Under conditions where there is substantial tissue destruction, local and systemic levels of DAMPs are increased. For instance, heat shock proteins, the nuclear protein HMGB1, host DNA, fibrinogen, FNEDA, and tenascin-C are observed in synovium of RA patients compared to normal synovium and synovium from osteoarthritis patients. Hence, the presence of DAMPs could have a negative effect on the pathophysiology of autoimmune diseases as both triggers of a tissue repair response that, under particular conditions, could lead to activation of self-reactive B and T cells, or as amplifiers of a pathological inflammatory response driven by autoantibodies and self-reactive T cells.

Interestingly, engagement of the same TLR (TLR4) by MAMPs (LPS) or DAMPs (C-tenascin) triggers distinct patterns of activation (Piccinini et al., 2016) which suggest that although TLRs are activated during sterile inflammation, the outcome differs from that obtained in response to infection.

Endosomal TLRs recognize nucleic acids in the form of double-stranded DNA (TLR9), double-stranded RNA (TLR3), and single-stranded RNA (TLRs 7 and 8) (Kawai and Akira, 2010; O'Neill and Bowie, 2007). Endosomal localization will restrict access of endogenous nucleic acids to these sensors (Crowl et al., 2017), but this protective compartmentalization can be lost in the presence of anti-DNA antibodies (Barrat et al., 2005) or deficiency in DNA degradation after uptake of apoptotic cells (see below) which will promote self-recognition and chronic inflammation.

## Scavenger Receptors

The macrophage scavenger receptors are a large family of structurally diverse receptors, which recognize a range of ligands including modified low-density lipoproteins (LDLs), selected polyanionic ligands, and microbial structures (Pluddemann et al., 2007). The Class A scavenger receptor I (SR-AI) was the first to be identified in studies by Brown and Goldstein who investigated the accumulation of cholesterol from LDL in atherosclerotic plaques. Other Class A scavenger receptors expressed on macrophages include two alternative splice variants of the SR-AI gene, SR-AII, and SR-AIII and the distinct macrophage receptor with collagenous structure (MARCO). The receptors are all trimeric type II transmembrane glycoproteins generally consisting of several domains including an  $\alpha$  helical coiled-coil domain, collagenous domain, and C-terminal cysteine-rich domain, although MARCO lacks the coiled-coil domain and has a longer collagenous domain. For SR-AI and SR-AII, the collagenous domain has been shown to be the ligand-binding domain, whereas for MARCO, this may lie within the cysteine-rich domain. SR-A is expressed on tissue macrophages and selected endothelia, but not resting monocytes, while MARCO is constitutively expressed on subpopulations of tissue macrophages (resident peritoneal, spleen marginal zone, and medullary lymph node macrophages). For Class B, scavenger receptors CD36 and SR-B, ligand binding is likely mediated via the central part of the extracellular loop structure and these receptors recognize not only modified LDL but also native lipoproteins (VLDL, LDL, and HDL) and play an important role in cholesterol transport, metabolism, and homeostasis. Other scavenger receptors expressed by macrophages include CD68 and FEEL-1 (predominantly expressed intracellularly), SREC, and SR-PSOX. SREC receptors have been shown to bind molecular chaperones (e.g., calreticulin, gp96, and heat shock protein 70), playing a role in the transport of ligands to the MHC Class-I antigen presentation pathway (Berwin et al., 2004). SR-PSOX is the chemokine ligand for a G-protein coupled CXC chemokine receptor 6 expressed on activated T cells and NKT cells, supporting the adhesion of these cells to DCs (Shimaoka et al., 2004).

Class A scavenger receptors SR-A and MARCO recognize oxidized and acetylated LDL and play a role in vascular disease by mediating uptake of these modified lipoproteins, leading to the formation of lipid-laden foam cells in atherosclerotic lesions (Krieger and Herz, 1994). SR-A and CD36 have also been implicated in the pathology of Alzheimer's disease, where microglia bind  $\beta$ -amyloid fibrils via SR-A and CD36, which stimulates the production of cytotoxic reactive oxygen molecules (Santiago-Garcia et al., 2001). Macrophages bind and endocytose-advanced glycation end products (AGE) via several receptors including the scavenger receptors SR-AII and CD36, and the AGE receptors 1, 2, and 3 (Lu et al., 2004). AGE are found in many tissues during oxidative stress and inflammation, such as atherosclerotic lesions of arterial walls and kidneys of diabetic patients with chronic renal failure (Nagai et al., 2000), as well as during ageing. Dietary AGE (e.g., from processed food) have also been linked to chronic kidney injury, for example, by suppressing AGER1 and inducing oxidative stress and inflammatory responses, thus contributing to pathogenesis and complications of diabetes mellitus (Vlassara and Striker, 2011).

## Lectin Receptors

Carbohydrates displayed by secreted and cell-surface molecules have major implications for their half-life and sensing of the tissue health status (Rabinovich et al., 2012; Schnaar, 2016). Accordingly, alteration in the normal processing of complex N-linked sugars through deletion of the  $\alpha$ -mannosidase-II leads to the accumulation of mannose-bearing ligands that causes the development of systemic autoimmunity with the characteristics similar to human SLE (Green et al., 2007). Carbohydrate-binding (lectin) receptors expressed by mononuclear myeloid cells mediate ligand uptake and cell adhesion. Consequences of carbohydrate recognition will be strongly influenced by the nature of the ligand as number, and distribution of sugar units will impact on the avidity of these low-affinity interactions.

Important lectin receptors expressed by macrophages belong to two main families: C-type lectin receptors (CLRs) (Dambuza and Brown, 2015; Drickamer and Taylor, 2015) and sialic acid binding Ig-like lectins (Siglecs)

([Macaulay et al., 2014](#)). CLRs contain one or more domains with a fold initially described in the mannose-binding lectin which initiates lectin pathway of complement activation. This chapter will focus on members of the Group 2 of CLRs that include dendritic cell-specific intercellular adhesion molecule (ICAM)-3 grabbing nonintegrin (DC-SIGN, CD209) ([Garcia-Vallejo and van Kooyk, 2013](#)), Dectin-2 (CLEC4N, CLEC6A), DCIR (CLEC4A), macrophage inducible C-type lectin (Mincle, CLEC4E), and myeloid inhibitory C-type lectin-like receptor (MICL, CLEC12A, and CLEC4D) ([Dambuza and Brown, 2015; Graham and Brown, 2009](#)), Group 5 that includes Dectin-1 (CLEC7A) ([Dambuza and Brown, 2015](#)), and Group 6 that includes the MR (CD206) ([Martinez-Pomares, 2012](#)).

DC-SIGN was originally described as a dendritic cell-specific marker but has now been documented in multiple macrophage populations that might represent subsets with an alternative phenotype related to the positive effect of IL-4 on DC-SIGN expression. DC-SIGN is a type II membrane protein that assembles as a tetramer and projects the CRDs 35 nm away from the membrane. DC-SIGN can bind fucosylated glycans, such as the blood-type Lewis antigens ( $\text{Le}^a$ ,  $\text{Le}^b$ ,  $\text{Le}^X$ ,  $\text{Le}^Y$ , and sulfo- $\text{Le}^a$ ) and high-mannose structures ([Garcia-Vallejo and van Kooyk, 2013](#)). DC-SIGN is both an uptake and adhesion receptor. Ligands for DC-SIGN include pathogens (HIV, Ebola virus, *M. tuberculosis*, *C. albicans*, *Schistosoma mansoni*, and *Helicobacter pylori*) as well as endogenous ICAM-2, ICAM-3, macrophage receptor 1, carcinoembryonic antigen, and, as mentioned above when describing type II FcRs, the Fc portion of immunoglobulins. DC-SIGN signaling in dendritic cells shows an inability to trigger signaling in isolation but rather modulates signaling triggers by “canonical PRRs” such as TLRs. Interestingly, the nature of the DC-SIGN ligand (mannosylated vs fucosylated) influences signaling outcome ([Gringhuis et al., 2009](#)), but in general, DC-SIGN coengagement is perceived to blunt cellular activation. In agreement with this concept, DC-SIGN expressing macrophages have been involved in the induction of transplantation tolerance ([Conde et al., 2015](#)).

Dectin-1 recognizes  $\beta$ -1,3-glucans present in the cell wall of many fungal species ([Brown et al., 2002; Taylor et al., 2002](#)) and has been implicated in antifungal immunity. Dectin-1 deficiency in humans can lead to susceptibility to certain fungal infections including chronic mucocutaneous candidiasis and recurrent vulvovaginal candidiasis ([Plato et al., 2015](#)). Dectin-1 also recognizes uncharacterized ligand(s) on *M. tuberculosis* and T cells as well as the self-molecules vimentin ([Thiagarajan et al., 2013](#)) and galectin-9 ([Daley et al., 2017](#)). Dectin-1 triggers cellular activation, including the production of ROS and cytokine production through direct recruitment of the Syk/caspase and recruitment domain (CARD)9 pathway via a hemi-TAM/ITAM like motif leading to NF $\kappa$ B activation ([Mocsai et al., 2010](#)). Dectin-1 has also been shown to induce TLR9 recruitment to endosomes containing  $\beta$ -1,3 glucan ([Khan et al., 2016](#)) suggesting control of nucleic acid recognition. Surprisingly, the interaction between Dectin-1 and its endogenous ligand Galectin-9, identified in the context of pancreatic carcinoma, has been shown to lead to the acquisition of a tolerogenic phenotype by macrophages. Lack of dectin-1 expression is protective against pancreatic carcinoma and induces immunogenic reprogramming of tumor-associated macrophages promoting tumor clearance ([Daley et al., 2017](#)). These results suggest an unexpected role for Dectin-1 in sterile inflammation under conditions of high galectin-9 expression.

Mincle (CLEC4E) engages Syk indirectly through association with the ITAM-containing adaptor FcR $\gamma$ . In addition to being involved in recognition of fungi ([Yamasaki et al., 2009](#)) and mycobacteria ([Ishikawa et al., 2009](#)), Mincle has also been implicated in the induction of sterile inflammation by recognizing SAP130 released by damaged cells ([Yamasaki et al., 2008](#)) which can be linked to its involvement in the inflammatory response in response to ischemic stroke ([Suzuki et al., 2013](#)) and traumatic brain injury ([de Rivero Vaccari et al., 2015](#)).

MICL (CLEC12A, CLL-1) recognizes uric acid crystals in necrotic cells ([Neumann et al., 2014](#)) and plays an important role in controlling sterile inflammation *in vivo* ([Neumann et al., 2014](#)). Its inhibitory activity is granted by the presence of an ITIM in its intracellular domain. MICL is required for the control of inflammation in a model of collagen antibody-induced arthritis ([Redelinghuys et al., 2016](#)), and although polymorphisms in MICL have not been associated with RA in humans, antibodies against MICL have been identified in a subset of RA patients ([Redelinghuys et al., 2016](#)).

The MR (CD206), unlike previous CLRs, is a type I membrane molecule and contains eight CTLDs. In addition, MR contains two additional domains, a cysteine-rich domain that binds sulfated glycans present in hormones produced by the anterior pituitary and a fibronectin type II domain that recognizes collagen ([Martinez-Pomares, 2012](#)). MR expression by tissue macrophages has been linked to phagocytic activity ([Noelia et al., 2017](#)) and, during inflammation, to M2 promoting conditions ([Martinez-Pomares, 2012](#)). The CTLD region in MR recognizes both microbial and endogenous ligands, including thyroid autoantigens ([Chazenbalk et al., 2005; Martinez-Pomares, 2012](#)) and the ANCA target myeloperoxidase ([Shepherd and Hoidal, 1990](#)). Safeguards against the endocytic activity of MR promoting presentation of self-antigens to the acquired immune system are provided by the lack of signaling motifs at its intracellular region, the restricted expression of MR in dendritic cells *in situ* and

the effective role played by MR expressed by macrophages and nonlymphatic endothelia in clearing potential autoantigens (Martinez-Pomares, 2012). In addition, a potential MR involvement in autoimmunity has not been supported by gene-association studies, although MR has been implicated in the uptake of agalactosyl IgG (Dong et al., 1999).

Siglecs are cell-surface transmembrane receptors comprising 2–17 Ig domains that include a V-set domain at the N-terminus that mediates binding to sialic acid (Macaulay et al., 2014). Most Siglecs contain an ITIM motif at the C-terminus that transduces negative signals through the recruitment of tyrosine phosphatases such as SHP1 and SHP2. Siglecs 14, 15, and 16 engage DAP-12 and are predicted to act as activating receptors through the recruitment of Syk. The first characterized Siglec, Siglec 1 is CD169, sialoadhesin, which lacks any obvious signaling motifs at the C-terminus. It contains 17 Ig domains and is selectively expressed by macrophages. In particular, metallophilic macrophages within the marginal zone of spleen express high levels of CD169 and have been implicated in tolerance to apoptotic cells (Ravishankar et al., 2014). Glycans terminating in sialic acid are considered as markers of self that can be exploited by pathogens and tumors, and it is fitting that most Siglecs transduce inhibitory signals. Indeed, sialylated antigens have been shown to induce a tolerogenic response when incubated with human dendritic cells (Perdicchio et al., 2016).

## Cytosolic Pattern Recognition Receptors

Cytosolic recognition of DAMPs and PAMPs is achieved, among others, through the action of PRRs belonging to three families: NLRs, PYHIN receptors and retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs), and cGAS.

All NLRs contain an N-terminal domain that mediates interaction with signaling adaptors, an intermediate NOD domain that is responsible for oligomerization and a C-terminal LRR. Members of the NLR family include NOD1 and NOD2 which have the basic structure CARD–NOD–LRR and CARD(X2)–NOD–LRR (Caruso et al., 2014). NOD1 and NOD2 signal through the kinase RICK (also called RIPK2) to trigger NF $\kappa$ B activation in response to the presence of peptidoglycan, a component of the bacterial cell wall. NOD1 has been involved in autophagy and in the detection of changes in RHO family GTPases caused by bacterial invasion of host cells (Keestra et al., 2013). NOD2 mutations have been associated with the development of Crohn's disease which could be linked to the ability of NOD1 and NOD2 to direct autophagy by recruiting ATG16L1 to the site of bacterial entry (Travassos et al., 2010).

Other members of the NLR family, together with the pyrin (PY)-HIN family member absent in melanoma 2 (AIM2) and PY, can nucleate multimeric structures termed inflammasomes that act as scaffolds for the recruitment and activation of caspase 1 (Guo et al., 2015; Rathinam et al., 2012; Schroder and Tschopp, 2010; Vanaja et al., 2015; von Moltke et al., 2013). Inflammasome-forming NLRs include NLR-family CARD domain-containing protein 4 (NLRC4), NOD, LRR, and PY domain-containing protein 1 (NLRP1), NLRP3, and NLRP6. The adaptor apoptosis-associated speck-like protein containing a CARD domain (ASC) which contains a CARD and a PY domain is essential for caspase 1 recruitment in the case of PY-containing NLRs. ASC requirement for CARD-containing NLRs, such as NLRC4 and NLRP1, is more complex with an ASC-independent pathway leading to cell death mediated by procaspase 1 and an ASC-dependent pathway promoting autoproteolytic processing of caspase 1 and efficient cytokine production (Broz et al., 2010). Caspase 1 is an inflammatory caspase that, similarly to the LPS-sensing human caspases 4 and 5 (Vigano et al., 2015) and mouse caspase 11, mediates processing of IL-1 $\beta$  and IL-18 and induction of a proinflammatory form of cell death termed pyroptosis (Blander, 2014; Man and Kanneganti, 2016), although both processes can occur independently (Broz et al., 2010). These caspases cleave gasdermin D; the resulting 31 kDa N-terminal fragment of gasdermin D, released from the repressor C-terminus, inserts itself and forms holes in the plasma membrane (Kovacs and Miao, 2017) leading to pyroptosis and release of IL-1 $\beta$  and IL-18 alongside DAMPs. Thus pyroptosis, unlike apoptosis, is an inflammatory form of cell death (Bergsbaken et al., 2009; Man and Kanneganti, 2016). Most of the NLR members known to trigger inflammasome formation act as sensors of infection and specific triggers for some of them have been identified. For instance, NLRP1 is activated by a lethal factor, a protease from *Bacillus anthracis*, and NLRC4 responds to bacterial proteins, which are directly recognized by NLR-family apoptosis inhibitory proteins (NAIPs) which are the ligands for NLRC4 (von Moltke et al., 2013). In mice, NAIP1 binds the bacterial type III secretory system (T3SS) needle protein, NAIP2 binds the bacterial T3SS rod protein, and both NAIP5 and NAIP6 bind bacterial flagellin. In humans, only one NAIP protein has been characterized, and it was found to bind only the T3SS needle protein. AIM2, which contains HIN200 DNA binding motifs and a PY domain, recognizes cytosolic dsDNA above 80 base pairs.

The molecular basis for NLRP1, NLRP3, and PY activation is more elusive, and a model is emerging by which these PRRs act as sensors of altered homeostasis (Liston and Masters, 2017). This model would explain their broad reactivity, in particular, in the case of NLRP3 that can be activated by infectious agents in addition to sterile products such as crystals, saturated fatty acids, ROS, and damaged mitochondria (Guo et al., 2015; Rathinam et al., 2012; Schroder and Tschopp, 2010; Vanaja et al., 2015; von Moltke et al., 2013). Upon inflammasome activation, ASC redistributes and forms aggregates (specks) that can be released from cells. Specks can cleavage extracellular pro-IL-1 $\beta$  and activate caspase 1 in macrophages when internalized in a process termed “inflammasome spreading” (Baroja-Mazo et al., 2014; Franklin et al., 2014). In addition to the substantial body of literature supporting inflammasome involvement in the development of autoinflammatory diseases (Liston and Masters, 2017), links between pyroptosis and SLE have been proposed (Magna and Pisetsky, 2015) and between polymorphisms in NLRP1 and Alzheimer’s disease (Pontillo et al., 2012). Blocking of IL-1, particularly IL-1 $\beta$ , is now standard therapy for many autoinflammatory diseases, such as rheumatoid arthritis, osteoarthritis, Blau syndrome, familial Mediterranean fever, and type 2 diabetes, among others (Dinarello, 2011).

The RLRs (RIG-I and melanoma differentiation associated factor 5, MDA-5) (Takeuchi and Akira, 2008; Yoneyama et al., 2015) contain a DExD/H-box RNA helicase domain and a C-terminal domain in addition to a CARD domain that mediates interaction with the adaptor molecule IFN- $\beta$  promoter stimulator-1, also called MAVS, which is located at the outer membrane of mitochondria. Upon interaction, there is recruitment of a signaling complex leading to the induced expression of IFN- $\beta$ , IRF3-target genes, and NF $\kappa$ B target genes. Both RIG-I and MDA-5 detect cytosolic RNA and are involved in viral recognition.

cGAS is a sensor of cytosolic DNA that binds and catalyzes the synthesis of cyclic GMP–AMP (cGAMP). cGAMP then binds to and activates STING, a transmembrane adapter protein on the endoplasmic reticulum that triggers the TBK1/IRF3 pathway. Broadly, the cGAS-STING pathway is involved in the response to infection by DNA viruses and retroviruses (Crowl et al., 2017).

## THE PHAGOCYTIC PROCESS

Macrophages exploit their impressive phagocytic capacity under steady-state conditions to (1) facilitate tissue differentiation, as exemplified by the role of microglia during neuronal development, (2) remove effete cells from the circulation, as in the case of splenic red pulp macrophage-mediated removal of aged red blood cells, and (3) facilitation of cell differentiation, as in the case of phagocytosis of extruded nuclei during erythrocyte generation. The same phagocytic capacity enables macrophages to minimize inflammation by timely removal of cells undergoing programmed cell death in healthy tissues and apoptotic neutrophils during the resolution phase of inflammation. The phagocytic process in macrophages also contributes to host defense by enabling the elimination of infectious agents. Receptors that trigger phagocytosis are numerous, and although there is overlapping receptor expression among macrophages in different tissues, selective expression also occurs depending on the population of macrophages under consideration and their activation state.

Autophagy is a mechanism which macrophages can use to capture cytoplasmic components in a double-membrane vacuole for degradation in lysosomes. Autophagy is induced by different families of receptors (e.g., TLRs and NLRs) and is not only a host defense mechanism against intracellular pathogens but can also be used as a source of nutrients during starvation. Alterations in the functions of autophagy proteins can lead to enhanced susceptibility to disease and have also been implicated in chronic inflammatory and autoimmune disease processes. For example, mutations in regulators of autophagy have been linked to Crohn’s disease (Levine et al., 2011). The contribution of autophagy to autoimmunity has been recently reviewed (Wu and Adamopoulos, 2017).

Phagocytosis refers to the uptake of particles above 0.5  $\mu$ m by cells into vesicles termed phagosomes (Flannagan et al., 2009; Groves et al., 2008; Stuart and Ezekowitz, 2005). It is initiated by engagement of surface receptors that undergo lateral clustering leading to extension of pseudopodia. Pseudopodia expand and surround the particle and fuse at the distal tip leaving the particle inside the phagocytic vesicle, which is then brought into the cell. Phagosomes undergo maturation that finalizes in the formation of a phagolysosome through fusion with lysosomes. Detection and capture of material are enhanced by the ability of macrophages to produce membrane protrusions called “ruffling.” Receptor phosphorylation is important, and exclusion of inhibitory phosphatases such as CD45 and CD148 from the phagocytic cup has been described. “Tonic signaling” by Syk and SFKs in macrophages maintains a dynamic actin meshwork that facilitates lateral clustering upon receptor engagement. Phagosome maturation occurs through endosome fusion and recycling (fission) events that sequentially change

the nature of the phagosome making it a degradative environment (Groves et al., 2008; Vieira et al., 2002). Thus maturing phagosomes transition from an early phase characterized by the presence of Rab 5 to a late phase through the fusion with late endosomes that expresses Rab7. In early phagosomes, Rab5 facilitates the production of PtdIns3P through the action of the PI3K Vp34, and Rab5 and PtdIns3P collaborate in the recruitment of early endosomal marker 1. Although cargo is targeted for degradation, some components are transported to the plasma membrane or the transgolgi network through retrograde transport for recycling. There are inward vesiculation and formation of intraluminal vesicles (ILVs) that are targeted for degradation, both cargo and membrane.

Late phagosomes are more acidic because they acquire increased copies of the proton-pumping V-ATPase with enrichment of ILVs, loss of PtIns3P, and appearance of PtIns-4P. Late phagosomes fuse with lysosomes to form phagolysosomes. Phagolysosomes contain lysosomal-associated membrane proteins-1 and -2 which are essential for the following maturation stages and microbial killing. The pH in phagolysosomes can reach 4.5–5 in some cell types, and acidification itself appears to promote phagosome maturation.

Phagosome acidification impedes microbial growth by affecting their metabolism, and it also facilitates the action of hydrolytic enzymes (Flannagan et al., 2009). Formation of ROS is mediated through the action of the NOX2 NADPH oxidase that transfers electrons from cytosolic NADPH to molecular oxygen releasing O<sub>2</sub><sup>-</sup> into the lumen. O<sub>2</sub><sup>-</sup> can be further processed through the action of dismutase to generate H<sub>2</sub>O<sub>2</sub>, which can react with O<sub>2</sub><sup>-</sup> to generate hydroxyl radicals and singlet oxygen. H<sub>2</sub>O<sub>2</sub> can be converted by myeloperoxidase into hypochlorous acid and chloramines. These ROS can kill microbes. Proteins within the phagosomes can act by preventing the growth of the organisms by limiting the availability of nutrients as in the case of lactoferrin (which sequesters iron) and NRAMP1 which extrudes divalent cations such as Zn<sup>2+</sup>, Fe<sup>2+</sup>, and Mn<sup>2+</sup> from the lumen. Other proteins include defensins, and enzymes capable of degrading carbohydrates (lysozyme, β-hexosaminidase), lipids (lysosomal phospholipase A2), and proteins (cathepsins, carboxypeptidases, and aminopeptidases).

Phagosome resolution is poorly characterized but is required for a return to hemostasis. This process will have major implications for the limitation of autoimmunity upon uptake of cellular material. Phagosome resolution requires disposal of nucleic acids, which is achieved through the action of DNaseII, which is delivered to phagosomes through lysosome fusion. Resulting nucleosides need to be transported to the cytosol. The amino acids resulting from protein degradation can serve as nutrients and are transported to the cytosol through solute carriers. Lipases enable digestion of lipids extracted from membranes by lipid transfer proteins and glycoproteins present in the phagosome membrane prevent digestion of its membrane (Levin et al., 2016).

## CLEARANCE OF APOPTOTIC CELLS BY MACROPHAGES

Apoptosis was discovered in 1965 by Lockshin and Williams who coined the term “programmed cell death” after observing that some cells were destined to die in the silkworm model. Kerr et al. in 1972 found in human tissues a form of cell death characterized by the cellular and nuclear condensation and fragmentation, termed apoptosis (Nagata and Tanaka, 2017). Single gene variations in genes involved in apoptotic cell clearance result in autoimmunity in mice (Petersen et al., 2017).

The mechanism of apoptosis induction has been well characterized, and two induction pathways have been identified (Nagata and Tanaka, 2017). The extrinsic pathway is triggered by the engagement of death receptors such as FAS (CD95). Binding of Fas cell surface death receptor (FAS) Ligand to FAS induces a conformational change in the FAS trimer that leads to the formation of a complex (death-inducing signaling complex) that includes the FAS-associated death domain protein and procaspase 8. Procaspsase 8 is processed into mature caspase 8 which in turn processes caspase 3. The intrinsic pathway is initiated when a developmental signal or genetic damage activates a member of the B cell lymphoma-2, BCL-2, family. In response to activation of BCL-2 proteins, mitochondria release components including cytochrome *c*. Cytochrome *c* forms a complex with procaspsase 9 and apoptotic protease-activating factor-1, leading to the generation of mature caspase 9 and processing of caspase 3. Caspase 3 can cleave more than 500 substrates to complete the apoptosis process. Defects in the apoptotic process have been intimately linked to autoimmunity as in the case of loss of function of the FAS–FAS Ligand pathway (Nagata and Tanaka, 2017).

Efferocytosis refers to the clearance of apoptotic cells; macrophages are the main phagocytic cells responsible for their uptake. Apoptotic cell uptake by macrophages should be considered antiinflammatory rather than “immunologically silent” (Blander, 2017; Nagata and Tanaka, 2017). Efficient clearance of apoptotic cells is required to avoid the release of intracellular cellular components through secondary necrosis. Exposed phosphatidyl serine (PtdSer) is an early sign of apoptosis. In healthy cells, PtdSer is maintained at the inner

side of the plasma membrane through an active process mediated by phospholipid-transporting ATPases (ATP11A and ATP11C). During early apoptosis, the asymmetry of the plasma membrane is lost by lack of function of the phospholipid-transporting ATPases, aided by action of a phospholipid scramblase (XK-related protein 8) that is activated by caspase 3. Apoptotic cells release “find me signals” that include nucleotides (ATP and UTP) as well as the chemokine fractalkine (CX3CL1) and the lipids lysophosphatidylcholine and sphingosine-1 phosphate. These signals could also improve the process of apoptotic cell recognition capacity of neighboring cells by increasing expression of receptors for apoptotic cells.

The recognition of apoptosis by macrophages is centered on, but not limited to, the recognition of PtdSer. Other motifs present on apoptotic cells include a modified form of ICAM-3, oxidized LDL, calreticulin (recognized by CD91), annexin1, cell surface-bound thrombospondin (recognized by CD36), and complement C1q (recognized by scavenger receptors SCARF1 and LAIR1, CD305). There are also changes in surface protein charge and glycosylation (Arandjelovic and Ravichandran, 2015; Blander, 2017; Nagata and Tanaka, 2017).

Receptors involved in direct PtdSer recognition include the following molecules: brain angiogenesis inhibitor 1, a G-protein coupled adhesion receptor that has been also implicated in inhibition of angiogenesis, and myoblast fusion among others; TIM-1, 3, and 4 (T cell-immunoglobulin domain containing); Stabilin-2 and RAGE as well as scavenger receptors CD36 and Class A scavenger receptor (Arandjelovic and Ravichandran, 2015). Indirect PtdSer receptors include the TAM receptors MerTK, Tyro3, and Axl and the integrins  $\alpha v\beta 3$  or  $\alpha v\beta 5$  which recognize MFG-E8, Gas-6, or Protein S that constitute the PtdSer receptors. TAM receptors are tyrosine kinases that activate Src and PI3K and phospholipase PLC. Tim-4 does not signal directly but acts as a tethering receptor. Mutations in TAM receptors and integrin  $\alpha v$ , Sacrf1, and C1q lead to the development of spontaneous autoimmunity (Arandjelovic and Ravichandran, 2015).

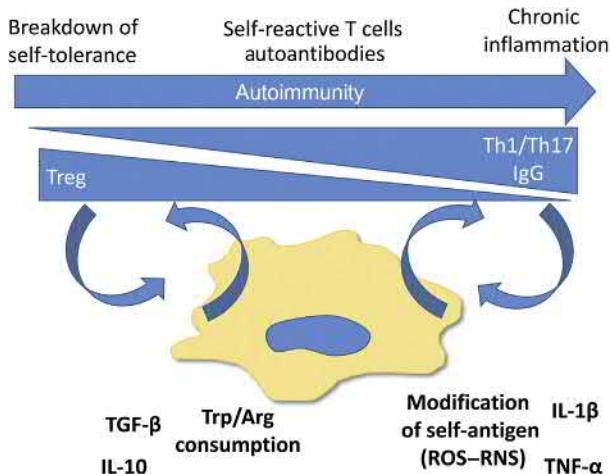

The cargo resulting from efferocytosis needs to be processed. This poses a metabolic burden on the macrophage and regulation is essential to avoid activation of PRRs by DAMPs. For instance, lack of DNaseII expression by macrophages leads to autoimmunity through activation of TLR-independent cytosolic nucleic acid-sensing PRRs (Baum et al., 2015; Gao et al., 2015). Works by Cummings et al. and Uderhardt et al. have highlighted the important roles of specific populations of myeloid cells in the maintenance of self-tolerance upon uptake of apoptotic cells. Cummings et al. (2016) identified a dendritic cell subset and two macrophage populations that mediate uptake of apoptotic intestinal epithelial cells and adopt an immunosuppressive gene expression signature. Uderhardt et al. established the important role of 12/15-lipoxygenase expressed by resident macrophages in the generation of oxidation products of phosphatidylethanolamine that interfere with the uptake of apoptotic cells by inflammatory LyC6<sup>high</sup> monocytes. Oxidized phosphatidylethanolamine at the membrane of resident macrophages sequesters the soluble PtdSer receptor MFG-E8 which mediates uptake of apoptotic cells by inflammatory monocytes. Loss of 12/15-lipoxygenase leads to uptake of apoptotic cells by inflammatory monocytes and lupus-like autoimmune disease (Uderhardt et al., 2012).

## CONCLUDING REMARKS; MACROPHAGES AND AUTOIMMUNITY

Macrophages as the “gatekeepers” of inflammation are, consequently, major players in the initiation and maintenance of chronic inflammatory conditions and, in turn, the induction and perpetuation of autoimmune diseases. Macrophage contribution to autoimmunity stems from its ability to sense their environment through detection of PAMPs and DAMPs by PRRs, degradative capacity, illustrated in this chapter by the uptake and processing of apoptotic cargo under homeostatic and inflammatory conditions, production of immunomodulators, and potential to cause damage.

Evidence for a primary pathogenic role in autoimmunity will depend on implicating molecules that are myeloid, if not macrophage restricted, or disease models in which myeloid-selective gene knockout, for example, of FAS, excludes primary lymphoid cell functions. The efficacy of anti-TNF and IL-1 $\beta$  treatment indicates that primarily macrophage-derived inflammatory products are major factors in tissue damage, even if part of a more complex immune network. Host proteins modified by myeloid-induced oxidative injury or amino acid modification, for example, by citrullination (Kinloch et al., 2008), can give rise to autoantigenicity (Nguyen and James, 2016).

In order to progress, technical challenges have to be overcome; in humans, improved cell phenotyping and population analysis in tissues, for example, by laser capture microscopy and immunocytochemistry, single cell analysis, before, early, as well as late in the development of autoimmune diseases. Analysis of macrophage-expressed gene polymorphisms in disease-prone individuals should emphasize negative as well as positive controls of macrophage growth, recruitment, activation, and turnover. The identification of biomarkers on readily

**FIGURE 10.3** Macrophages and autoimmunity. Macrophages play central roles in homeostasis and inflammation through cross talk with cellular and soluble components of the immune system. In the context of autoimmune diseases, macrophages will respond to antiinflammatory cytokines produced by Tregs and restrict T cell proliferation through consumption of arginine and tryptophan and promote resolution. On the other hand, immune complexes and cytokines produced by Th17 and Th1 cells which are dominant in autoimmune diseases will promote macrophage activation. Activated macrophages can further promote chronicity by causing tissue damage and producing proinflammatory cytokines.

accessible blood monocytes could improve diagnosis and be used to follow the natural history of systemic autoimmune diseases; a recent example has indicated a correlation between monocyte subsets and Th17 responses (Rossol et al., 2012). In mouse models, better methods are required for selective and efficient macrophage depletion, silencing, and conditional genetic manipulation, distinct from dendritic and other myeloid cells.

The balance of activation and inhibition of tissue macrophage phenotypes determines the outcome of many autoimmune diseases and provides targets for treatment (Fig. 10.3). While the role of macrophage activities and products in diseases such as rheumatoid arthritis and type 1 diabetes is established (Navegantes et al., 2017), their possible contribution to systemic autoimmune diseases such as scleroderma, for example, is obscure. The relevance of mouse models to human disease is often problematic. Above all, the predilection of many autoimmune diseases to affect selected tissues such as eyes, joints, and endocrine organs remains obscure. The presence of resident macrophages and possibly organ-specific stromal cells (McGettrick et al., 2012) at these sites and their response to many types of local injury make them attractive targets for further investigation.

## INTRODUCTION

Dendritic cells (DCs) are highly specialized leukocytes with the potent ability to uptake, process, and present antigens (Ags) to the T cells. DCs are found in lymphoid and non lymphoid tissues, and display heterogeneity in both functional subsets and maturation state. In the 1970s Steinman et al. first identified DCs (Steinman and Cohn, 1973) as a separate antigen presenting population with high major histocompatibility complex (MHC) expression and strong induction of mixed lymphocyte reaction (Steinman and Witmer, 1978; Steinman et al., 1979). After 40 years of research on DCs, in 2011, the Nobel Prize in Physiology or Medicine was awarded to Bruce A. Beutler and Jules A. Hoffmann for their discoveries in innate immune recognition and to Ralph M. Steinman for his discovery of the functional role of DCs and their importance in vaccination. As outlined in this chapter, DCs play a role for both T-cell activation and tolerance induction and as such are central modulators of immune responses. Dysregulation of DC function can contribute to autoimmunity, and correcting these defects has the potential to treat autoimmune disease.

## ANTIGEN UPTAKE, PROCESSING, AND PRESENTATION BY DENDRITIC CELLS

DCs take up diverse antigenic material (e.g., soluble and particulate, self, and foreign) by a variety of processes including phagocytosis, pinocytosis, and receptor-mediated endocytosis. In contrast to other phagocytic cells such as macrophages that rapidly and completely degrade phagocytosed material, DCs conserve antigenic material for a prolonged period, allowing continuous processing and presentation of antigen. Certain DCs are equipped with receptors for recognition of apoptotic or necrotic cells (Sancho et al., 2009; Zhang et al., 2012). Some critical DC functions are dependent on the maturation process that is induced by innate immune activation and lead to the expression of proinflammatory cytokines and costimulatory molecules. Mature DCs are specialized for robust T-cell stimulation. Immature or steady-state DCs are especially active in antigen uptake. Maturation shuts off some uptake processes, but mature DCs can still capture soluble antigens (Platt et al., 2010). Receptor-mediated endocytosis and phagocytosis are two key processes for mature DCs to capture antigens. Captured antigens are transported to late endosomes or lysosomes and loaded on MHC class II (MHCII) for presentation. Therefore DCs can continue to acquire new antigens for activation of T cells under inflammatory condition (Drutman and Trombetta, 2010).

There are several antigen processing routes in DC (Trombetta and Mellman, 2005; Wilson and Villadangos, 2005). Exogenous antigens are usually processed in endocytic vesicles, leading to appropriate peptides being loaded onto MHCII molecules. The MHCII associated antigens then presented to CD4 T cells will include peptides from exogenous foreign antigens, along with peptides from self, such as recycling DC surface molecules. When conventional DCs (cDCs) are activated, the MHCII peptide complexes shift to the cell surface and are no longer recycled, so for their limited lifespan, the mature DC presents a “snapshot” of the antigenic environment at the time of activation.

DCs, along with most other cells, produce, as a by-product of protein synthesis, peptides that are loaded onto MHC class I (MHCI) for presentation to CD8 T cells. Such endogenously derived antigens will include viral antigens if the DC is infected with a virus. Some DCs have the additional ability to take up and shuttle exogenous antigens into the MHCI presentation pathway. Only particular DC subtypes are proficient for this specialized function, termed “cross-presentation,” and this capacity is induced as a late step in their development (Heath et al., 2004; Shortman and Heath, 2010). Cross-presentation of exogenous antigens, including material from dead cells, is important for the generation of cytotoxic T-cell responses to intracellular pathogens that do not infect the DCs themselves (Heath and Carbone, 2001). The pathways of cross-presentation are still being determined but involve the movement of antigen from the endocytic vesicles through the cytosol into the endoplasmic reticulum to join the MHCI loading pathway (Mantegazza et al., 2013). Another way DCs may present exogenous antigens on MHCI is via a process termed “cross-dressing” in which either soluble peptides are directly loaded into cell surface MHCI or entire MHCI peptide complexes are transferred from other cells via membrane exchange or exosomes (Maravillas-Montero and Martínez-Cortés, 2017; Robbins and Morelli, 2014).

## Migration

Another attribute that distinguishes DCs from other antigen presenting cells (APC) types is the ability to more efficiently traffic from tissues, where antigen is first encountered and taken up, to the draining lymph node via the lymph. This trafficking is primarily mediated by CCR7 and allows optimal activation of naïve T cells that are mostly present in lymphoid tissues (Randolph et al., 2005). Recent studies have shown that specific DC subsets preferentially migrate to different parts of the T-cell zone to allow optimal contact with the relevant T cells. XC-chemokine receptor 1 (XCR1) + conventional dendritic cell 1 (cDC1) that activate CD8 + T cells preferentially migrate to CD8 T-cell areas, and DCIR2 + conventional dendritic cell 2 (cDC2) that are better at activating CD4 + T cells preferentially migrate to CD4 T-cell areas (Calabro et al., 2016; Gerner et al., 2015). Most other APC mainly presents antigen to T cells in an anatomical site close to where these cells picked up antigen. Because naïve T cells have very minimal trafficking to nonlymphoid organs, the initial priming of T cells (i.e., the first peripheral encounter with antigen) is mediated by DCs. Therefore the types of nonantigenic signals the DCs give during priming can greatly influence the type of T-cell responses that ensues.

## PATTERN RECOGNITION RECEPTORS AND DENDRITIC CELL ACTIVATION

All DCs express receptors that recognize microbial products or damaged cells or other altered aspects of the environment. These receptors, collectively called pattern recognition receptors (PRR), are not all expressed on all

DC subsets and indeed the differential expression of PRR is a major functional discriminator of DC subsets (Hochrein and O'Keeffe, 2008). In addition, DC subset expression patterns of particular PRR are not always the same in different species, which can confound the application of PRR stimulation results from animal models to human disease settings. Pathogen-associated molecular patterns directly interact with PRR on DCs, which is crucial for the induction of primary T-cell responses. PRRs exist on the plasma membrane, in the cytoplasm, and on endosomal membranes of cells. They belong to four major families: Toll-like receptors (TLR), Rig-like helicases (RLH), C-type lectin receptors, and nucleotide-binding domain, leucine-rich repeat containing (NLR) receptors. The engagement of PRR provides signals that are needed to activate DC to full immunogenic function. The signaling pathways downstream of PRR converge on the activation of the transcription factor family NF- $\kappa$ B, interferon (IFN) response factors, and mitogen-activated protein kinases, leading to the production of cytokines and the upregulation of costimulatory molecules and MHC molecules on the DC surface (Diebold, 2009; Kawai and Akira, 2007; Mohammad Hosseini et al., 2015). The PRRs recognize a variety of pathogen-derived or endogenous molecules. For recent reviews see TLR (Kawai and Akira, 2010, 2011; Kawasaki and Kawai, 2014), NLR (Davis et al., 2011; Elinav et al., 2011; Martinon and Tschopp, 2005), RLH (Barbalat et al., 2011; Loo and Gale, 2011), and C-type lectin receptors (Kerrigan et al., 2009; Osorio and Reis e Sousa, 2011; Robinson et al., 2006). Self-derived endogenous ligands can be increased in autoimmune-susceptible individuals and can contribute to disease pathogenesis. TLR signaling is important in DC-mediated activation of adaptive T cells by inducing proinflammatory cytokines and expression of costimulatory molecules. Considering TLRs are important in the context of linking innate and adaptive immune response, aggressive or dysregulation of TLR signaling may lead to autoimmune pathogenesis such as failure of maintaining self-tolerance. For example, PRR activation in autoimmune disease may involve the activation of discrete DC subsets exemplified by the activation of plasmacytoid DC (pDC) in patients with lupus (see next).

## Alignment of Mouse and Human Dendritic Cell Subsets by Function and Development

Recent work shows that the major subsets of DCs defined by both development and function are parallel between mouse and human. This has been appreciated only relatively recently because some of the surface markers that identify these subsets do differ between species, and because of single cell RNAseq that allows for a better understanding of cellular heterogeneity (Villani et al., 2017). This topic has been well reviewed elsewhere (Guilliams and van de Laar, 2015; Guilliams et al., 2014). Briefly, the mononuclear phagocytic system that includes DCs is broadly divided into three components defined by development: tissue-resident macrophages, monocyte-derived cells, and DCs. The bona fide DCs develop from a common precursor and are divided into cDCs and pDCs. cDCs are further divided into cDC1 that are capable of cross-presentation and activate CD8+ T cells and cDC2s that drive optimal CD4+ T-cell activation. Separately, some monocyte-derived cells can upregulate MHCII and share some functions with cDC2s but tend to be less migratory or capable of priming naïve T cells. The cells, sometimes termed moDCs, are upregulated with inflammation. Although these are the main DC subsets, the specific markers and functions of the DCs can vary depending on the tissue location of the DCs and the inflammatory state of the environment. Migratory DC collects antigen in peripheral tissues then migrates to lymph nodes for presentation to T cells. DCs from specific tissues can have specialized phenotypes. For example, in the gut, DCs have increased transforming growth factor- $\beta$  (TGF- $\beta$ ) and retinoic acid signals and are potent inducers of regulatory T cells (Tregs). The lymphoid tissue-resident DC collects antigen within the lymphoid organs, either directly or as antigen acquired from other cell types, including migratory DC.

It is also useful to distinguish the DC found in normal, healthy "steady state" from activated "inflammatory" DCs that are generated, sometimes in substantial numbers, in response to inflammation or infection. Inflammatory DCs can develop from monocytes that upregulate MHCII and are sometimes called moDCs. These moDCs share some markers with cDC2 and are modeled in vitro by culturing monocytes from bone marrow with cytokines including granulocyte-macrophage colony-stimulating factor (GM-CSF), although recent reports suggest that macrophage colony-stimulating factor (M-CSF) may actually be the crucial growth factor required by these DC (Greter et al., 2012). In the past, the term myeloid DC has been used to refer to different populations depending on the author, including cDC2, all cDCs, or monocyte-derived cells. Likewise, lymphoid DCs have been used to describe either pDCs or cDC1. These terms are less useful because of their inconsistent use and because they do not reflect ontogeny as we now understand.

## DEVELOPMENT OF DENDRITIC CELL SUBSETS

Generation of cDCs and pDCs starts in the bone marrow from common monocyte-DC precursors and differentiates into either common monocyte progenitors that develop into monocytes and monocyte-derived DCs, or common DC precursors (CDPs). CDPs initially give rise to pre-DCs that express Zbtb46 transcription factor and convert into cDCs that find the destination of lymphoid or nonlymphoid tissue via circulation. Other molecules that also discriminate cDCs from macrophages include Flt3, c-kit (the receptor for stem cell factor), and the chemokine receptor CCR7 (Förster et al., 1999; Maraskovsky et al., 1996; McKenna et al., 2000). Maintenance of cDCs needs Flt3 cytokine and their ability to respond to Flt3L. Flt3 is a key regulator of DC commitment in hematopoiesis and signals via pSTAT3. Both interleukin-2 (IL-2) and GM-CSF signal via pSTAT5 and can inhibit Flt3L-mediated DC development (Esashi et al., 2008; Lau-Kilby et al., 2011); for IL-2, this effect is mediated by an increase in apoptosis-inducing protein Bim, and a decrease in CD135, the receptor for Flt3L and pSTAT3 activation (Guerrero et al., 2014). Flt3 expression is present on pre-DCs but the expression is lost in precursors that become committed to non-DC populations such as monocytes. Monocyte-derived DCs are functionally distinct from cDCs and display different developmental paths that mainly occur in the context of inflammation (Cheong et al., 2010) and are dependent on GM-CSF.

### DENDRITIC CELL SUBSET PHENOTYPES

#### Conventional Dendritic Cell 1

CD8 $\alpha$  has been a useful marker in mice for identifying lymphoid-resident cDC1s, although its function on DCs is unknown and it is not expressed on human DC. More recently, XCR1 and Clec9a have been identified as markers on cDC1 in both mouse and human. XCR1 is a chemokine receptor for XCL1 expressed by activated T cells; the importance of XCR1 for DC migration is not clear but may be important for colocalization of DCs with T cells. Clec9a is a lectin receptor that allows efficient antigen uptake from dying cells and recognizes the filamentous form of actin (F actin), exposed when the membrane of a cell is disrupted (Sancho et al., 2009; Zhang et al., 2012). cDC1 as well as having the unifying DC function of presenting exogenous antigens on MHCII have the additional capacity for “cross-presentation,” that is, the ability to present exogenous antigen in the context of MHC I (Villadangos and Schnorrer, 2007). Accordingly, cDC1s are particularly efficient at inducing CD8 + T cells in response to exogenous antigens. Upon activation through PRR, cDC1s can produce high IL-12p70 production (Hochrein et al., 2001; Maldonado-López et al., 1999; Reis e Sousa et al., 1997) that can bias activated T cells to an inflammatory Th1 response. CD70 expression by cDC1 also provides an IL-12-independent path toward Th1 development (Soares et al., 2007). Mouse cDC1 expresses TLR3, TLR9 that recognize dsRNA or ssDNA, respectively, but in human TLR9 is restricted to pDCs. With the dual functions of cross-presentation and dead cell uptake, the cDC1s are perfectly equipped to protect against viral or bacterial antigens, but in an autoimmune setting could be particularly detrimental as they may be activated by self-nucleic acids taken up in dead cells and self-antigen presentation may lead to activation of cytotoxic T cells. In nonlymphoid tissue, the cDC1 subset expresses CD103, integrin marker ( $\alpha_E\beta_7$ ) (Bursch et al., 2007). CD103 + cDC, a minor but important migratory DC subset, was discovered in the skin dermis express langerin, a pathogen recognition molecule expressed not only at high levels in Langerhans cells but also at lower levels in some other DC (Kubo et al., 2009). Development of CD8 + or CD103 + cDC1s is orchestrated by the same transcription factors such as the inhibitor of DNA binding 2 (Id2), interferon regulatory factor 8 (IRF8), basic leucine zipper ATF-like 3 transcription factor (BATF3), and the nuclear factor IL-3 regulated (Mildner and Jung, 2014). IRF8 is known as the master regulator of CD8 + and CD103 + cDC development. IRF8 is necessary for the development of Id2-expressing DC precursors but BATF3 is actually induced in later stages of DC development.

#### Conventional Dendritic Cell 2

cDC2s, which are more abundant in lymphoid tissue than cDC1, can be identified by expression of DCIR2 or CD11b in mice and CD1c in human. Although cDC2s are not proficient for cross-presenting antigens, they show superior activity in inducing CD4 + T-cell responses, potentially due to higher expression of MHCII machinery (Dudziak et al., 2007; Lewis et al., 2011). The CD11b + cDCs express very high levels of intracellular Rig-like helicase receptors (RLR) that recognize dsRNA in the cytoplasm (Luber et al., 2010). The high expression of RLR and

some NLR suggests that the cDC2s are particularly primed to rapidly respond to intracellular viral and bacterial infection. cDC2s express high levels of chemokines including CC-chemokine ligand 5 (CCL5) (RANTES), CCL3 (MIP-1 $\alpha$ ), and CCL4 (MIP-1 $\beta$ ). Several transcription factors control cDC2 development, including RelB (Wu et al., 1998), NOTCH2 (Lewis et al., 2011), RBP-J (Caton et al., 2007), IRF2 (Ichikawa et al., 2004), and IRF4 (Suzuki et al., 2004). IRF4 controls MHCII presentation and migration. Since cDC2s are very heterogeneous in both mouse and human, lack of IRF4 and NOTCH2 only partially impairs their development and shows differential penetrance in different tissues (Lewis et al., 2011).

## Plasmacytoid Dendritic Cells

pDCs share with cDC the dependence on Flt3L for their development and the ability to prime T cells after activation (Kingston et al., 2009; Sapoznikov et al., 2007). The development and homeostasis of pDCs are controlled by the helix-loop-helix transcription factor E2-2 (also known as TCF4) (Cisse et al., 2008) that suppresses the expression of Id2 (Ghosh et al., 2010), a transcription factor critical for cDC development (Hacker et al., 2003). pDCs accumulate mainly in the blood and other lymphoid tissues. Because of the low expression of MHCII and other costimulatory molecules, pDCs are inefficient antigen presenting cells. pDCs express high levels of TLR7 and TLR9. If given specific PRR stimuli, they can induce some T-cell division, more than B cells or macrophages but typically in the order of 10-fold or less that of the cDC (Villadangos and Young, 2008). Unlike cDC, the pDCs continually present antigens on MHCII molecules once they are activated and as a result can continue to present new viral antigens during the course of infection (Villadangos and Young, 2008). The importance of this function of pDC during an ongoing infection is not yet elucidated. pDCs can contribute to tolerance induction via maintaining Treg activation and expansion, in part through indoleamine 2,3-dioxygenase (IDO) (Beaudoin et al., 2014; Lippens et al., 2016; Matta et al., 2010). pDCs can also function as an innate cell and are renowned for their high production of Type I interferons (IFN-I) upon recognition of foreign nucleic acids, including ssDNA via TLR9 (Gilliet et al., 2008; Kadokami et al., 2000). As a consequence of endoplasmic reticulum to lysosome internal trafficking of TLR9 and differential expression of molecules that are involved in the TLR9 signaling complex, such as high constitutive expression of IRF7, the pDCs are specialized to produce extremely high levels of IFN-I upon TLR9 ligation (Gilliet et al., 2008). Upon activation, pDCs can also produce proinflammatory cytokines and chemokines, including IL-6, IL-12, CXC-chemokine ligand 8 (CXCL8), CXCL10, CCL3, and CCL4. As a result, pDCs could influence on activating T cells by presenting antigens as well as contribute to B-cell activation, plasma cell generation, and antibody secretion through the production of IFNs-I, IL-6, B cell-activating factor, and a proliferation-inducing ligand (Swiecki and Colonna, 2015).

## Tissue-Specific Dendritic Cells

In addition to the general features of the main DC subsets described above, in particular tissues, DCs can obtain specialized functions and markers. For example, in the gut, DCs can express high levels of TGF- $\beta$  and retinoic acid that allows efficient induction of Foxp3 $^{+}$  Tregs both in the mucosal tissue and in the mesenteric draining lymph nodes (Coombes et al., 2007).

Because human skin is more accessible for study compared to other tissues, DCs from skin have undergone extensive characterization and serve as a model for the heterogeneity of tissue APCs. Skin is composed of two distinct layers, epidermis and dermis. In mice where langerin $^{+}$  migratory DCs are depleted, anti-DEC-205-mediated antigen-specific delivery to DCs is no longer able to induce antigen-specific Tregs in the spleen and skin-draining lymph nodes and results in a loss of immune tolerance (Bennett et al., 2005; Idoyaga et al., 2013). Importantly, langerin $^{+}$  migratory DCs may, in fact, uniquely contribute to the induction of Tregs and the maintenance of peripheral tolerance, as the specific depletion of langerin $^{+}$  DCs, has no effect on the initiation of anti-viral responses (Anandasabapathy et al., 2014). This latter finding suggests that specific DC subsets found in unique environments may have specialized roles.

Several subsets of DCs are found in the dermis including XCR1 $^{+}$  cDC1s, CD11b $^{+}$  cDC2s, and XCR1 $^{-}$ CD11b $^{-}$  double-negative cDCs (Malissen et al., 2014; Tan et al., 2015). Dermal cDCs express CD207 and could be either CD103 $^{+}$  or CD103 $^{-}$ . Dermal cDC1s carry antigens from skin commensals to cutaneous lymph nodes and induce IL-17-producing CD8T cells that migrate to the skin. These skin CD8 T cells are further activated by IL-1 cytokine released by the resident cDC2s or moDCs. T cells activated by this dermal DC-mediated antigen presentation are thought to provide skin protection from pathogens in an IL-17-dependent manner.

(Naik et al., 2015). pDCs are rare in healthy human skin but accumulate in inflamed tissue and facilitate disease pathogenesis in systemic lupus erythematosus (SLE) and psoriasis (Blanco et al., 2001; Nestle et al., 2005). Inflammatory myeloid DCs infiltrate both epidermis and dermis of psoriatic lesions and are proposed to play a major role in psoriasis pathogenesis by production of the inflammatory mediators, inducible nitric oxide synthase, and TNF- $\alpha$  (Lowes et al., 2005; Zaba et al., 2009).

## DENDRITIC CELL SUBSETS AND TOLERANCE

The process of central tolerance in the thymus eliminates potentially autoreactive thymocytes by negative selection and promotes T-cell differentiation into various Treg subsets via additional selection processes (Baldwin et al., 2004; Hogquist et al., 2005; Klein et al., 2014; Labrecque et al., 2011; Pobezinsky et al., 2012). Although thymic DC may serve the same sentinel role as in other tissues, their main role is likely to be in the selection of the antigen receptor repertoire of developing T cells, so ensuring tolerance to self (Ardavín, 1997; Audiger et al., 2017). Central tolerance is, in fact, highly dependent on the presentation of self-antigens to T cells by both thymic epithelial cells and DCs (Gallegos and Bevan, 2004; Guerri et al., 2013; Jenkinson et al., 1992). Early work showed that MHC expression on thymic bone marrow-derived APC contributes to central tolerance induction (van Meerwijk et al., 1997). In vitro organ culture showed the dominant role of DCs in central tolerance when compared with other APCs, like macrophages or B cells (Guerri et al., 2013). Three thymic DC subsets contribute to central tolerance, namely, resident DC ( $CD8\alpha^+ SIRP\alpha^-$ ), migratory DC ( $CD8\alpha^- CD11b^+ SIRP\alpha^+$ ), and pDC ( $CD11c^{int} CD45RA^{int}$ ) (Corcoran et al., 2003; Lahoud et al., 2006; Vremec et al., 2000; Wu and Shortman, 2005). Interestingly, and likely due to the experimental challenges associated with separating central and peripheral tolerance processes, the general outcome of a defect in DC-mediated central tolerance on the potential development of an autoimmune phenotype has yet to be clearly defined. DCs can induce tolerance by increasing IL-10, TGF- $\beta$ , IL-4, or IDO levels. Tolerogenic DCs express low levels of costimulatory molecules CD80, CD86, and CD40 (Steinman et al., 2003; Stoop et al., 2011). Together, these signals allow antigen presentation in a noninflammatory environment, leading to T-cell deletion, anergy, or induction of Tregs.

Although thymic selection eliminates most self-reactive T cells, some remain and must be kept in check with additional peripheral tolerance mechanisms to avoid autoimmunity. Several factors can alter DC-mediated tolerance including the extent of DC maturation and level and timing of antigen presentation. Thus understanding these conditions under which DC remains activated or immature informs modulation of tolerance in pathogenic settings (Ardouin et al., 2016; George et al., 2003; Wallet et al., 2005). In this context, DC-induced T-cell activation does not always correlate with common maturation/activation markers in part because Treg uses some of the same signals including CD80/CD86. Therefore directly assessing the signals given to T cells, including Tregs and the ability of DCs to elicit functional T-cell activation, ideally in vivo, is often needed to define tolerogenic and immunogenic DCs (Salomon et al., 2000; Yamazaki et al., 2003; Zheng et al., 2004; Ardouin et al., 2016). Tregs activated by DCs in vitro display strong autoimmune inhibition (Tarbell et al., 2004, 2007). Particular subsets have specialized roles for maintaining Tregs. Migratory DCs are potent inducers of peripheral Treg generation. Similarly, pDCs are also capable of migrating to lymph nodes and increase peripheral Treg generation (Ochando et al., 2006; Seth et al., 2011). DCs, whether in the steady state or in inflamed conditions, may have differential expression of a wide variety of molecules that together determine if the sum of these signals is sufficient to break or maintain self-tolerance. Vaccination with tolerogenic DC can prevent disease onset and limit disease severity in the collagen-induced arthritis mouse model, a commonly used model of rheumatoid arthritis. Likewise in non-obese diabetic (NOD) mice, transfer of tolerogenic DC or targeting autoantigens to tolerogenic DCs prevents or delays the onset of diabetes (Giannoukakis et al., 2008; Mukherjee and Dilorenzo, 2010; Mukhopadhyaya et al., 2008).

Steady-state DCs are exposed to commensal microorganisms and other tonic inflammatory signals that can induce the expression of maturation markers at low levels and become immunoregulatory and less migratory to the draining lymph nodes. DC migration is associated with significant change in the transcriptional level, suggesting that immunoregulatory function of steady-state DCs is an active process (Ardouin et al., 2016). Induction of inhibitory molecules including programmed cell death protein 1 (PD-1), TGF- $\beta$ , or IDO and downregulation of costimulatory molecules or cytokines are important correlates of regulatory DC function (Kaliński et al., 1997; Selenko-Gebauer et al., 2003). Although DCs under inflamed conditions can display increased effector T-cell activation and inflammatory cytokine production, these DCs can also be immunoregulatory. For example, there are different types of inflammatory signals that counter-regulate each other such as IL-1 and IFN-I. A DC activated

by the environment to increase IFN-I responses could downmodulate an IL-1-driven response (Rahman et al., 2016). Therefore IFN-I can be regulatory and block autoimmunity in some contexts (Kasper and Reder, 2014; Rahman et al., 2018; Tarbell and Egen, 2018; Trinchieri, 2010). Upon infection with *Listeria monocytogenes*, DCs suppress T-cell activity mainly by IL-10 and cyclooxygenase 2-mediated mechanisms (Popov et al., 2008; Schmidt et al., 2012). In chronic viral infection, DCs can become immunosuppressive, losing their surface expression of MHC I and MHC II and costimulatory molecules (Sevilla et al., 2004).

## DENDRITIC CELLS AND AUTOIMMUNE DISEASE

Alterations in central or peripheral tolerance can precipitate development of autoimmune pathology. DC subsets integrate many environmental signals and, in response to these signals, are capable of a wide spectrum of functions ranging from induction of thymic and peripheral tolerance to the induction of potent inflammatory responses. Any imbalances introduced in these DC responses, from complex genetic to environment factors, could lead to or enhance autoimmune disease. Although the role DCs play in orchestrating responses in each autoimmune disease can differ, these diseases do have overlapping pathogenic processes. In general, autoimmune diseases can be categorized into systemic (such as SLE) or tissue-specific [such as type 1 diabetes (T1D)]. In addition, when the targeted tissue is at an interface with the external environment, such as with psoriasis and colitis, signals from commensal organisms in those tissues can alter the balance between autoimmunity and tolerance. In the following sections, some examples are discussed.

### Systemic Lupus Erythematosus

In patients with SLE, autoreactive B- and T-cell responses target nuclear proteins and self-nucleic acids. Genetic influences, including human leukocyte antigen (HLA) loci, play a major role in determining susceptibility to SLE. Other susceptibility genes include many involved in proinflammatory cascades, for example, genes encoding Fc $\gamma$  receptors, TNFSF4, IRAK1, STAT4 (Delgado-Vega et al., 2010; Deng and Tsao, 2010; Sestak et al., 2011). Many of these genes are involved in innate immune pathways leading to production of IFN-I or responses to IFN-I. Patients with SLE displaying an increased IFN gene signature, and these IFN-I responses are pathogenic in the development of SLE (Rönnblom and Pascual, 2008; Ferreira et al., 2014; Obermoser et al., 2010).

IFN-I in SLE is predominantly produced by pDCs that respond to nucleic acid/autoantibody complexes via signaling through TLR7 and TLR9 (Means et al., 2005; Rönnblom and Pascual, 2008). Delivery of nucleic acid complexes to pDC in SLE depends on Fc receptor (FcR) that binds antinucleic acid immune complexes (Means et al., 2005) or nucleic acid complexes associated with neutrophils. Dying neutrophils in SLE patients release neutrophil extracellular traps; these neutrophils die from “netosis,” thereby releasing large amounts of DNA/DNA-binding antimicrobial protein complexes that allow increased uptake of DNA by pDC and subsequent IFN-I production by TLR9-induced activation (Garcia-Romo et al., 2011). pDCs from these patients are more prone to induce pathogenic T-cell responses (Chaussabel et al., 2008; Palucka et al., 2002). The number of circulating pDCs in patients with SLE is decreased and correlates with disease pathogenesis. Recruitment of pDCs into the draining lymph nodes or diseased tissues might contribute to SLE progression.

IFN-I production in SLE is seen as a major contributor to the etiology of this disease since it greatly enhances activation of DC, self-reactive B cells and T cells, and the production of many other proinflammatory cytokines. Indeed, this pathway has recently been the target of new drugs being tested in clinical trials, and blocking IFN-I signals can decrease SLE disease severity, especially in the individuals showing higher IFN-I-driven gene expression prior to treatment (Narain and Furie, 2016). The biggest effects on SLE pathogenesis have been observed with anifrolumab that blocks the IFN-I receptor, but this was also associated with higher adverse events associated with viral infections, specifically increases in herpes zoster and influenza infections. Therefore targeting innate pathways can be powerful for modulating autoimmune pathogenesis, but blocking these signals can also increase infections, narrowing the therapeutic window.

### Inflammatory Bowel Disease—Crohn’s Disease and Ulcerative Colitis

Inflammatory bowel diseases (IBD) ulcerative colitis (UC) and Crohn’s disease (CrD) likely manifest as a result of dysregulated immune responses to the intestinal microbiota, but the pathology is autoimmune in nature.

Mutations in NLR family members NOD2 and NLRP3 are highly associated with CrD (Cho, 2008; Villani et al., 2009). These PRRs are mainly expressed by DC and macrophages and emerging evidence suggests they play a crucial role in maintaining immunological homeostasis in the intestine (Strober, 2009; Strober et al., 2006; Zaki et al., 2011). NOD2 functions as a receptor for the bacterial cell wall component muramyl dipeptide. Triggering of NOD2 in human MoDC in vitro stimulates processing and presentation of bacterial antigens to CD41 T cells, so generating an antibacterial response due to an increased production of antibacterial IL-17 (van Beelen et al., 2007; Cooney et al., 2010). NLRP3 is activated by a wide variety of microbial agonists and drives IL-1 $\beta$  secretion that activates the antimicrobial functions of innate immune cells such as macrophages and DC and induces CD41 Th17 immune responses (Schroder et al., 2010). Thus abnormal signaling by DC in response to the intestinal microbiota, consequent to mutations in these PRR, likely contributes to the pathogenesis of CrD.

Further evidence derived from mice and humans suggests that an imbalance in intestinal DC subsets, distribution, and function plays a crucial role driving inflammation and disease pathogenesis (Ng et al., 2011; Varol et al., 2010). Depletion of DC in mouse models of colitis leads to increased or decreased disease severity depending on the time point, demonstrating a crucial role for DC in both the downregulation and exacerbation of intestinal inflammation. The balance between the functions of mouse intestinal CD103 and CX3CR1 DC subsets regulates immune homeostasis and controls inflammatory responses. CD103 DCs are migratory DC that reside in the lamina propria and transport microbial antigens to the lymph nodes where they play an essential role in the induction of peripheral Tregs and the generation of oral tolerance. In contrast, the levels of CX3CR1 DC are dramatically increased in mouse colitis models and augment the severity of disease. pDCs also accumulate in intestinal tissue in mouse colitis models (Karlis et al., 2004) and are contributors to the protective effects of GM-CSF treatment on colitis (Sainathan et al., 2008).

CD11c + MHCII + DC can be found in the lamina propria of the human colonic mucosa (Ng et al., 2010), but their phenotype, function, and degree of alignment with mouse DC subsets are poorly characterized. Increased numbers of activated cDC are found in inflamed tissue in CrD compared to noninflamed tissue, supporting a role for DC in disease pathogenesis (Ng et al., 2010). These DCs express CD40 and CD83, TLR2 and TLR4 and produce proinflammatory cytokines including IL-6, tumor necrosis factor (TNF), and IL-12. An increased number of pDC are also present in the colonic mucosa and mesenteric lymph nodes of patients with CrD and UC (Baumgart et al., 2011). However, pDC infiltration in the lamina propria is associated with a clinical response and remission in patients with CrD following granulocyte-colony stimulating factor (G-CSF) treatment (Mannon et al., 2009). Thus the contribution of pDC to IBD pathogenesis remains unclear.

## Psoriasis and Psoriatic Arthritis

Psoriasis is a common chronic inflammatory skin disorder associated with increased accumulation of natural killer cells, type 3 innate lymphoid cells, TH17 cells, and  $\gamma\delta$  T cells that drive production of inflammatory cytokines like IL-17 and IL-22 (Guttmann-Yassky et al., 2011). Approximately 2% of the US population has psoriasis, and up to 30% of those will develop psoriatic arthritis. The pathology of psoriasis is better understood than that of associated arthritis, but some evidence points to common antigens (Dolcino et al., 2015), suggesting a shared role for dysfunctional APCs. CD11c + DCs are greatly increased in number in the psoriatic skin, either mature or immature forms. Mature DCs often aggregate with the lesional infiltrating T cells. T cells within the lesions are highly proliferating and show a memory phenotype; therefore accumulated DCs within the lesions are thought to be acting as cellular nidus that contribute to the activation of T cell by presenting autoantigens (Bos et al., 1989; Chang et al., 1992). In this regards, it has been shown that depletion of DCs in CD11c-diphtheria toxin receptor-transgenic mice prevents disease onset suggesting the involvement of DCs in disease pathogenesis. pDCs are also increased in psoriatic plaques, produce large amounts of IFN-I. There are several molecules that have been recently tested against psoriasis treatment based on the fact that reducing the ability of DCs to interact with T cells may limit the pathogenic T-cell activity. Alefacept or Efalizumab, which both block the interaction of DCs with T cells by binding to CD2 or intercellular adhesion molecule 1, respectively, shows good clinical therapeutic efficacy.

## Type 1 Diabetes

T1D is an autoimmune disorder that results from the defective induction or maintenance of T-cell tolerance against islet  $\beta$ -cell self-antigens. There are multiple layers of immune cell activation during the progression

of disease. In this context, both genetic and environmental factors contribute to the development of T1D (Hotta-Iwamura and Tarbell, 2016). Genome-wide association studies and disease association studies have identified >50 polymorphic loci that lend susceptibility or resistance to insulin-dependent diabetes mellitus. In parallel, diabetes susceptibility regions known as insulin-dependent diabetes loci have been identified in the nonobese diabetic mouse, a model for human T1D, providing a better understanding of potential immunomodulatory factors in T1D risk (Hotta-Iwamura and Tarbell, 2016). Both innate and adaptive immune cells are activated in an inflammatory environment dominated by IL-1 and IFN-I. A chronic inflammatory environment establishes later, but before the onset of T1D. The immune equilibrium is disrupted by chronic stimulation with autoantigens and altered cytokine stimulation. DCs contribute to early diabetes pathogenesis (Calderon et al., 2011; Diana et al., 2013; Ferris et al., 2014), but because of their role in maintaining Tregs, increasing DCs at later stages of T1D can block disease (Darrasse-Jèze et al., 2009). DCs presenting self-antigen can increase self-specific Treg numbers, function, and activation, and these DC-driven Tregs are potent for inhibiting autoimmunity. Autoimmunity disrupts DC-mediated steady-state tolerance either through intrinsic genetic alterations or because of endogenous innate signals that induce some level of maturation (Rönnblom et al., 2006; Turley et al., 2003). Like SLE, one critical inflammatory signal for diabetes pathogenesis is IFN-I cytokine that increases in early life and remains high until the onset of disease. Early blockade of IFN-I signal inhibits diabetes pathogenesis (Carrero et al., 2013; Rahman et al., 2016; Sen et al., 2003), which suggests a role for IFN-I in breaking tolerance. However, when chronic inflammation establishes, the role of IFN-I appears to shift and blocking IFN- $\alpha$  receptor signals later actually accelerates diabetes development. This has been shown by the fact that despite increased chronic IFN-I exposure, DCs from older prediabetic NOD mice display impaired IFN-I responses (Rahman et al., 2016) due in part to down-modulation of IFN- $\alpha$  receptor (Sen et al., 2003; Weaver et al., 2001). Increased expression of PGE2 and one receptor for PGE2, EP4 in NOD, also down-modulates IFN signals, and blocking EP4 signals decreases lymphocytic infiltrate (Rahman et al.). Despite this decreased IFN-I response, APCs are still hyperactive due to the altered regulation of NF- $\kappa$ B activation that enhances antigen presentation to CD8 T cells (Blanco et al., 2008; Mayer-Barber and Yan, 2017). The role of DC subsets in different autoimmune conditions may differ. For example, both CD8 $\alpha^+$ DEC-205 $^+$  and CD11b $^+$ DCIR2 $^+$  DCs are tolerogenic in normal mice, but only the CD11b $^+$ DCIR2 $^+$  DCs are able to induce CD4 tolerance in NOD mice (Price and Tarbell, 2015; Price et al., 2014). CD8 $\alpha^+$ DEC-205 $^+$  DCs in NOD mice play a more pathogenic role as demonstrated in NOD Batf3 $^{-/-}$  mice that lack CD8 $\alpha^+$  T cell-mediated cross-presentation (Ferris et al., 2014). The progress of DC-based immunotherapy is currently being evaluated with DC generated from blood precursors and treated with antisense oligonucleotides in vitro (Giannoukakis et al., 2008). In vitro generated DCs are then injected intradermally at a site proximal to the pancreas and are expected to migrate to nearby lymph nodes and the pancreas.

## TARGETING OF DENDRITIC CELLS IN AUTOIMMUNE DISEASE

DCs are critical for maintaining a tolerogenic state and preventing the development of autoimmune disease. More importantly, increasing evidence also shows that, in an autoimmune environment, DCs can become inflammatory and override their tolerogenic state. Therefore solutions for manipulating DCs toward stable tolerogenic states for treatment of autoimmune diseases are desired approaches. For the goal of antigen-driven tolerance, one consideration is how best to induce dominant tolerance, namely, the ability of tolerance directed at a single antigen specificity to promote tolerance to other antigens expressed in the same tissue. Unfortunately, ex vivo manipulation of DC is logically impractical and needs to be tailored specifically for individual patients. Most preclinical studies and ex vivo human assays have used monocyte-derived DCs, but new methods for generation of Flt3 ligand-based human cDCs may broaden the types of DCs available (Lee et al., 2015). Delivering antigen to DC directly in vivo using antibodies specific for DC-associated molecules such as DEC-205 can overcome many of the current limitations of DC therapy (Tacken et al., 2007). This approach is currently in early phase clinical trials for cancer and is being explored in preclinical experimental models for autoimmune diseases. In the absence of adjuvant, targeting antigen to DC in vivo using antibodies to DEC-205 induces antigen-specific T-cell deletion and unresponsiveness to myelin oligodendrocyte glycoprotein (MOG) in a model of autoimmune experimental acute encephalomyelitis and to model antigens including ovalbumin (Bonifaz et al., 2002; Hawiger et al., 2004). Furthermore, DEC-205 targeting of autoantigens in the NOD and other mouse models of T1D prevents disease onset and progression (Bruder et al., 2005; Mukhopadhyaya et al., 2008). However, because autoimmune

individuals inherently have tolerance defects, “steady-state” DC tolerance may fail (Price and Tarbell, 2015). Therefore adding tolerogenic signals may be necessary.

An alternative approach being developed is microspheres carrying CD40, CD80, and CD86 antisense oligonucleotides. Vaccination with these microspheres can prevent and reverse the new onset of T1D in NOD mice, presumably via uptake by DC *in vivo* and the expansion of Tregs (Phillips et al., 2008). Targeting the innate functions of DC, such as cytokine production, is also likely to be helpful in autoimmune diseases. The example of SLE cited above is a key candidate for pDC targeting. Targeting strategies that block TLR7 and 9, for example, would extinguish the IFN-I production by pDC in response to self-nucleic acids in SLE. For any of these current or future treatments, defining reliable biomarkers is critical. Biomarkers could potentially identify the subset of patients who have particular tolerance defects and who may respond to a particular treatment. Baseline alterations in DC phenotype may be useful because the genetic and environmental modulators of DC function will vary among individuals with T1D. Biomarkers can also identify efficacy and responsiveness to specific modulations, and this type of marker will likely include T-cell readouts, but assessing the function and stability of tolerogenic DCs after treatment would also be informative.

## CONCLUSION AND FUTURE PROSPECTS

Through both antigen presentation functions and innate immune functions, DCs are critical for the initiation and maintenance of self-tolerance that is broken in autoimmune disease. But DCs are also central contributors of autoimmune pathology by giving autoreactive T-cell activation and differentiation signals. Because of this, modulation of DC has the potential to both increase tolerance induction and block the expansion of self-specific effector T cells. But increasing these tolerogenic effects can be difficult to do without at the same time exacerbating pathogenic effects of DCs. For example, DC-specific expression of some of the same phenotypic markers can both increase Tregs and autoreactive Teff. Conversely, decreasing DC maturation to avoid activation of pathogenic cells can also interfere with Treg homeostasis. Therefore to balance the effects on both Treg and Teff, the specific phenotype of the tolerogenic DC is critical.

New techniques such as single cell RNAseq that allow elucidation of the diversity of cell phenotype with small numbers of cells have allowed a better understanding of DC function in different contexts. From these and accompanying functional assays, the role of DC subsets in both mice and human is now better understood (Villani et al., 2017). In the future, more information of how DCs change in pathological contexts will further design of therapies that can modulate DCs for treatment of disease. Targeting self-antigen to DCs has the potential to treat autoimmunity but challenges remain. Importantly, key self-antigens need to be defined. Because T cells against many antigens facilitate autoimmune pathogenesis, targeting antigen must induce dominant tolerance.

Another approach is to adjust DCs to a tolerogenic phenotype without exogenous delivery of antigen and rely on endogenous self-antigen presentation. For this approach, the drawback is potential effects on immunity to infectious agents. Blocking TNF and other inflammatory cytokines have been efficacious for the treatment of arthritis and other chronic autoimmune conditions and work in part through effects on DCs (Khan et al., 2009). Surprisingly, 20 years of experience with this class of drug shows that, although a small (20%) increase in infections does occur, this is not a major side effect and does not often lead to patients stopping treatment (Minozzo et al., 2016). But only a minority of autoimmune patients are successfully treated with inhibitors of inflammatory cytokines. Specific infections, such as tuberculosis, for which TNF is critical show a larger increase under TNF blockade. New ways of pushing DCs toward tolerance are needed, but with more potent effects on blocking autoimmunity may come a larger inhibition of immunity to infection.

Combination approaches that deliver antigen to tolerogenic DCs along with increasing signals that encourage tolerance may have the best chance of success.

## Acknowledgments

This chapter is based on the DC chapter authored by Kristen Radford, Ken Shortman, and Meredith O’Keeffe that was included in the fifth edition of this book. This work was supported by the intramural programs of NIDDK and NHLBI.

## INTRODUCTION TO NATURAL KILLER CELLS

Natural killer (NK) cells were described in the 1970s as large granular lymphocytes exhibiting “natural cytotoxicity” against several types of tumor cells (Kiessling et al., 1975). Significant progress has been made since then in the dissection of additional functional traits of NK cells (See chapter 18). By their cytotoxic potential, they can kill many more types of cells than tumor cells, for example, virus-infected cells and several types of activated immune cells (Vivier et al., 2008). To carry out these functions, and to discriminate target cells from nonactivated “normal” cells, NK cells are equipped with a molecular detection system that includes a variety of cell surface–activating and inhibitory receptors (Lanier, 2005). Activating NK cell receptors can detect the presence of ligands on cells in “distress,” such as stress-induced self-ligands (Bryceson et al., 2006a). In parallel, NK cells use inhibitory receptors to monitor the presence of constitutively expressed self-major histocompatibility complex (MHC) class I molecules (Long, 2008); MHC class I expressing cells are normally spared while cells lacking these molecules can be targeted by NK cells, a recognition strategy originally referred to as “missing-self” recognition (Ljunggren and Kärre, 1990). NK cells are also critical components of the innate immune response, because of their ability to produce a variety of cytokines and chemokines (Vivier et al., 2008). Thus NK cells may drive, shape, and regulate the activities of other immune cells and by these means

affect the development of adaptive immune responses. NK cells respond to initial cues from myeloid cells including myeloid-derived dendritic cells (DCs), as well as macrophages and plasmacytoid DC. This response is possible because NK cells express receptors for several myeloid-derived cytokines (Caligiuri, 2008; Vivier et al., 2008). Thus secondary to triggering of myeloid cells by pattern recognition receptors, NK cells can relay and amplify key cytokine signals. Perhaps the best characterized cytokine produced by NK cells is interferon (IFN)- $\gamma$ . However, NK cells also secrete a number of other additional cytokines and other factors, including tumor necrosis factor (TNF)- $\alpha$  and immunoregulatory cytokines such as interleukin (IL)-5, IL-10, IL-13, the growth factor GM-CSF, and chemokines CCL3 (MIP-1 $\alpha$ ), CCL4 (MIP-1 $\beta$ ), CCL5 (RANTES), and CXCL8 (IL-8). The ability to respond to a variety of cytokines suggests that the local microenvironment in which NK cells exist may shape and modulate their function (Caligiuri, 2008; Vivier et al., 2008). Consistent with their functions as innate sentinels, NK cells are spread throughout lymphoid and nonlymphoid tissues. In many tissues, they represent a minor fraction of total lymphocytes. However, in other tissues such as the liver and pregnant uterus they are abundant (Vivier et al., 2008).

Although important aspects of NK cell biology have been revealed using mice as a model organism, it should be noted that many central NK cell receptors are rapidly evolving in evolutionary terms. Thus significant differences between the mouse and human immune systems exist, particularly with respect to NK cells (Mestas and Hughes, 2004). Our review is focused on the phenotype and function of human NK cells, highlighting recent advances in understanding their role in autoimmune diseases.

## NATURAL KILLER CELL DEVELOPMENT AND DIFFERENTIATION

NK cells belong to the hematopoietic system. They are derived from CD34 $^{+}$  hematopoietic precursor cells (HPCs). In transcriptional terms, NK cells are most closely related to cytotoxic T lymphocytes (Sun and Lanier, 2011) and in humans typically defined as CD3 CD56 $^{+}$  lymphocytes. According to a newly proposed nomenclature, NK cells have been categorized as belonging to the family of innate lymphoid cells (ILCs) and more specifically the group 1 ILCs (Spits et al., 2013). In addition to differential transcriptional regulation, NK cells are distinguishable from other ILCs as NK cells do not express CD127. Furthermore, ILCs lack cytotoxic function as well as several functional NK cell markers including NKG2A and NKG2D. However, the exact relationships and plasticity between the NK cells and other ILCs remain to be further elucidated, especially in humans (Spits et al., 2013).

During fetal development, NK cells are among the first immune cells to appear. It is generally accepted that most NK cells develop in the bone marrow, based on evidence from early studies of bone-marrow ablation in mice (Haller and Wigzell, 1977). Bone marrow–derived human CD34 $^{+}$  HPCs can also be manipulated to differentiate *in vitro* into NK cells (Miller et al., 1992). In this setting, NK cell development is dependent on bone-marrow stroma (Miller et al., 1994). Furthermore, it requires IL-2 and/or IL-15 (Miller et al. 1992, 1994) and is potentiated by flt3-ligands (Yu et al., 1998). One important question is, do NK cell precursors, formed in the bone marrow, traffic to distinct peripheral anatomical locations for their final stages of development? Several lines of research support this notion; for example, immune precursor cells with NK cell developmental potential are selectively enriched in human secondary lymphoid tissues (SLT), such as lymph nodes and tonsil (Freud et al., 2005). These CD34 $^{+}$ CD45RA $^{+}$  cells represent more than 95% of all HPCs in SLT, but are infrequent in bone marrow and blood.

Based on this, and other insights, a continuous SLT NK cell developmental pathway has been proposed (Freud et al., 2006; Freud and Caligiuri, 2006). In this pathway, “stage 1” NK cells (pro-NK cells) are characterized by a CD34 $^{+}$ CD117 CD94 phenotype, the lack of expression and transcription of CD122 (IL-2/15 receptor  $\beta$ -chain), and unresponsiveness to IL-15. Upon stimulation with flt3-ligand, IL-3, and IL-7, possibly in a stroma cell-dependent manner, these pro-NK cells acquire a “stage 2” NK cell (pre-NK cells) phenotype characterized by upregulation of CD122 that provides responsiveness to IL-15 (Freud et al., 2006). CD34 $^{+}$  CD117 $^{+}$  CD94 pre-NK cells are not fully committed to the NK cell lineage and can also give rise to other immune cells such as T cells and myeloid DCs. Furthermore, they lack characteristic NK cell functions, such as cytotoxicity and the capacity to produce IFN- $\gamma$ . However, with IL-15 stimulation, pre-NK cells develop into “stage 3” NK cells [immature NK (iNK) cells] characterized by loss of CD34 and a step-wise acquisition of CD56 together with a functional commitment to the NK cell lineage. Finally, these iNK cells progress into “stage 4” NK cells characterized by bright expression of CD56 (CD56 $^{\text{bright}}$  NK cells). This progression is marked by the acquisition of the inhibitory receptor CD94/NKG2A and such NK cell-associated activating receptors as NKp46 and NKG2D,

as well as by the capacity to produce IFN- $\gamma$  and to release perforin and granzyme-containing granules (Freud et al., 2006). NK cell expression of killer cell immunoglobulin-like receptors (KIRs) for self-MHC class I confers NK cells with effector potential in a yet molecularly poorly defined process termed “education” or “licensing” (Kim et al., 2005; Anfossi et al., 2006; Elliott and Yokoyama, 2011). At present, many open questions remain with respect to how NK cell function relates to development and to what extent NK cell differentiation can be regarded as linear or branched.

Key transcription factors that regulate NK cell development and differentiation have recently been characterized (Klose et al., 2012; Cichocki et al., 2013). STAT5B has been implicated in the early stages of NK cell differentiation, alongside E4BP4 that induces ID2 and GATA3. Without any one of these transcription factors, NK cell development is grossly impaired with a block at the pre-NK to iNK stage. Similarly, but in an apparently parallel pathway, TOX is required for the pre-NK to iNK transition. TBX21 (T-bet) is also required for early NK cell development, while expression of EOMES is required for sustenance of NK cells in a mature stage. Importantly, NK cell selective deficiencies have been associated with autosomal dominant mutations in *GATA2* and *MCM4* (Gineau et al., 2012; Mace et al., 2013). Much more information is needed to get a better view of how transcription factors program NK cell development and differentiation.

## PHENOTYPE AND TISSUE LOCALIZATION

In humans, “mature” NK cells are divided into CD56<sup>bright</sup> and CD56<sup>dim</sup> subsets, defined by expression levels of CD56 (Lanier et al., 1986; Jacobs et al., 1992; Cooper et al., 2001; Caligiuri, 2008). These two subsets are present at varying proportions in different compartments of the human body. In blood, bone marrow, and spleen, CD56<sup>dim</sup> NK cells dominate, representing around 90% of all NK cells. On the other hand, in tonsils and other SLT, CD56<sup>bright</sup> NK cells dominate. The liver, in contrast, contains nearly equal proportions of CD56<sup>dim</sup> and CD56<sup>bright</sup> NK cells. The CD56<sup>bright</sup> and CD56<sup>dim</sup> NK cell subsets differ in phenotype and function. In brief, CD56<sup>bright</sup> NK cells are negative for, or express only low levels of, the low-affinity Fc-receptor CD16, express few inhibitory KIRs, or cytotoxic molecules such as perforin and different granzymes (Cooper et al., 2001). On the other hand, CD56<sup>bright</sup> NK cells uniformly express the inhibitory CD94/NKG2A receptor, as well as CD62L and the high-affinity IL-2 receptor  $\alpha$  chain (CD25). CD56<sup>dim</sup> NK cells display a variegated expression of KIRs, NKG2A, and CD62L, express high levels of CD16 on their surface, and contain intracellular granules with large amounts of perforin and granzymes (Cooper et al., 2001). With respect to function, CD56<sup>bright</sup> NK cells were generally believed to produce large amounts of cytokines but have little capacity to perform cytotoxicity, whereas CD56<sup>dim</sup> NK cells were believed to be efficient killers but poor at producing cytokines (Fehniger et al., 2003; Ferlazzo et al., 2004a,b; Morandi et al., 2006; Burt et al., 2009). However, recent work suggests that CD56<sup>bright</sup> NK cells also can mediate some cytotoxicity and produce cytokines in response to exogenous cytokine stimuli, whereas CD56<sup>dim</sup> NK cells both have efficient capacities for performing cytotoxicity and producing cytokines upon specific target-cell recognition (Fauriat et al., 2010).

CD56<sup>bright</sup> and CD56<sup>dim</sup> NK cell subsets might represent two sequential stages of NK cell differentiation, with CD56<sup>bright</sup> cells being less mature (Lanier et al., 1986; Caligiuri, 2008). Several lines of (sometimes indirect) evidence support this hypothesis. First, CD56<sup>bright</sup> NK cells appear earlier in immune reconstitution settings than do CD56<sup>dim</sup> NK cells, and the former can represent up to 70%–80% of all peripheral blood NK cells a few months after hematopoietic stem-cell transplantation (Jacobs et al., 1992; Shilling et al., 2003). Second, CD56<sup>bright</sup> NK cells have a more immature phenotype compared to CD56<sup>dim</sup> NK cells with, for instance, expression of CD117 (c-kit) (Matos et al., 1993), which is typically expressed by immature HPCs. CD56<sup>bright</sup> NK cells also display longer telomeres (25) and, morphologically, constitute both granular and agranular cells, whereas all CD56<sup>dim</sup> NK cells are granular (Romagnani et al., 2007). Furthermore, in humanized mice, purified CD56<sup>bright</sup> NK cells were recently shown to differentiate into CD56<sup>dim</sup> NK cells (Huntington et al., 2009). Hence, a substantial amount of evidence suggests CD56<sup>bright</sup> (stage 4) NK cells to be precursors of CD56<sup>dim</sup> (stage 5) NK cells. Until recently, CD56<sup>dim</sup> NK cells were considered an “end stage” of human NK cell differentiation. However, recent data have demonstrated that even CD56<sup>dim</sup> NK cells undergo a continuous differentiation process, the latter characterized by a gradual shift from NKG2A<sup>+</sup> CD62L<sup>+</sup> CD57 KIR cells toward more terminally differentiated NKG2A CD62L CD57<sup>+</sup> KIR<sup>+</sup> cells (Björkström et al., 2010).

Besides CD56<sup>bright</sup> and CD56<sup>dim</sup> NK cells, which constitute the majority of NK cells in human peripheral blood and tissues at variable relative frequencies, a distinct population of CD56<sup>superbright</sup> NK cells has been characterized in the endometrium which becomes the dominant lymphocyte population in the decidua of pregnant

women (Manaster and Mandelboim 2010). Such uterine NK cells may represent relatively iNK cells and display a unique phenotype, expressing the tetraspanin CD9, high frequencies of activation markers CD69 and HLA-DR, as well as inhibitory NKG2A and KIR. Interestingly, they do not express CD16 or CD57.

## FUNCTIONAL RESPONSES BY NATURAL KILLER CELLS

NK cells and cytotoxic T cells (CTLs) are thought to share mechanisms for target-cell elimination. Cytotoxicity by both NK cells and CTLs relies on directed release of their lytic granule contents. These lytic granules are specialized secretory lysosomes that contain perforin, granzymes, and Fas ligand that all contribute to target-cell killing (Dustin and Long, 2010; Griffiths et al., 2010). Imaging studies comparing target-cell recognition by NK cells and CTLs in vitro and in vivo suggest some noteworthy distinctions. In vitro, CTLs rapidly establish cytoskeletal polarity, whereas NK cells are more tentative in their interactions with target cells (Wulfing et al., 2003). In vivo, CTLs form stable contacts with tumor cells expressing cognate antigen, whereas NK cells establish mainly dynamic contacts (Deguine et al., 2010). These observations suggest differences in the molecular machinery underlying NK cell and CTL recognition and elimination of target cells.

Recent studies of NK cell responses have also highlighted considerable heterogeneity among human peripheral blood NK cells, including hierarchies that govern the strength of activation stimuli needed for induction of specific responses (Bryceson et al., 2005, 2009, 2011). For example, induction of inside-out signals for leukocyte functional antigen (LFA)-1-mediated adhesion exhibits a markedly low threshold for activation. Induction of chemokines such as MIP-1 $\beta$  requires stronger activating stimuli, whereas degranulation and production of cytokines such as TNF- $\alpha$  and IFN- $\gamma$  display the most stringent requirements for induction (Bryceson et al., 2011). Some of the functional heterogeneity in different NK cell populations can be accounted for by differences in cellular differentiation (Björkström et al., 2010; Juelke et al., 2010; Lopez-Verges et al., 2010). For example, relatively immature CD56<sup>bright</sup> NK cells excel at cytokine production in response to exogenous cytokines such as IL-2, IL-12, IL-15, and IL-18. The same cells, however, express low levels of perforin and are, consequentially, less cytotoxic than CD56<sup>dim</sup> NK cells and do not produce cytokines as readily in response to target-cell recognition. In contrast, relatively more differentiated (NKG2A<sup>+</sup> CD62L<sup>+</sup> CD57 KIR) CD56<sup>dim</sup> NK cells produce significant amounts of IFN- $\gamma$  in response to exogenous cytokines, express higher levels of perforin, and have a stronger ability to mediate cytotoxicity. They can also produce ample amounts of cytokines in response to target-cell recognition. Finally, highly differentiated (NKG2A CD62L CD57<sup>+</sup> KIR<sup>+</sup>) CD56<sup>dim</sup> NK cells express high levels of perforin and display potent cytotoxic capacity. These cells are also strong producers of cytokines in response to target-cell recognition. However, the response of these NK cells to exogenous cytokines is comparatively blunted.

In parallel to the continuous maturation process, recognition of self-MHC class I molecules by inhibitory receptors potentiates the NK cell's ability to respond functionally, a process referred to as "education" or "licensing" (Kim et al., 2005; Anfossi et al., 2006; Elliott and Yokoyama, 2011). Superimposing differentiation and education processes on NK cell functionality do not, however, fully explain the heterogeneity in NK cell responses. Studies have revealed that the thresholds for effector responses are highly dynamic. For example, different molecular pathways are likely used depending on activation by different cytokines and triggering of different (combinations of) cellular receptors and gives rise to differences in response rates (Bryceson et al., 2009, 2011).

## NATURAL KILLER CELL RECEPTOR SIGNALING AND EFFECTOR FUNCTIONS

A multitude of activating NK cell receptors that belong to different receptor families have been described (Table 12.1). They contain highly divergent cytoplasmic signaling domains. The signaling pathways orchestrated by some activating NK cell receptors are known, whereas others are significantly less well characterized (Bryceson et al., 2006a; Watzl and Long, 2010). In contrast, structurally distinct inhibitory NK cell receptors all contain immunoreceptor tyrosine-based inhibition motifs (ITIMs). The signaling by such motifs has been extensively studied and is mainly mediated through activation of tyrosine phosphatases such as SHP-1 as well as the tyrosine kinase c-Abl (Long, 2008; Peterson and Long, 2008). Some inhibitory receptors engage other negative regulators such as SHIP, an inositol 5-phosphatase, and the Src family tyrosine kinase CSK. Taken together, today's knowledge suggests that potent NK cell effector functions such as cytotoxicity and

**TABLE 12.1** Specificity and Signaling of Human Natural Killer (NK) Cell Receptors

Receptor	Signaling	Cellular ligand	Function
FcgRIIIa (CD16)	Activation (ITAM)	IgG	Elimination of ADCC
NKp30 (CD337)	Coactivation (ITAM)	B7-H6	NK cell-myeloid cell cross-talk, tumor recognition
NKp44 (CD336)	Activation (ITAM)	?	?
NKp46 (CD335)	Coactivation (ITAM)	?	Surveillance of mitotic cells
KIR (CD158a, b, etc.)	Activation (ITAM)	HLA class I	?
CD94/NKG2C (CD159c)	Activation (ITAM)	HLA-E	?
NKG2D (CD314)	Coactivation (YxNM)	ULBP, MICA, MICB	Surveillance of tumor cells and genotoxic stress
NKp80	? (hemi-ITAM)	AICL	NK cell-myeloid cell cross-talk
DNAM-1 (CD226)	Coactivation	CD112, CD155	Surveillance of tissue integrity
2B4 (CD244)	Coactivation (ITSM)	CD48	Interaction with hematopoietic cells
CRACC (CD319)	Coactivation (ITSM)	CRACC (CD319)	Interaction with hematopoietic cells
NTB-A	Coactivation (ITSM)	NTB-A	Interaction with hematopoietic cells
CD2	Coactivation	CD58	Interaction with hematopoietic and endothelial cells
KIR2DL4 (CD158d)	?	HLA-G (soluble)	Trophoblast-induced vascular remodeling
LFA-1 (CD11a/CD18)	Granule polarization	ICAM	Recruitment and activation during inflammation, efficient cytotoxicity
KIR (CD158)	Inhibition (ITIM)	HLA class I alleles	Assess loss of MHC class I alleles
LIR1, LILR1 (CD85j)	Inhibition (ITIM)	HLA class I	Assess loss of MHC class I expression
CD94/NKG2A (CD159a)	Inhibition (ITIM)	HLA-E	Gauge MHC class I expression
KLRG1	Inhibition (ITIM)	E-cadherin	Assess loss of tissue integrity
NKR-P1 (CD161)	Inhibition (ITIM)	LLT1	?
LAIR-1 (CD305)	Inhibition (ITIM)	Collagen	Control activation in extracellular matrix
Siglec-7 (CD328)	Inhibition (ITIM)	Sialic acid	?

cytokine production require dynamic integration of signals derived from multiple receptors (Liu et al., 2009). The following sections will focus on advances in our understanding of the molecular processes underlying NK cell effector responses.

## Natural Killer Cell Contact and Adhesion to Target Cells

A first step in NK cell responses to pathogen-infected target cells or tumor cells involves recruitment of NK cells to the site of inflammation/infection or to the tumor. NK cells express several chemokine receptors. The mechanism of NK cell trafficking to inflamed tissues is fairly well understood and has recently been reviewed elsewhere (Gregoire et al., 2007). During inflammation, NK cells can be recruited by chemokines that bind the CCR2, CCR5, CXCR3, and CX3CR1 chemokine receptors. However, the degree to which NK cells constitutively traffic in normal tissues is relatively less well understood. How NK cells detect and discriminate target cells has recently been studied quite extensively. The initial contact between NK cells and target cells may involve any of a number of different receptors, leading to adhesion mediated by the integrin LFA-1. Activating receptors, including CD16, 2B4, NKG2D, DNAM-1, as well as LFA-1 itself, can rapidly induce necessary inside-out signals for the activation of LFA-1 in freshly isolated human NK cells, promoting the initial signals required for adhesion (Bryceson et al., 2009). As opposed to activating receptors, inhibitory receptor signals can abrogate adhesion to

target cells (Burshtyn et al., 2000; Bryceson et al., 2009). The signals for induction of inside-out activation of LFA-1 are not well defined. As the activating NK cell receptors have distinct cytoplasmic domains, their signaling cascades differ. Live cell imaging of NK cells on supported planar lipid bilayers carrying ligands for LFA-1, NKG2D, 2B4, and CD16 has shown that, indeed, these receptors induce quite diverse behaviors by NK cells (Liu et al., 2009). In regards to signals for inside-out activation of LFA-1, phosphorylation and activation of VAV1 have been postulated to be a common denominator of signaling pathways downstream of activating receptors including LFA-1 itself. Concomitantly, VAV1 phosphorylation provides a point at which inhibitory receptor signals can oppose signals from activating receptors. Specifically, phosphorylated VAV1 is a substrate of SHP-1 that is recruited by inhibitory NK cell receptors and acts to prevent NK activation (Stebbins et al., 2003). Several other signaling proteins, including WASP, Cdc42, Ras, Rap1, CrkL, and HS1, have been implicated in signaling for adhesion.

### Natural Killer Cell Lytic Granule Polarization and Maturation

Besides adhesion, LFA-1 has a key role in promoting perforin-containing granule polarization toward the target cell, facilitating efficient cytotoxicity (Barber et al., 2004; Bryceson et al., 2005). Moreover, such granule polarization toward the immune synapse is the result of two different molecular processes. First, granules rapidly converge in dynein-dependent, minus-end directed motion to the microtubule-organizing center (MTOC) (Mentlik et al., 2010). In the NK cell line YTS, antibody-mediated blockade of LFA-1 impairs granule convergence at the MTOC upon target-cell contact, suggesting that LFA-1-mediated signals facilitate this process (Mentlik et al., 2010). Second, following convergence of the granules and within minutes, the MTOC and granules polarize toward the interaction site in an LFA-1-dependent manner (Bryceson et al., 2005; Mentlik et al., 2010). In regards to the signaling pathways involved in LFA-1-mediated polarization, several key proteins have been identified. Talin, binding to the cytoplasmic tail of LFA-1, is required for the recruitment of WASP, Arp2/3, vinculin, and actin (Mace et al., 2009, 2010). Furthermore, WASP is required for the accumulation of F-actin at the synapse. Moreover, silencing of WASP interacting protein (WIP) in the human NK cell line YTS impaired lytic granule polarization but had no effect on the formation of conjugates with target cells (Krzewski et al., 2008). The second messenger, diacylglycerol, was required for MTOC polarization and cytotoxicity by CTL (Quann et al., 2009); however, the extent to which diacylglycerol regulates LFA-1-mediated MTOC polarization in NK cells remains to be established. Recent evidence indicated that signaling for granule polarization by LFA-1 in IL-2-expanded human NK cells also involved CD3 $\zeta$ -chain phosphorylation, SYK recruitment and activation, and PLC- $\gamma$  activation (March and Long 2011). Activation of PLC- $\gamma$  resulted in hydrolysis of phosphatidylinositol (4,5)-bisphosphate (PIP2) to generate the second messengers, diacylglycerol and inositol (1,4,5)-trisphosphate (IP3). Downstream of LFA-1, PLC- $\gamma$  activation led to PKC activation, and pharmacological inhibition of PLC- $\gamma$  abrogated granule polarization (March and Long 2011). Upon recognition of susceptible target cells, the tyrosine kinase PYK2 was also recruited to the immune synapse, and transfection of dominant negative PYK2 blocked MTOC and paxillin movement to the synapse (Sancho et al., 2000). In summary, a number of studies suggest pathways involving talin, WASP, WIP, PYK, JNK, and paxillin, as well as CD3 $\zeta$ , SYK, and PLC- $\gamma$  for granule polarization.

### Natural Killer Cell Cytolytic Granule Exocytosis

Vesicle exocytosis is a requirement for NK cell cytotoxicity (Bryceson et al., 2006b). Studies of knockout mice have demonstrated an essential role for PLC- $\gamma$  in granule exocytosis (Tassi et al., 2005; Caraux et al., 2006). Following the activation of PLC- $\gamma$ , IP3 can trigger cytoplasmic release of Ca<sup>2+</sup> from the endoplasmic reticulum (ER). Engagement of CD16 is sufficient to induce robust intracellular Ca<sup>2+</sup> mobilization, whereas several other receptors do not. Rather, coactivation receptors trigger intracellular Ca<sup>2+</sup> mobilization when engaged in specific pair-wise combinations (Bryceson et al., 2006b). Additional data suggest that the molecular basis for such coactivation involves complementary phosphorylation of SLP-76 as well as overcoming a threshold for activation of VAV1 that is set by the ubiquitin ligase c-Cbl (Kim et al., 2010). PLC- $\gamma$  activation leads to IP3-mediated Ca<sup>2+</sup> release from the ER, which ultimately results in depletion of intracellular Ca<sup>2+</sup> stores and induction of store-operated Ca<sup>2+</sup> entry (SOCE). NK cells from patients with mutations in either STIM1 or ORAI1 display defective degranulation, demonstrating a requirement for ORAI1 channel-mediated SOCE for lytic granule exocytosis (Maul-Pavicic et al., 2011). Notably, the ORAI1 deficiency does not affect signals for adhesion or granule

polarization (Maul-Pavicic et al., 2011). Further downstream, several proteins required for NK cell exocytosis have been identified through studies of patients with hyperinflammatory syndromes caused by defective lymphocyte cytotoxicity. These proteins include Rab27a that facilitates terminal trafficking of lytic granules to sites of exocytosis, Munc13-4 that primes lytic granule exocytosis, as well as syntaxin-11 and Munc18-2 that facilitate membrane fusion (Stinchcombe et al., 2001; Feldmann et al., 2003; Bryceson et al., 2007; Wood et al., 2011). Furthermore, results suggest that distinct endosomal compartments fuse prior to lytic granule fusion with the plasma membrane, facilitating the exocytic process (Menager et al., 2007; Wood et al., 2009). Finally, for efficient cytotoxicity, lytic granules must traverse the actin-rich immunological synapse to enable exocytosis. The adenosine triphosphate-dependent actin motor protein myosin IIA has been shown to associate with lytic granules in NK cells and play a role in mediating lytic granule traversal for exocytosis (Sanborn et al., 2009).

## Natural Killer Cell Chemokine and Cytokine Production

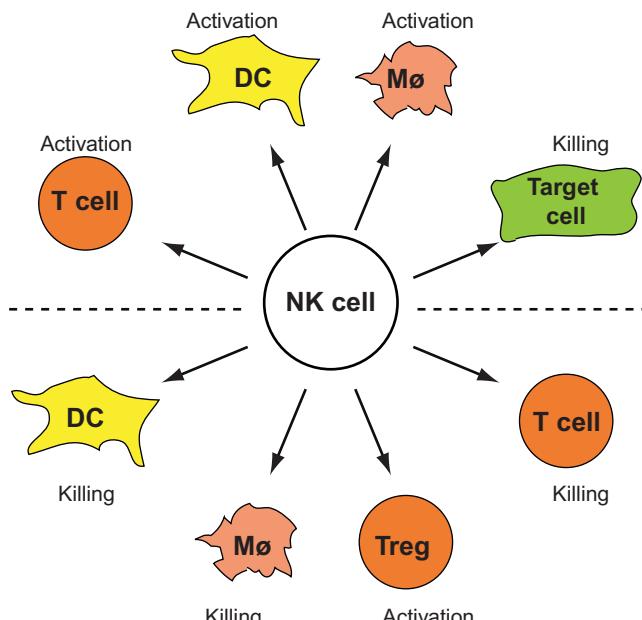

Target-cell recognition by freshly isolated human NK cells induces a set of chemokines, including CCL3, CCL4, CCL5, as well as the cytokines TNF- $\alpha$  and IFN- $\gamma$  (Fauriat et al., 2010). Chemokines are induced within 1 hour of stimulation, whereas secretion occurs several hours after activation. Importantly, experiments varying the signaling input for NK cell activation have revealed a hierarchy in requirements for the induction of chemokines and cytokines, with chemokines induced by weakly activating signals, degranulation induced by intermediate levels of activating stimuli, and cytokines requiring the strongest activation. This hierarchy is reflected in the requirements for induction of different effector responses. PLC- $\gamma$  is required for all responses (Tassi et al., 2005; Caraux et al., 2006). A deficiency in SOCE, as seen in NK cells from humans with autosomal recessive STIM1 and ORAI1 mutations, results in defective degranulation and cytokine production induced upon target-cell recognition but only partially impairs chemokine production (Maul-Pavicic et al., 2011). Notably, NK cells from PI3K p110 $\delta$ -deficient mice displayed selectively impaired cytokine production, whereas knockout of both p110 $\delta$  and p110 $\gamma$  was required to impair cytotoxicity (Kim et al., 2007; Tassi et al., 2007). Moreover, PKC $\theta$ -deficient mice had defects in IFN- $\gamma$  transcription and secretion due to impaired JNK, AP-1, and NFAT activation (Tassi et al., 2008). Yet, NK cell-mediated cytotoxicity was not impaired in PKC $\theta$ -deficient mice. Curiously, a Rap1b deficiency in mice selectively deters NK cell chemokine and cytokine production, but not cytotoxicity (Awasthi et al., 2010). Thus a few proteins, including PI3K p110 $\delta$  and PKC $\theta$ , may be specifically required for transcription of cytokine genes. Further studies are required to understand how these proteins are integrated in the signaling pathways for NK cell activation and how the engagement of different activating receptor controls their function.

## NATURAL KILLER CELLS AND HUMAN AUTOIMMUNITY

Classically, autoimmune diseases typify syndromes caused by an inappropriate activation of cells of the adaptive immune system, that is, T cells and B cells, resulting in cell-specific, organ-specific, or systemic tissue damage. Typical examples of such diseases include multiple sclerosis, rheumatoid arthritis, and insulin-dependent type 1 diabetes. Autoimmune diseases often display sexual bias. In this respect, several studies indicate somewhat higher NK cell numbers and activity in men than in women, but these differences often do not reach statistical significance with studies of relatively small sample sizes. Autoimmune diseases have been thought to be initiated in steps, including release of self-antigens from the target organ, a priming step in secondary lymphoid organs, and finally immune cell homing to the target organ/tissue and subsequent tissue destruction (Ji et al., 1999). NK cells can likely act at all these steps, that is, as mediators of initial target damage leading to release of self-antigens, at the level of T-cell priming in secondary lymphoid organs, and at the level of the target organ as immunomodulatory or effector cells (Pazmany, 2005; Shi and van Kaer, 2006; Perricone et al., 2008; Flodström-Tullberg et al., 2009) (Fig. 12.1).

Most research results pointing toward a role for NK cells in human autoimmune diseases are, obviously, correlative. Associations between NK cell activity and autoimmune conditions appear in several reports, including those describing studies finding altered numbers, phenotypes, and functions of NK cells (Shi and van Kaer, 2006; Pazmany, 2005; Perricone et al., 2008; Flodström-Tullberg et al., 2009). Some older studies are, however, difficult to interpret since they fail to distinguish NK cells from regulatory NKT cells or T cells expressing NK cell-associated receptors. An additional problem is determining if abnormalities in NK cell populations are a cause and/or an effect of a given disease state. Finally, most studies rely on assessment of NK cells from

### Promotion of autoimmune disease

### Protection from autoimmune disease

**FIGURE 12.1** NK cells may affect autoimmune diseases in many different ways, for example by promoting or preventing functions of other cells, or by killing them. The figure illustrates possible interactions between NK cells and other cells as well as their outcomes. NK, Natural killer. Source: Figure modified from Flodström-Tullberg, M., Bryceson, Y.T., Shi, F.D., Höglund, P.H., Ljunggren, H.G., 2009. Natural killer cells in human autoimmunity. *Curr. Opin. Immunol.* 21, 634–640.

peripheral blood, not from appropriate secondary lymphoid organs or affected tissues. Despite these shortcomings a substantial amount of evidence supports a direct involvement of NK cells in human autoimmunity.

### Defective Control of other Immune Cells Links Natural Killer Cells to Autoimmune Diseases

The impaired NK cell cytotoxic function frequently observed in some humans with autoimmune diseases and/or other inflammatory conditions highlights the role of NK cells in controlling other cells, for example, macrophages. Macrophage activation syndrome (MAS) is associated with several rheumatic diseases, most commonly with systemic juvenile idiopathic arthritis (sjIA) ([Villanueva et al., 2005](#); [Kelly and Ramanan, 2007](#)) (Chapter 37: The Autoimmune Myopathies). Clinically, this syndrome closely resembles familial hemophagocytic lymphohistiocytosis (FHL), a life-threatening genetic disorder in which NK cell function is absent or depressed ([Bryceson and Ljunggren, 2007](#); [Wood et al., 2011](#)). As in FHL, patients with MAS have profoundly decreased NK cell cytotoxic activity ([Ravelli et al., 2012](#)). Therefore impaired NK cell cytotoxicity might be, at least in part, causative of MAS. Supporting this notion, an sjIA patient with low NK cell cytotoxic function was found to harbor compound heterozygous splice-site and missense mutations in UNC13D, a gene associated with FHL ([Hazen et al., 2008](#)). Another link between NK cells and macrophages comes from studies showing that CD56<sup>bright</sup> NK cells accumulate in certain inflammatory lesions and, in the appropriate cytokine environment, can engage with monocytes in a reciprocal activation fashion, thereby amplifying the inflammatory response. Moreover, CD56<sup>bright</sup> NK cells can trigger the differentiation of monocytes into DCs ([Zhang et al., 2007](#)). Such positive feedback loops could well promote the pathogenesis of chronic inflammatory conditions such as rheumatoid arthritis ([Dalbeth et al., 2004](#)). Moreover, naturally occurring mutations in genes that cause a defect in NK cells are found in patients with abnormalities in TAP-peptide transporters, who typically suffer from chronic infections in childhood and autoimmune manifestations later in life. Notably, although interactions with macrophages are particularly relevant to organ-specific autoimmunity, NK cells also modulate innate and adaptive immunity by interacting with many other cell types, for example, other lymphocytes including effector

and regulatory T cells (Carnaud et al., 1999; Assarsson et al., 2004; Ferlazzo et al., 2004a,b; Martin-Fontecha et al., 2004; Ghiringhelli et al., 2006; Shanker et al., 2007).

A specific point at which NK cells cytotoxicity can act to modify immune responses is through killing of activated T cells. Interestingly, upon cytomegalovirus infection in mice, NK cells can kill activated CD4<sup>+</sup> T cells, thereby affecting CD8<sup>+</sup> T-cell function and exhaustion (Waggoner et al., 2011). In a mouse model of arthritis, blockade of the NK cell receptor NKG2A facilitated NK cell elimination of pathogenic CD4<sup>+</sup> T cells, arresting disease progression (Leavenworth et al., 2011). Such NK cell–mediated modulation of immune responses may well have implications for human autoimmunity. Moreover, NK cells may limit responses through modes other than cellular cytotoxicity. In studies of lupus, at least in vitro, NK cells can potentiate IFN- $\alpha$  production by plasmacytoid DC by up to a thousand-fold. IFN- $\alpha$  is a key cytokine involved in driving the pathogenesis of the disease (Eloranta et al., 2009). The NK cell–mediated enhancement of IFN- $\alpha$  production by plasmacytoid DC is contact dependent and partially relies on secretion of the chemokine CCL4 (MIP-1 $\beta$ ) by NK cells (Hagberg et al., 2011). Thus NK cell immunoregulatory interactions may also exacerbate autoimmune responses.

Although less is known in contexts of autoimmunity, roles for NK cells as inducers of organ-specific and systemic tissue damage have also recently been suggested in certain acute and chronic viral infections. For instance, during flares of chronic hepatitis B virus infection, NK cells have been implicated to mediate liver damage via the apoptosis-inducing molecule TRAIL (Dunn et al., 2007). During acute human hantavirus infection, a hemorrhagic fever-inducing virus infection with high mortality, NK cells are highly activated and damage arises to the vasculature system long after the virus has been cleared from the body (Björkström et al., 2011).

## Genetic Association Studies Revealing Links Between Natural Killer Cells and Autoimmune Diseases

Linkage analysis in several autoimmune disease conditions has implicated various NK cell receptors in pathogenesis (Kulkarni et al., 2008). For example, certain *KIR* receptor genes, the products of which are expressed on NK cells and some T-cell subsets, have been associated with the development of autoimmune diseases. *KIR* genes are polymorphic and the *KIR* gene complex is polygenic, encoding varying numbers of inhibitory and activating receptors. Interactions of the independently segregating *KIR* and HLA loci are important for NK cell education/licensing and target-cell recognition (Jonsson and Yokoyama, 2009). The existence of *KIR*–HLA genotypes that tune NK cells toward activation are favorable in some infectious diseases but might also predispose to autoimmunity (Kulkarni et al., 2008). A number of associations predisposing to autoimmune diseases have been identified in which activating *KIR* or *KIR*/HLA genotypes are accompanied by lack of inhibition. For example, scleroderma, a disease of tissue fibrosis, inflammation, and vascular injury, has been linked to the presence of activating *KIR2DS2*, in the absence of a corresponding inhibitory *KIR2DL2* (Momot et al., 2004). Likewise, the risk of psoriatic arthritis is enhanced in patients carrying *KIR2DS1* and/or *KIR2DS2*, and this effect is augmented in the absence of ligands for the inhibitory *KIR2DL1* and *KIR2DL2/3*, respectively (Nelson et al., 2004). Similarly, for rheumatoid arthritis, increased risk is associated with a presence of the *KIR2DS2* gene (Yen et al., 2001). Type 1 diabetes is associated with the expression of *KIR2DS2* HLA ligand pairs in an environment of weak inhibitory interactions (van der Slik et al., 2003, 2007). In primary sclerosing cholangitis, a claimed autoimmune liver disease characterized by progressive destruction of the biliary tract, homozygosity for HLA-C1, a ligand for *KIR2DL3*, is associated with increased susceptibility for disease (Karlsen et al., 2007; Hov et al., 2010). Finally, ankylosing spondylitis shows a strong relationship to HLA-B27, a ligand for *KIR3DL2*; NK cells from patients with this disease have predominant *KIR3DL2* expression and show an activated phenotype as measured by CD38 expression (Chan et al., 2005). Thus the interplay between human NK cell inhibitory and activating receptor-MHC class I ligand pairs has provided significant evidence with respect to the involvement of NK cells in human autoimmunity. Noteworthy, however, the function of *KIR* may in some instances also be exerted at the level of autoimmune T cells, for example, through augmentation of low-affinity activation signals (Björkström et al., 2012).

In addition to receptors that bind MHC class I molecules, a number of other receptors that bind stress-induced ligands or regulate interactions with other immune cells may dictate NK cell specificity. Inappropriate expression of activating receptor NKG2D ligands can lead to detrimental NK cell activation, which, in turn, may trigger or exacerbate autoimmunity. The best characterized NKG2D ligands are the MICA/B cellular stress-induced molecules that act as danger signals to alert NK cells and CD8T lymphocytes (Bauer et al., 1999). Acquisition of MICA/B ligands on the surfaces of potential target cells may cause the breakdown of tolerance. MICA/B molecules, when inappropriately expressed, may thus trigger or worsen an autoimmune response. The involvement

of NKG2D and its ligands in autoimmunity was first revealed in patients with rheumatoid arthritis (Groh et al., 2003). It has also been demonstrated that MICA/B are overexpressed on gut epithelium during active celiac disease (Hüe et al., 2004). However, in situations of MICA/B upregulation, these molecules may be targets not only for NK cells but also for T cells, as demonstrated in several studies (Meresse et al., 2004). Polymorphisms of human MICA have been associated with a variety of autoimmune disorders. One such example is patients with primary sclerosing cholangitis in whom several studies have identified the *MICA\*008* allele in association with increased disease susceptibility (Norris et al., 2001; Wiencke et al., 2001). The functional implications of such polymorphism are, however, far from clear, and *MICA* associations frequently reflect a linkage disequilibrium with *HLA-B* alleles (Field et al., 2008). Still to be established is whether mutations in the NKG2D gene (*KLRK1*) might underlie some autoimmune diseases. Recently, however, a single-nucleotide polymorphism (SNP) in *CD226*, conferring an amino acid substitution in the DNAM-1 receptor, was linked to the development of multiple sclerosis, rheumatoid arthritis, type 1 diabetes, and autoimmune thyroid disease (Hafler et al., 2009). In addition, two intronic SNPs in *CD244*, that likely increase 2B4 receptor surface expression, have been connected with the development of rheumatoid arthritis in a Japanese cohort (Suzuki et al., 2008). However, in a mouse model of lupus, *Cd244*-deficiency exacerbated autoantibody production in an NK cell-independent manner (Brown et al., 2011). Together, these data implicate activating NK cell receptors in susceptibility to multiple autoimmune diseases. We should note, however, that despite the often-used term “NK cell receptors,” these receptors are also expressed on other lymphocyte populations, and it remains to be established to what degree genetic associations are conferred by alterations specifically in NK cell function.

## CONCLUSIONS

With the exception of genetic linkage analysis, relatively few studies have been undertaken to explore the role of NK cells in human autoimmunity compared to other diseases where NK cells are more directly implicated. Much knowledge on the role of NK cells in autoimmunity still comes from studies in experimental animal models, and caution must be taken before translating those results directly to human conditions. The emerging view, however, is that NK cells may function as important regulatory cells during the priming phase of adaptive immune responses and as regulatory and effector cells at the sites of target organ during inflammation. NK cell control of macrophage activation may be one important checkpoint at the level of the target organ in the development of autoimmunity. The ability of NK cells to influence adaptive immune responses and to control immune cell homeostasis in humans clearly deserves further attention. Improved comprehension of how NK cells affect numerous autoimmune conditions may furthermore pave the way for new immunotherapeutic approaches toward alleviating or preventing such diseases.

## NEUTROPHILS

### Basic Biological Principles and Role in Immunity

Neutrophils, the most copious circulating white blood cells, are short lived, terminally differentiated cells that emanate from the bone marrow to target pathogens (Amulic et al., 2012; Kolaczkowska and Kubes, 2013). They attack pathogens using different mechanisms including phagocytosis, degranulation, and release of granular antimicrobial peptides such as neutrophil elastase (NE), myeloperoxidase (MPO), and matrix metalloproteinases (MMPs), and degradation through the synthesis of reactive oxygen species (ROS) within phagolysosomes (Gupta and Kaplan, 2016). When they meet a microorganism, neutrophils undergo a respiratory burst, a vital phenomenon in host defense, with activation of the complex nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and subsequent synthesis of superoxide (Kobayashi and DeLeo, 2009). Superoxide and its ensuing products, hypochlorous acid and hydrogen peroxide, have key antimicrobial roles (Kobayashi and DeLeo, 2009). Mitochondria (Fossati et al., 2003) and peroxisomes (Fransen et al., 2012) are other important sources of ROS in neutrophils.

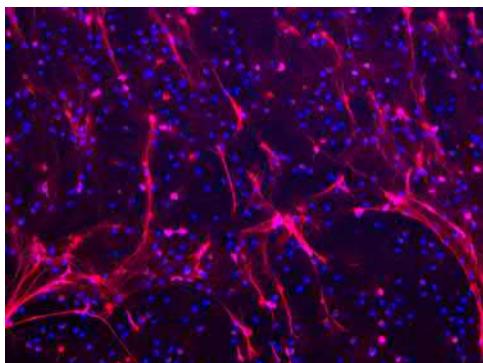

Besides their central role in the innate immune response, neutrophils regulate the adaptive immune response (Mantovani et al., 2011). In lymphoid organs, neutrophils engage with B and T cells and antigen-presenting cells (Scapini et al., 2008; Huard et al., 2008; Tvinnereim et al., 2004; Fazio et al., 2014; Megiovanni et al., 2006; Yang et al., 2010). The uptake of apoptotic neutrophils by dendritic cells (DCs) may increase dendritic antigen presentation (Megiovanni et al., 2006; Yang et al., 2010). Neutrophils can stimulate and inhibit T-cell responses and synthesize cytokines essential for B-cell development including, among others, the B-cell activating factor (BAFF) (Scapini et al., 2008) and the proliferation-inducing ligand A proliferation-inducing ligand (APRIL) (a molecule intimately related to BAFF) (Huard et al., 2008). In the spleen, neutrophils can act as B-cell helpers on a T-cell independent basis (Puga et al., 2011).

## Neutrophils and Neutrophil Extracellular Traps

A different form of defense used by neutrophils is the extrusion of a network of chromatin coated with proteases, histones, and cytosolic proteins in a process called neutrophil extracellular trap (NET) formation (Brinkmann et al., 2004; Jorch and Kubes, 2017; Kenny et al., 2017). NETs were discovered in 1996 as a form of cell death different from apoptosis or necrosis (Takei et al., 1996), and NETosis defines the process of NET production and release by neutrophils (Jorch and Kubes, 2017). This process plays an important role in the innate immune response by allowing neutrophils to immobilize and capture viruses, bacteria, or fungi (Gupta and Kaplan, 2016; Jorch and Kubes, 2017). NETs are induced by many microorganisms, by different autoantibodies, cytokines, and immune complexes (ICs), and, *in vitro*, by phorbol 12-myristate 13-acetate (PMA) or calcium ionophores (Fig. 13.1) (Lood et al., 2016). Although the molecular mechanisms leading to NETosis are not completely characterized, histone citrullination and ROS production appear to be essential (Brinkmann et al., 2004; Wang et al., 2009).

The term “NETosis” was first used to indicate neutrophils’ death as they discharged NETs. However, microorganism-derived stimulation of neutrophils can in some cases cause a fast and vital form of NETosis, where neutrophils can still accomplish their phagocytic role after producing NETs (Jorch and Kubes, 2017). The type of NETosis (i.e., inducing vital NETosis or resulting in cell death) seems largely determined by the type of stimulus. Suicidal NETosis is induced by diverse stimuli, such as autoantibodies or PMA, and occurs within hours of stimulation. In suicidal NETosis, production of ROS and activation of protein-arginine deiminase 4 (PAD4) occur through NADPH oxidase activation and results in chromatin decondensation, translocation of MPO and NE into the nucleus to boost additional chromatin unfolding, and nuclear membrane disruption. After chromatin is released into the cytosol, it becomes decorated with cytosolic and granular proteins and, eventually, disruption of the plasma membrane leads to NET release and neutrophil death (Jorch and Kubes, 2017; Yipp and Kubes, 2013). By contrast, vital NETosis is induced within minutes by *Staphylococcus aureus* through both Toll-like receptor (TLR) 2 (TLR2) ligands and complement receptors, or by *Escherichia coli* via TLR4 or TLR4-activated platelets. The subsequent activation of PAD4 leads to chromatin decondensation. As in suicidal NETosis, NE is translocated into the nucleus to boost further chromatin unfolding and nuclear membrane disruption. However, protein-decorated chromatin is discharged through vesicles, and the neutrophil remains alive for other functions such as phagocytosis (Jorch and Kubes, 2017; Pilsczek et al., 2010; Yipp et al., 2012).

Besides infection, NET-associated proteins may have a role in other diseases, including, but not restricted to, autoimmune diseases (Jorch and Kubes, 2017; Thieblemont et al., 2016). Several autoantibodies can promote NET

**FIGURE 13.1** Neutrophil extracellular traps. Human control neutrophils underwent NET formation upon stimulation with lipopolysaccharide. Visualization of NETs by staining of nuclear material (4',6-diamidino-2-phenylindole, blue) and neutrophil elastase (green). Original magnification,  $\times 40$ . NET, Neutrophil extracellular trap. Source: Modified from Kaplan, M.J., 2013. Role of neutrophils in systemic autoimmune diseases. *Arthritis Res. Ther.* 15 (5), 219. Licensed under the Creative Commons Attribution License (CC BY). Copyright: Kaplan M.J.

release and molecules exteriorized through NETosis [e.g., MPO and double-stranded DNA (dsDNA)] are known autoantigens in systemic autoimmune diseases. Neutrophils from subjects with some autoimmune diseases are more likely than those from healthy controls or subjects without autoimmune diseases to undergo NETosis. The association between NETosis and autoantibodies may promote a cycle by which autoantigen release by NETs results in autoantibody formation, which, in turn, boosts the release of antigens (Gupta and Kaplan, 2016).

## Neutrophils in Systemic Autoimmune Diseases: Pathogenic Role

### ***Systemic Lupus Erythematosus***

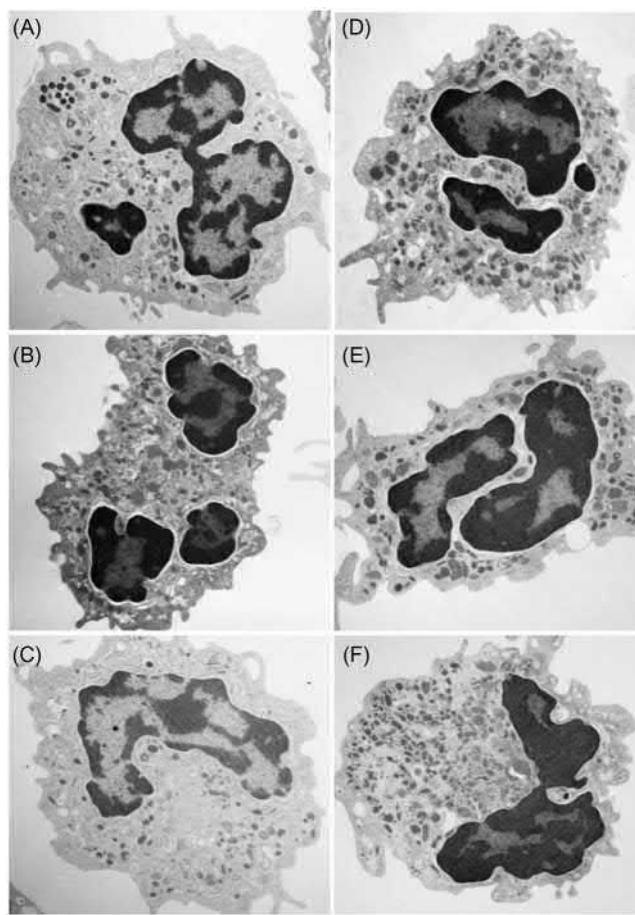

#### DYSREGULATED NEUTROPHIL PHENOTYPE AND FUNCTION AND PROINFLAMMATORY ROLE OF NEUTROPHIL PROTEASES IN SYSTEMIC LUPUS ERYTHEMATOSUS

Besides a dysregulation of B and T cells, neutrophils from patients with systemic lupus erythematosus (SLE) display various abnormalities in their phenotype and function such as a defective phagocytic ability (Brandt and Hedberg, 1969; Cairns et al., 2001), failure to be cleared by the apoptotic pathway mediated by C1q/calreticulin and CD91 (Donnelly et al., 2006), increased aggregation (Denny et al., 2010; Abramson et al., 1983), abnormal oxidative activity, increased numbers of circulating low-density granulocytes (LDGs), and an increased apoptosis that may result in neutropenia [which is observed in 20%–40% of SLE patients (Carli et al., 2015)] (Denny et al., 2010; Abramson et al., 1983; Courtney et al., 1999; Bennett et al., 2003).

The reduced expression of L-selectin (or CD62L) and C5a receptor and the normal expression of CD11B (or integrin  $\alpha$ -M) (Furebring et al., 2002; Bengtsson et al., 2014) in neutrophils from SLE patients indicates an altered rather than activated phenotype (Thieblemont et al., 2016). LDGs deserve a special consideration. These cells are a subgroup of pathogenic granulocytes that synthesize more cytokines with proinflammatory properties [e.g., type I interferons (IFNs)] than regular-density granulocytes and are toxic to endothelial cells (ECs) (Gupta and Kaplan, 2016; Denny et al., 2010; Villanueva et al., 2011). This subset of granulocytes has an activated phenotype and, though their nuclear morphology is similar to that of immature cells, they express surface markers of mature cells (Fig. 13.2) (Denny et al., 2010; Bennett et al., 2003; Kaplan, 2011). Studies have shown that circulating levels of LDGs in SLE correlate with levels of dsDNA antibodies and disease activity scores (Midgley and Beresford, 2016). Sera from SLE patients exhibit increased concentrations of defensins released by LDGs and/or neutrophils (Sthoeger et al., 2009; Vordenbäumen et al., 2010) and messenger RNA for several bactericidal proteins and alarmins [e.g., cathepsin G (CTSG), NE, and proteinase 3 (PR3)] are significantly overexpressed in LDGs from SLE patients compared with regular-density granulocytes from SLE patients and from healthy controls (Villanueva et al., 2011; Lyons et al., 2010; Kim et al., 2014).

The process that leads to autoimmunity in SLE may involve an increase in apoptotic neutrophils (which have a greater expression of autoantigens) and their impaired elimination by phagocytes (Potter et al., 2003). Autoimmunity pathogenesis also involves a decrease in ROS production by granulocytes, which has been associated with the severity of disease (Bengtsson et al., 2014). The lower production of ROS is accompanied by a lower number of circulating neutrophils with absent CD10 and reduced CD16 expression (CD10 $^-$ /CD16 $^{\text{low}}$ ) newly released from the bone marrow (Bengtsson et al., 2014). Neutrophil depletion in SLE leads to spontaneous activation of autoimmune B cells and natural killer cells *in vivo* (Huang et al., 2015a).

Chronic activation of plasmacytoid DCs (pDCs) by circulating ICs and the subsequent secretion of type I IFNs is recognized as an initial trigger of autoimmunity in SLE (Thieblemont et al., 2016). Animal models suggest that the production of tumor necrosis factor (TNF) damages selectively erythroid precursors via TLR7-driven neutrophil activation, causing the anemia frequently seen in SLE patients (Zhuang et al., 2014; Papadaki et al., 2002; Santiago-Raber et al., 2003). Immune cells, including myeloid cells, stimulate ribonucleoprotein (RNP)-containing ICs, which requires activation of both TLR and Fc receptors (FcRs) (Lau et al., 2005; Clynes et al., 1998). TLRs including TLR2, 4, 5, 7, 8, and 9 are implicated in the pathogenesis of SLE (Geering et al., 2013; Wu et al., 2015b), with TLR7 being essential for the recognition of RNP-associated autoantigens, and TLR9 being involved in DNA or RNA-associated autoantigen detection. Subsets of human neutrophil express all the members of the TLR family, except for TLR3, allowing them to start immune responses after recognition of endogenous or exogenous ligands (Geering et al., 2013; Huebener et al., 2015). The pathogenesis of SLE also comprises the release of high mobility group box 1 protein which, after binding DNA and anti-DNA autoantibodies through its receptor for advanced glycation endproducts, may prompt the recruitment of neutrophils, contributing to kidney damage in anti-DNA autoantibody-induced lupus nephritis (Thieblemont et al., 2016).

**FIGURE 13.2** Morphology of a low-density granulocyte under transmission electron microscopy in a patient with systemic lupus erythematosus. (A–C) show a normal-density granulocyte and (D–F) display a low-density granulocyte with different types of cytoplasmic granules. Dark (heterochromatic) and lighter (euchromatic) areas are well defined in both types of granulocytes. Whereas the normal-density granulocyte has nuclear lobes, there are less lobulated nuclei in the low-density granulocyte. Source: Permission to reproduce this figure was obtained from Springer-Verlag [Carmona-Rivera, C., Kaplan, M.J., 2013. *Semin. Immunopathol.* 35 (4), 455–463].

#### SYSTEMIC LUPUS ERYTHEMATOSUS AND NETOSIS

It has been suggested that NETs and NET-associated proteins may be potential inducers of autoantibody production in SLE (Jorch and Kubes, 2017), including anti-RNP and anti-DNA antibodies (Gupta and Kaplan, 2016). In vitro studies with type I IFN-primed neutrophils from SLE patients have shown that RNP-containing ICs, commonly present in lupus, can induce NETosis (Garcia-Romo et al., 2011). Moreover, LDGs display an enhanced spontaneous NETosis ex vivo (Villanueva et al., 2011). In contrast to their regular density or healthy counterparts, LDGs from SLE patients have an enhanced capability to produce NETs at baseline in vitro that remains unaffected in the presence of the NET inducer PMA, suggesting that LDGs might be extremely stimulated in vivo (Gupta and Kaplan, 2016; Villanueva et al., 2011). In contrast to NETs generated by neutrophils from healthy controls, NETs from SLE patients have greater levels of autoantigens and immunostimulatory molecules such as dsDNA, LL-37 (a cathelicidin antibacterial peptide that is a key mediator of pDC activation), and MMP-9 (Garcia-Romo et al., 2011; Lande et al., 2011; Leffler et al., 2012; Carmona-Rivera et al., 2015).

NETs are not appropriately removed from the circulation in a significant number of SLE patients because of the oxidation of nucleic acids externalized by NETs, complement activation within NETs (Lood et al., 2016; Leffler et al., 2012; Gehrke et al., 2013), and the existence of DNase 1 inhibitors or of anti-NET antibodies, which hinder the DNase 1 access to NETs (Hakkim et al., 2010).

The autoimmune response in patients with SLE can be further triggered by NETs exposing cathelicidin–DNA complexes, which enhance the synthesis of type I IFNs by pDCs via endosomal TLR activation (Garcia-Romo et al., 2011; Lande et al., 2011). Type I IFNs in myeloid cells can be stimulated by oxidized nucleic acids in NETs

through the activation of the stimulator of IFN genes (STING) pathway (Lood et al., 2016). In lipopolysaccharide-primed macrophages, cathelicidin can stimulate the nucleotide-binding domain leucine-rich repeat-containing receptor P3 (NLRP3) inflammasome via interaction with the purinergic receptor X7 (P2X7) and stimulation of potassium efflux, leading to interleukin (IL)-1 and IL-18 release. In turn, IL-1 and IL-18 promote NETosis, thus amplifying the inflammatory pathways at tissue and organ sites (Kahlenberg et al., 2013).

It is of note that mitochondria are a source of ROS and mitochondrial DNA participates in inflammatory responses (White et al., 2014; Oka et al., 2012; Shimada et al., 2012). NETs produced by LDGs are enriched in oxidized mitochondrial DNA and mitochondrial ROS can prompt NETosis upon RNP-containing ICs stimulation both in vitro and in LDGs in SLE subjects ex vivo (Lood et al., 2016). NETs might also contribute to the occurrence of early cardiovascular disease in patients with SLE (Barnado et al., 2016). Neutrophils and NETs in SLE can enhance the apoptosis of ECs in vitro (Villanueva et al., 2011), and SLE patients exhibit a dysfunction and an accelerated apoptosis of ECs (Rajagopalan et al., 2004) that leads to a loss of nitric oxide release, impaired vasodilation, and potentiation of atherosclerosis and thrombotic events (Rajagopalan et al., 2004; Smith et al., 2014).

### ***Antineutrophil Cytoplasmic Autoantibody-Associated Vasculitides***

#### **NEUTROPHIL-INDUCED VASCULITIC ORGAN DAMAGE**

The antineutrophil cytoplasmic autoantibody (ANCA)-associated vasculitides (AAVs) are characterized by a necrotizing inflammation of small vessels and comprise three clinical entities: (1) microscopic polyangiitis, (2) granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis), and (3) eosinophilic granulomatosis with polyangiitis (EGPA) (formerly known as Churg–Strauss syndrome). The vascular lesions differ depending on the size of affected vessels, their localization, and the pathogenic mechanism involved (Thieblemont et al., 2016).

The neutrophil enzymes MPO and PR3 are the main autoantigens recognized by ANCAs. MPO is solely found in neutrophil azurophilic granules and has the exclusive property to produce chlorinated oxidants including chloramines and hypochlorous acid (Nauseef, 2007), the latter exerting toxic effects on microorganisms and host cells. Proteinase 3 is expressed by both neutrophils and monocytes and is localized in the neutrophil azurophilic granules along with its neutrophil serine protease family homologs NE, CTSG, and azurocidin (Campanelli et al., 1990). Upon phagocytosis of microorganisms, PR3 carries out its microbial function after being secreted into the phagolysosome. Animal models have revealed that PR3, NE, and CTSG have proinflammatory activities (Pham, 2006). Both MPO and PR3 share proinflammatory properties and can modulate the inflammatory process acting on a synergistic basis (Witko-Sarsat et al., 2000).

Several in vitro and in vivo studies have shown that ANCA can be pathogenic. In short, priming of neutrophils causes their accumulation at the inflammatory sites in medium- and small-sized vessels and capillaries (mainly pulmonary and glomerular). Membrane expression of MPO and PR3 is enhanced by such priming and both enzymes can bind ANCA to prompt the activation of neutrophils. TNF-primed neutrophils incubated with sera containing anti-MPO or anti-PR3 ANCAs can release granular proteins and produce superoxide anion (Jennette and Falk, 2014; Falk et al., 1990). The pathophysiological mechanisms sustaining the antigenic specificity of AAV (Csernok et al., 2006) have been described in genome-wide association studies (Lyons et al., 2012).

#### **NEUTROPHIL EXTRACELLULAR TRAPS AND ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY-ASSOCIATED VASCULITIDES**

The formation of NETs comprising DNA ejected by dying neutrophils and granule-derived cationic proteins, including MPO and PR3, could participate in the pathophysiology of AAV (Kessenbrock et al., 2009). Neutrophils from AAV patients have an enhanced ability to generate NETs in vitro (Kessenbrock et al., 2009; Tang et al., 2015). Serum levels of NET remnants, such as MPO–DNA complexes (Kessenbrock et al., 2009), are increased in AAV patients and correlate positively with AAV disease activity and neutrophil count and inversely with ANCA levels (Söderberg et al., 2015). NETs and NET-associated molecules have been detected in areas of fibrinoid necrosis and in the arterial walls of renal biopsies from AAV patients with necrotizing glomerulonephritis (Kessenbrock et al., 2009; Yoshida et al., 2013). NETs can present MPO and PR3 to DCs (Sangaletti et al., 2012), which then incorporate NET material and induce ANCAs against MPO, PR3, and dsDNA when transferred to mice, leading to autoimmune vasculitis. Serum from AAV patients can induce NETosis and inhibit NET degradation (Nakazawa et al., 2014). By using whole blood from AAV patients, Grayson et al. (2015) observed a gene expression signature which overlapped with an LDG signature formerly detected in SLE patients (Villanueva et al., 2011). Increased transcripts for PR3 identified in circulating mononuclear cells from AAV patients were

associated with higher disease activity scores and a lack of therapeutic response (Grayson et al., 2015). Furthermore, neutrophils and LDGs from patients underwent an increased spontaneous NETosis in culture, with NETs staining positive for MPO and PR3 (Grayson et al., 2015).

Finally, it is well known that thrombosis is a relatively frequent consequence of ANCA-associated blood vessel inflammation (Rao et al., 2015) and that increased NET formation may cause thrombus formation [i.e., histones within NETs can bind platelets and blood coagulants (Xu et al., 2009; Fuchs et al., 2010)]. Thus the role of NETs in thrombosis in AAV patients might have clinical significance (von Scheven et al., 2003). A study in patients with acute myocardial infarction demonstrated an interaction of neutrophils with thrombin-activated platelets at the plaque rupture site, with local NETosis and activation of tissue factor, a protein that triggers coagulation and thrombin formation and that is expressed in leukocytes and the endothelium (Stakos et al., 2015). Activated tissue factor has also been detected in patients with AAV (Kambas et al., 2014). Specifically, ANCA-induced NETs produced by C5a-primed neutrophils cause enhanced inflammation and thrombosis in AAV by promoting the expression of tissue factor (Kambas et al., 2014; Huang et al., 2015b).

### **Rheumatoid Arthritis**

#### **PROINFLAMMATORY EFFECTS OF NEUTROPHIL PROTEASES AND REACTIVE OXYGEN SPECIES IN RHEUMATOID ARTHRITIS**

Rheumatoid arthritis is characterized by a dysregulation of innate and adaptive immune responses, with an increased production of inflammatory cytokines (including IL-1, 6, and 17, TNF- $\alpha$ , and granulocyte/macrophage-colony stimulating factor) and a defective tolerance to self-antigens, most notably citrullinated peptides (Wright et al., 2014; McInnes et al., 2016; Burmester et al., 2014; McInnes and Schett, 2011). The inflammatory pannus characteristic of rheumatoid arthritis contains activated synovial fibroblasts, lymphocytes, macrophages, and neutrophils (Thieblemont et al., 2016).

Circulating neutrophils of patients with rheumatoid arthritis have an activated phenotype, with an abnormal regulation of apoptosis (Wright et al., 2011; Weinmann et al., 2007), activation of transcription factors (Wright et al., 2011; Turrel-Davin et al., 2010), increased chemotactic and phagocytic ability (Talbot et al., 2015; de Siqueira et al., 2015), and FcRs upregulation, which leads to ROS production by ICs (including rheumatoid factor) (Rollet-Labelle et al., 2013; Watson et al., 1993; Quayle et al., 1997). In addition, synovial neutrophils release collagen-degrading proteases, cytotoxic ROS, cytokines, and chemokines (Wright et al., 2014). ICs at the synovial fluid induce degranulation and release of ROS into it (Robinson et al., 1992), and activated neutrophils adhere to synovial tissue ICs, leading to a direct degranulation onto the joint surface (Wright et al., 2014; Pilling and Abramson, 1995). Synovial fluid from patients with rheumatoid arthritis contains high levels of NE, PR3, CTSG as well as neutrophil MMP-8 and MMP-9, lipocalin, and gelatinase (Wright et al., 2014; Sopata et al., 1995; Wong et al., 2009; Momohara et al., 1997; Nzeusseu Toukap et al., 2014; Katano et al., 2009). These neutrophil proteases can split collagen within its matrix and digest hyaluronic acid (Pham, 2006; Van den Steen et al., 2002; Lefrançais et al., 2012; Hurst et al., 2001).

#### **NEUTROPHIL EXTRACELLULAR TRAPS AND NETOSIS IN RHEUMATOID ARTHRITIS**

NETs and suicidal NETosis may participate in the pathogenesis of rheumatoid arthritis (Jorch and Kubes, 2017). Neutrophils from patients with rheumatoid arthritis generate more NETs and higher levels of ROS than those from healthy subjects (Jorch and Kubes, 2017).

Citrullinated autoantigens are crucial autoantigens in rheumatoid arthritis (Khandpur et al., 2013). The presence of extracellular citrullinated autoantigens in the joints of rheumatoid arthritis patients (van Beers et al., 2013) may be explained by an increased NETosis and, indeed, NETs are a source of extracellular citrullinated autoantigens (van Beers et al., 2013), which can trigger inflammatory responses in synovial fibroblasts of affected patients, with release of proinflammatory cytokines, adhesion molecules, and chemokines (Khandpur et al., 2013; Pratesi et al., 2014).

NETs have been detected in rheumatoid nodules, synovial tissue, and skin of patients with rheumatoid arthritis. A significant correlation has also been observed between the proportion of circulating netting neutrophils and serum levels of autoantibodies to citrullinated protein antigen (ACPA) (i.e., highly specific autoantibodies targeting citrullinated proteins), erythrocyte sedimentation rate, C-reactive protein, and IL-17 (Khandpur et al., 2013). Markedly, autoantibodies including ACPA and inflammatory cytokines (e.g., IL-17 and TNF- $\alpha$ ) can induce NETosis in patients with rheumatoid arthritis (Khandpur et al., 2013).

### **Primary Sjögren Syndrome**

A few research studies have shed light on the potential implication of neutrophils in the etiopathogenesis of primary Sjögren syndrome. Autoantibodies to the La/SSB complex (anti-SSB antibodies) are frequently detected in patients with this disease (van Venrooij et al., 1991). These antibodies appear in up to 87% of patients with Sjögren's syndrome and are commonly associated with extraglandular manifestations such as purpura, vasculitis, neurological involvement, leucopenia, and lymphopenia (Hsieh et al., 2003).

The La or Sjögren syndrome antigen B (La/SSB) is an RNP reported to be involved in RNA biogenesis, maturation of RNA polymerase III transcripts, translation of viral and cellular messenger RNAs, and to influence telomere homeostasis (Wu et al., 2015a). Hsieh et al. (2003) reported that La/SSB is expressed in the surface membrane and nucleus of human neutrophils and that anti-SSB antibody concomitantly increases the synthesis of IL-8 and the apoptosis of neutrophils, with release of La/SSB after cell death.

In a study aimed to investigate the effect of La/SSB on human neutrophils, Wu et al. (2015a) reported that human La/SSB together with SSB-anti-SSB ICs induces IL-8 production from normal neutrophils, suggesting that this antigen might act as an endogenous dangerous molecule to enhance the expression of the IL-8 gene in human neutrophils.

Other reported data pointing at a possible role of neutrophils in the pathogenesis of primary Sjögren syndrome include (1) neutrophils are activated in this disorder (Torsteinsdóttir et al., 1998), (2) neutropenia is observed in one-third of cases and is strongly associated with anti-SSB antibodies (Brito-Zerón et al., 2009), and (3) the expression of La/SSB may be upregulated in inflamed tissues such as the labial salivary glands (van Woerkom et al., 2004).

### **Systemic Sclerosis**

Barnes et al. (2011) reported that serum from patients with systemic sclerosis can induce in vitro an activation and apoptosis of ECs, in a process dependent on the presence of neutrophils and mediated by IL-6. By studying the ROS generation ex vivo of neutrophils from patients with systemic sclerosis compared with neutrophils from control subjects, Barnes et al. (2012) subsequently reported that neutrophils from systemic sclerosis patients can be primed for ROS production. Since endothelial dysfunction appears to be fundamental in the pathogenesis of systemic sclerosis (Fleming and Schwartz, 2008), the authors suggested that binding of neutrophils to activated endothelium may induce local generation of ROS, sustaining endothelial dysfunction and facilitating fibrosis in systemic sclerosis (Barnes et al., 2012).

In a modified murine model that mimicked human systemic sclerosis with skin lesions and lung fibrosis, Liang et al. (2015) detected the presence of neutrophils in the skin of the murine model but not in the skin of control mice. Also, an enhanced expression of chemokine (C-X-C motif) ligand 2 (CXCL2), which is chemotactic for neutrophils, was observed in the skin lesions of mice with systemic sclerosis both at initial and later stages, suggesting that neutrophils could play a role in the progression of the disease (Liang et al., 2015).

### **Antiphospholipid Antibody Syndrome**

Patients with antiphospholipid antibody syndrome have autoantibodies against phospholipids and surface proteins (Barnado et al., 2016). Antiphospholipid and anti-β2-glycoprotein I (β2GPI) antibodies may promote thrombosis by activating ECs, platelets, and monocytes (Gupta and Kaplan, 2016). While NETs can activate the coagulation cascade and are important components of venous and arterial thrombi (Gupta and Kaplan, 2016; Fuchs et al., 2010; Massberg et al., 2010; Brill et al., 2012), neutrophils and NETosis have recently been implicated in the pathogenesis of antiphospholipid antibody syndrome. Specifically, the antiphospholipid antibody syndrome autoantigen β2GPI can stimulate NETosis in vitro when interacting with neutrophils through a ROS- and TLR4 signaling-dependent process (Yalavarthi et al., 2015). A positive correlation has also been observed between serum levels of anti-β2GPI antibodies and circulating levels of NETs (Yalavarthi et al., 2015).

Like SLE, sera of patients with antiphospholipid antibody syndrome have a decreased capacity to degrade NETs and this defect seems to correlate with the presence of higher concentrations of antibodies against both NETs and neutrophil remnants (Leffler et al., 2014). Likewise, as in SLE, serum and plasma from patients with antiphospholipid antibody syndrome have increased levels of NET remnants and cell-free DNA. Neutrophils from these patients can also produce spontaneous NETs ex vivo (Yalavarthi et al., 2015), and their sera and IgG are able to stimulate NET release from neutrophils of control individuals (Yalavarthi et al., 2015).

### **Polymyositis and Dermatomyositis**

A study by Lu et al. (2017) showed that, compared with healthy subjects, patients with early polymyositis and dermatomyositis had an increased LL-37 expression localized to neutrophils in muscle tissue samples. Neutrophils in the skin of symptomatic and nonsymptomatic patients with myositis also expressed LL-37, suggesting that unaffected skin of patients with both polymyositis and dermatomyositis contained an increased proportion of neutrophils with LL-37 expression. Moreover, compared with skin samples of the same patients or with muscle tissue samples of healthy controls, muscle tissue samples of patients with early polymyositis and dermatomyositis had a higher proportion of LL-37-positive cells (Lu et al., 2017). Interestingly, LL-37 muscular expression correlated with serum creatine phosphokinase levels, suggesting that, upon stimulation, LL-37-positive neutrophils could trigger inflammation, with subsequent necrosis of muscle fibers (Lu et al., 2017).

In another study in patients with polymyositis and dermatomyositis with and without interstitial lung disease, Zhang et al. reported that the DNase I activity and NET degradation were reduced in both groups of patients. However, those with interstitial lung disease displayed the lowest NET degradation in vitro as a result of a significant decrease in DNase I activity (Zhang et al., 2014). Besides, compared with healthy individuals, patients with polymyositis and dermatomyositis had a markedly higher capacity for inducing NETs, as supported by the presence of raised concentrations of plasma LL-37 and circulating cell-free DNA in them (Zhang et al., 2014).

### **Neutrophils in Systemic Autoimmune Diseases: Therapeutic Implications**

Undeniably, NETs are a promising therapeutic target in SLE and possibly other autoimmune disorders. As mentioned above, NETs release ROS as a defense against microorganisms. Treatment of neutrophils with ROS scavengers, specifically N-acetyl cysteine, blocks NET formation and ROS release in vitro (Patel et al., 2010). Two small studies reported an improved outcome of patients with SLE treated with ROS scavengers (Garcia et al., 2013; Lai et al., 2012). However, the production of ROS does not inhibit vital NETosis, which might lead to further autoimmune development (Jorch and Kubes, 2017). Treatment with the specific scavenger MitoTEMPO for mitochondrial ROS production in vivo in a mouse model of lupus reduced type I IFN responses and disease severity with reduced spontaneous NETosis by neutrophils from the bone marrow (Lood et al., 2016). An endogenous NET inhibitor that does not suppress the production of ROS (signal inhibitory receptor on leukocytes-1) was recently shown to block the release of NETs from neutrophils upon stimulation with plasma from SLE patients (Van Avondt et al., 2013).

Inhibition of PAD4, which suppresses NETosis without affecting the oxidative burst, represents another promising therapy for inhibiting NETosis (Jorch and Kubes, 2017; Barnado et al., 2016). Although the most frequently used NET inhibitor is DNase, it does not suppress NET production but rather dismantles its structure (Jorch and Kubes, 2017). Clinical studies have shown that DNase therapy has no toxicity. In mouse models of lupus, the administration of DNase led to disrupted NETs and decreased disease severity (Macanovic et al., 1996). Whereas DNase1 can dismantle DNA and is an important degrader of NETs, it has a trivial effect on elastase, histones, and other components with the potential to attach to vessel walls, thus causing ongoing inflammation (Kolaczkowska et al., 2015).

Both IL-17 and TNF induce NETosis in neutrophils from patients with rheumatoid arthritis. The administration of specific antibodies that block these cytokines can lead to less NETosis and an improved clinical progression (Khandpur et al., 2013). However, since it is not known whether it is a NETosis-specific mechanism, similar findings might be observed with the inhibition of other proinflammatory mediators (Jorch and Kubes, 2017). Last, MPO may participate in NET production, and an MPO inhibitor (PF1355) was reported to reduce vasculitis in mouse models (Zheng et al., 2015).

## **BASOPHILS**

### **Basic Biological Principles and Role in Immunity**

Basophils represent less than 1% of circulating leukocytes and are an important source of IL-4, pointing at their potential role in T helper (Th) 2 (Th2)-type immune responses including antiparasitic immunity and allergy (Karasuyama and Yamanishi, 2014; Karasuyama et al., 2011). Basophils can also be central immunomodulatory cells in other disorders, particularly in autoimmune diseases (Dijkstra and Meyer-Bahlburg, 2017; Denzel et al., 2008; Rodriguez Gomez et al., 2010).

Basophils modulate B-cell differentiation into antibody-producing plasma cells and produce numerous mediators after activation or during degranulation. In addition to IL-4, these mediators include leukotrienes, other ILs (3, 6, 8, and 13), vascular endothelial growth factor, histamine, heparin, and macrophage inflammatory protein (MIP)-1 $\alpha$  (MIP-1 $\alpha$ ) (Dahinden et al., 1989; Schroeder et al., 2009; Jeon et al., 2015; Clark et al., 1976; Li et al., 1996a,b; de Paulis et al., 2006). Basophils express in their surface different markers that stimulate neighboring cells such as CD40L, CD62L, OX40L (a ligand for CD134), and the receptor activator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF- $\kappa$ B) ligand (Gauchat et al., 1993; Charles et al., 2010; Di et al., 2015; Poli et al., 2015). Basophils can respond to several mediators because of their expression of receptors for TLR ligands, cytokines (Komiya et al., 2006; Suurmond et al., 2014), thymic stromal lymphopoietin (Giacomin et al., 2012), IgE (Fc $\epsilon$ RI  $\alpha$ ) (Ishizaka and Ishizaka, 1977), and IgG (Fc $\gamma$ RIIa/IIb) (Cassard et al., 2012), thus easing antigen-specific basophil responses. Therefore basophils are well resourced to react to an extensive variety of signals, and to modulate the functions of other cells, especially B cells (Mack et al., 2005). Importantly, the hematopoiesis of basophils seems to be influenced by serum IgE concentrations (Hill et al., 2012) and, in fact, increased IgE concentrations correlate with increased numbers of circulating basophils in both humans and mice (Hill et al., 2012; Cahenzli et al., 2013).

## Basophils and IgE Antibodies in Autoimmune Diseases: Pathogenic Role

### ***Basophils and IgE Antibodies in Systemic Lupus Erythematosus***

The potential pathogenic relevance of basophils in autoimmune diseases is mainly attributable to their influence on Th2 polarization by producing IL-13, IL-4, and thymic stromal lymphopoietin, and to their effects on B-cell activation, differentiation, survival, and promotion of autoantibody production through IL-4, IL-6, and BAFF (Sharma and Bayry, 2015).

A breakthrough in the pathogenic role of basophils in SLE came in 2010 when Rivera et al. (Charles et al., 2010) demonstrated that basophils promote lupus nephritis in mice in an IgE- and IL-4-dependent manner. In particular, Rivera's team showed that ICs along with IgE antibodies with specificity for dsDNA and nuclear components activated basophils in *Lyn*<sup>-/-</sup> mice, triggering their homing to lymphoid organs (Charles et al., 2010). The tyrosine protein kinase Lyn regulates negatively B-cell functions, and mice lacking Lyn (*Lyn*<sup>-/-</sup> mice) develop a late lupus-like nephritis with glomerular deposition of ICs consisting of IgA, IgG, IgM, and C3. Rivera et al. demonstrated that IL-4 and BAFF produced by activated basophils promoted the polarization of Th2 cells, with B-cell activation and differentiation and eventual antibody production. Also, while patients with active SLE had increased titers of autoreactive IgE and activated circulating basophils, *in vivo* reduction of basophils led to a substantial improvement of the autoimmune and pathological signatures (Charles et al., 2010).

Despite the new findings, however, an inherent weakness in the *Lyn*<sup>-/-</sup> model of lupus nephritis is that these mice display early atopy-like allergic inflammation (Sharma and Bayry, 2015). To distinguish allergic inflammation from autoimmune inflammatory, Rivera et al. further investigated the effect of the IgE–basophil network on lupus pathogenesis. The investigators used two different strains of mice deficient for the inhibitory IgG Fc receptor Fc $\gamma$ RIIb, namely, *Fc $\gamma$ RIIb*<sup>-/-</sup> mice and *Fc $\gamma$ RIIb*<sup>-/-</sup>. *Yaa* mice [i.e., mice with a chromosomal translocation of the *Y-linked autoimmune acceleration locus* (*Yaa*)], and demonstrated that IgE creates an inflammatory environment by providing signals for innate immune cells' migration to secondary lymphoid organs (Dema et al., 2014). Specifically, both strains of mice developed a lupus-like disease, though with a more aggressive disease phenotype with raised levels of dsDNA-specific IgE and accelerated development of organ pathology in *Fc $\gamma$ RIIb*<sup>-/-</sup>. *Yaa* mice. In a further experiment, *Fc $\gamma$ RIIb*<sup>-/-</sup>. *Yaa* mice with IgE deficiency had a delayed onset of disease, a significant reduction in the number of B and plasma cells, and a reduced autoantibody production compared with their IgE-generating counterparts. A reduced amount of DCs, neutrophils, monocytes, and eosinophils was also observed in the secondary lymphoid organs of IgE-deficient mice, indicating that these innate cells expressed the  $\alpha$ -subunit of the IgE receptor, Fc $\epsilon$ RI (Dema et al., 2014).

More recently, Henault et al. (2016) reported that IgE can trigger IFN production, intensifying the self-destructive autoimmune responses. The researchers found that IgE antibodies specific for dsDNA activate pDCs in human SLE, resulting in the secretion of considerable amounts of IFN- $\alpha$ . In addition, serum levels of dsDNA-specific IgE correlated with the severity of disease and potentiated the functions of pDC by triggering phagocytosis through Fc $\epsilon$ RI with subsequent TLR9-mediated DNA sensing in phagosomes (Henault et al., 2016).

### **Basophils and IgE Antibodies in Bullous Pemphigoid**

The etiopathogenesis of bullous pemphigoid (BP), the most frequent pemphigoid disease (around 80% of cases), involves the activation of mast cells in the skin in an IgE autoantibody-mediated process (Sanjuan et al., 2016). The best studied autoantigen in BP is the hemidesmosomal protein BP180. Autoantibodies of the IgE class specific for BP180 have been reported in up to 90% of patients with this skin disease (Dimson et al., 2003; Messingham et al., 2014). Basophils from patients with BP, but not from healthy subjects, can undergo a degranulation in vitro on a BP180-induced cross-linking (Dimson et al., 2003). Fairley et al. (2007) demonstrated that, compared with injection of IgE from control subjects, injection of IgE purified from patients with BP into human skin grafted onto athymic nude mice produced the lesions that are typically observed in the early phase of human BP (i.e., urticarial plaques with dermal edema, eosinophilic inflammation, and mast cell activation and degranulation). Altogether, these findings suggest a pathogenic role of IgE autoantibodies in patients with BP through an Fc $\epsilon$ RI-induced degranulation of basophils and mast cells.

### **IgE Antibodies in Other Autoimmune Disorders**

Although several studies have reported the occurrence of increased levels of IgE autoantibodies (and total IgE) in patients with other autoimmune conditions (Table 13.1), their potential pathogenic significance has not been established.

### **Basophils and IgE Antibodies in Autoimmune Diseases: Therapeutic Implications**

The strongest evidence of the pathogenic implication of IgE autoantibodies in autoimmune diseases came from clinical trials investigating the effectiveness of omalizumab in patients with bullous pemphigous (Sanjuan et al., 2016). Administration of omalizumab, an anti-IgE monoclonal antibody that prevents the interaction of IgE with Fc $\epsilon$ RI, led to reduced urticarial plaques, decreased itching, and a reduction in eosinophilic inflammation (Fairley et al., 2009; Yu et al., 2014). Notably, improvement was achieved in spite of high concentrations of IgG autoantibodies with similar autoantigen specificity, which suggests that low concentrations of IgE autoantibodies can be enough to contribute to the disease process, almost certainly as a consequence of their interaction with Fc $\epsilon$ RI.

Based on the high prevalence of IgE autoantibodies in patients with SLE and the outstanding research by Rivera et al. (Charles et al., 2010; Dema et al., 2014) and Henault et al. (2016), these autoantibodies may well be involved in SLE autoimmunity. In this respect, an ongoing trial is investigating the effectiveness of omalizumab in SLE patients (NCT01716312) (Sanjuan et al., 2016).

Despite the biological differences between human and mouse basophils and the different pathways involved in the activation of basophils, the role of these cells in the etiopathogenesis of autoimmune disorders means that the investigation and development of therapies to target basophils should be actively pursued. The design of targeting therapies should consider the nature of the stimuli (cytokines, antibodies, and TLRs) that prompt basophil activation (Sharma and Bayry, 2015).

**TABLE 13.1** Autoimmune Diseases With Increased Levels of IgE Autoantibodies and Total IgE

Anti-IgE autoantibodies in systemic sclerosis (Kaufman et al., 1989)

Anti-SSA IgE autoantibodies in mothers with fetal loss (Sekigawa et al., 2008)

IgE autoantibodies against retinal S antigen in uveitis (Muiño et al., 1999)

Granulocyte- and organ-specific antinuclear IgE autoantibodies in rheumatoid arthritis (Permin and Wiik, 1978)

IgE reactive with myelin-derived peptides in multiple sclerosis (Mikol et al., 2006)

IgE autoantibodies against thyroid peroxidase in Hashimoto thyroiditis and Graves' disease (Guo et al., 1997; Sato et al., 1999)

IgE autoantibodies against dsDNA (Ishizaka and Ishizaka, 1977; Chang et al., 2015) and thyroglobulin and thyroperoxidase (Chang et al., 2015; Concha et al., 2004; Altrichter et al., 2008) in chronic idiopathic urticaria<sup>a</sup>

<sup>a</sup>Although chronic idiopathic urticaria is not considered a characteristic autoimmune disease, there is conclusive evidence for autoimmunity in some patients. dsDNA, Double-stranded DNA; SSA, Sjögren's-syndrome-related antigen A.

Modified from Sanjuan, M.A., Sagar, D., Kolbeck, R., 2016. Role of IgE in autoimmunity. *J. Allergy Clin. Immunol.* 137 (6), 1651–1661.

## EOSINOPHILS

### Basic Biological Principles and Role in Immunity

Eosinophils are multifunctional granulocytes with granular proteins including eosinophil cationic protein, major basic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin. Eosinophils degranulate upon activation by exocytosis or by piecemeal degranulation with secretion of individual granule contents without disruption of the cell membrane (Khoury et al., 2014). In healthy subjects, over 90% of eosinophils reside in tissues, mostly in the gastrointestinal tract, lymph nodes, spleen, thymus, uterus, and mammary glands. However, in disease conditions, eosinophils can move along chemokine gradients to inflammation sites. Migration of mature eosinophils into circulation is mainly regulated by IL-5 (Khoury et al., 2014), with eosinophils being the main source of this IL. Of note, IL-5 plays a central role in their proliferation and maturation of eosinophil progenitors in the bone marrow, their migration across ECs at tissue sites, and the prevention of eosinophil apoptosis (Khoury et al., 2014; Varricchi et al., 2016; Broughton et al., 2015; Shahabuddin et al., 2000; Ochiai et al., 1997).

Several mediators are involved in directing circulating eosinophils to bind with integrins and selectins with subsequent migration into tissues. These mediators comprise the eotaxins [including eotaxin-1 or chemokine (C-C motif) ligand 11 (CCL11), eotaxin-2 or CCL24, and eotaxin-3 or CCL26], CCL5 (or RANTES), CCL28, and other factors such as the platelet activating factor and C5a (Hogan et al., 2008; Moqbel and Lacy, 2000; Walsh, 2001). Different inhibitory receptors regulate the survival and activation of eosinophils including the sialic acid-binding Ig-like lectin 8 (SIGLEC8), killer activating receptors, CD300A, Fc $\gamma$ RIIb, and potassium inwardly rectifying channel (Varricchi et al., 2016a).

Eosinophils have different functions including the production of numerous cytokines, growth factors, and chemokines that mediate allergic inflammation as well as thrombosis and fibrosis (Khoury et al., 2014). Besides expressing class II molecules of the major histocompatibility complex and costimulatory molecules such as CD80 or CD86 proteins, eosinophils stimulate T cells and process antigens (Varricchi et al., 2016a). Eosinophils prime B cells and promote the activation of DCs through CpG DNA and eosinophil-derived neurotoxin (Munitz et al., 2006). Following allergen sensitization, eosinophils regulate, together with DCs, the recruitment of Th2 cells by producing CCL22 and CCL17 (Munitz et al., 2006). Eosinophils can also promote the differentiation of T follicular helper cells via IL-6 production (Varricchi et al., 2016b).

### Eosinophils in Autoimmune Diseases: Pathogenic Role

#### ***Eosinophils in Eosinophilic Granulomatosis With Polyangiitis***

EGPA is characterized by three overlapping clinical stages that evolve at different intervals: (1) asthma, (2) tissue and blood eosinophilia, and (3) necrotizing small-vessel vasculitis with eosinophilic granulomas (Khoury et al., 2014; Churg and Strauss, 1951; Lanham et al., 1984). The pathogenic implication of eosinophils in EGPA remains to be fully explained. However, there is evidence showing that eosinophils are implicated in all three stages.

Eosinophils are likely implicated in the initial EGPA stage. The presence in sputum of increased numbers of eosinophils and increased levels of eosinophil granule proteins are characteristic of the first EGPA stage (Nair et al., 2013). Likewise, eosinophils are present in the second EGPA stage, characterized by blood and tissue eosinophilia. The typical pathologic finding of the third EGPA stage, with eosinophilic tissue infiltration, eosinophilic vasculitis, and granulomas with a central area of eosinophilic necrosis surrounded by multinucleated giant cells and palisading histiocytes, reflects the major role of eosinophils in this disease (Lie, 1990; Katzenstein, 2000).

Although ANCAAs can be detected in 30%–40% of patients with EGPA (Sablé-Fourtassou et al., 2005; Sinico et al., 2005), there are no reported data indicating that these autoantibodies are pathogenic in this disease.

The etiopathogenesis of EGPA is mainly inferred from clinical studies. On account of the initial allergic inflammation presentation and the increase in circulating levels of Th2-type cytokines that promote the recruitment, activation, and delayed apoptosis of eosinophils (Kiene et al., 2001; Jakiela et al., 2012), EGPA has been classically regarded as a Th2-mediated disease (Khoury et al., 2014).

The chemokine CCL17 (or thymus and activation-regulated chemokine) recruits Th2 cells and is associated with active EGPA (Khoury et al., 2012). Eosinophils in EGPA also produce IL-25, which enhances the production of Th2-type cytokines (Khoury et al., 2014; Varricchi et al., 2016a). Serum levels of IL-25 in EGPA correlate with disease activity and with levels of eosinophils (Terrier et al., 2010), suggesting that interactions between the

innate and adaptive immune systems may contribute to EGPA pathogenesis. It is of note that IL-5 seems to be upregulated in active EGPA (Varricchi et al., 2016a; Jakielka et al., 2012). There are other cytokines and chemokines produced by eosinophils and by other cell types that may be involved in EGPA pathogenesis (Table 13.2).

Some authors have proposed that serum concentrations of different cytokines, chemokines, and surface receptors that participate in the activation and recruitment of eosinophils should be used as biomarkers of disease activity in EGPA (Khoury et al., 2014). For instance, serum levels of eotaxin-3, an eotactic chemokine produced by endothelial and epithelial cells which may contribute to the tissue influx of eosinophils (Zwerina et al., 2011), correlate with eosinophil and total IgE levels in patients with EGPA but not with those in subjects with other eosinophilic conditions and vasculitis (Polzer et al., 2008).

### **Eosinophils in Other Vasculitis**

Eosinophilia, both peripheral and at tissue sites, has been reported in other AAV, specifically in granulomatosis with polyangiitis, albeit at mild or moderate levels (Potter et al., 1999; Schnabel et al., 2000). Patients with Kawasaki disease have been reported to have mild peripheral eosinophilia with substantial eosinophilic infiltrates in the epicardial microvasculature (Terai et al., 2002). Peripheral and tissue eosinophilia can be a prominent feature in drug-induced vasculitis (Mullick et al., 1979). However, there is no reported evidence about the role of eosinophils in the etiopathogenesis of these diseases.

### **Eosinophils in Eosinophilic Granulomatosis With Polyangiitis: Therapeutic Implications**

Treatments that modulate the production, survival, or recruitment of eosinophils might be effective in EGPA. For example, corticosteroids, which are the therapeutic cornerstone of EGPA, decrease the number of circulating and tissue eosinophils by promoting cell death and clearance (Fulkerson and Rothenberg, 2013). As mentioned, the eosinophil-specific cytokine IL-5 has crucial roles in the differentiation, maturation, migration, and survival of eosinophils (Gupta and Kaplan, 2016) and appears to be upregulated in active EGPA (Jakielka et al., 2012). Several agents currently used for the treatment of EGPA can reduce the levels of IL-5 [e.g., corticosteroids (Druilhe et al., 2003) and rituximab (Pepper et al., 2008)] (Khoury et al., 2014; Varricchi et al., 2016a). Preliminary data from two studies using mepolizumab, a humanized anti-IL-5 antibody, as a remission maintenance treatment in patients with EGPA indicate that it is safe agent that enables corticosteroid tapering, even though the lung function remains unmodified (Kim et al., 2010; Herrmann et al., 2012). Moreover, a pilot study in EGPA

IL-5 (Jakielka et al., 2012)

IL-25 (Terrier et al., 2010)

sIL-2R (Khoury et al., 2012; Schmitt et al., 1998)<sup>a</sup>

IL-4 (Kiene et al., 2001)<sup>b</sup>

IL-13 (Kiene et al., 2001)<sup>b</sup>

<sup>a</sup>Cytokine receptor.

<sup>b</sup>Th2-type cytokines.

CCL11, (C-C motif) ligand 11; IL, interleukin; sIL-2R, soluble IL-2 receptor.

Modified from Khoury, P., Grayson, P.C., Klion, A.D., 2014. Eosinophils in vasculitis: characteristics and roles in pathogenesis. *Nat. Rev. Rheumatol.* 10 (8), 474–483.

patients showed that omalizumab, a recombinant humanized anti-IgE monoclonal antibody, had corticosteroid-sparing properties and caused a decrease in the number of circulating eosinophils and an improved lung function (Detoraki et al., 2016).

## CONCLUSIONS

The potential role of granulocytes in the pathogenesis of systemic autoimmune diseases is being actively investigated. The altered phenotype and function of neutrophils in SLE, illustrated by an abnormal oxidative activity, an increased apoptosis with an impaired elimination of apoptotic cells, and an increased number of circulating LDGs which are toxic to ECs, could be partly responsible for the etiopathogenesis of this disease. Research studies with neutrophils and LDGs from SLE patients have also shown that NETs, which are not properly cleared from the circulation in these patients, and enhanced NETosis can exacerbate the autoimmune responses with eventual organ damage. As such, the potential of therapies targeting NETs in SLE and possibly other autoimmune disorders is enormous. The relevance of neutrophils in the pathophysiology of AAV has been extensively investigated over the last 25 years. More recent evidence indicates that NETs composed of DNA expelled by dying neutrophils and granule-derived proteins, including the autoantigens MPO and PR3, could contribute to the pathogenesis of AAV. Of note, neutrophils and LDGs from patients with AAV can undergo an increased spontaneous NETosis and serum from these patients can induce NETosis and inhibit the degradation of NETs. Both circulating and synovial neutrophils of patients with rheumatoid arthritis play an active pathogenic role through the production of cytotoxic ROS and collagen-degrading proteases. Like SLE and AAV, NETs and NETosis seem to be implicated in the etiopathogenesis of rheumatoid arthritis. Remarkably, NETs in rheumatoid arthritis are a source of extracellular citrullinated autoantigens, which can trigger inflammatory responses in synovial fibroblasts, with release of proinflammatory cytokines and chemokines. Neutrophils and NETosis have been involved in the pathogenesis of antiphospholipid antibody syndrome. When interacting with neutrophils *in vitro*, the autoantigen  $\beta$ 2GPI can stimulate NETosis through a TLR4- and ROS-signaling-dependent process. Also, while neutrophils from patients with antiphospholipid antibody syndrome can produce spontaneous NETs *ex vivo*, serum levels of anti- $\beta$ 2GPI antibodies correlate positively with circulating levels of NETs. A few studies have investigated the role of neutrophils in other autoimmune diseases including primary Sjögren syndrome, systemic sclerosis, and polymyositis/dermatomyositis. However, their potential pathogenic relevance is less conclusive.

Regarding basophils, in addition to their role in allergy and antiparasitic immunity, they have a key immunomodulatory role in some autoimmune diseases due to their influence on Th2 polarization and their effects on B-cell activation, differentiation, survival, and promotion of autoantibody production. Studies have shown a close correlation between increased numbers of circulating basophils and increased serum levels of IgE. The pathogenic potential of these cells in SLE has mainly been investigated in murine models, where basophils not only promote lupus nephritis in an IgE- and IL-4-dependent manner but the IgE–basophil network creates an inflammatory environment by delivering effective signals for the migration of innate immune cells to secondary lymphoid organs. Basophils and IgE also play an active role in the pathophysiology of BP. Indeed, there is a need to design specific therapies to target basophils.

Finally, the involvement of eosinophils in the etiopathogenesis of EGPA remains to be clarified. There is some evidence that eosinophils participate in the three stages of EGPA and that chemokines and cytokines produced by eosinophils, and by many other cell types, may contribute to its pathogenesis. Importantly, IL-5 plays a fundamental role in the production, recruitment, and survival of eosinophils and seems to be upregulated in active EGPA. Consequently, therapies aimed to decrease the levels of IL-5, especially anti-IL-5 antibodies, are being actively investigated with promising preliminary results.

<b>Control of Complement Activation</b>	266		
Fluid Phase Regulators	266		

## THE COMPLEMENT SYSTEM AND COMPLEMENT ACTIVATION PATHWAYS

In the 1890s Jules Bordet observed that bactericidal activity of serum essentially requires two components, one which is present prior to immunization and heat-labile that he named Alexin (from Greek *alexein*: to ward off) and the other component, which is heat-stable and generated by immunization. He demonstrated in 1898 that the same basic mechanisms that compose the bacteriolytic activity of immune sera are responsible for the hemolytic activity of serum toward erythrocytes of other species, a methodology that was used to analyze the biological activities of complement for decades to come. The prevailing name “complement” for this bacteriolytic plasma component was coined by Paul Ehrlich at about the same time to underline that this component was essential for “amboceptors” (the name he proposed for antibodies) to lyse cells and thereby “complement” their function (Dunkelberger and Song, 2010; Schmalstieg and Goldman, 2010). Up to the present day, the bactericidal (or hemolytic) activity of complement mediated through the formation of a lytic membrane attack complex (MAC) (formed following the activation of the terminal complement components C5b–C9) is still the most widely known biological activity of the complement system.

Complement is composed of a very complex system of zymogen precursor components, their substrates, fluid phase or cell surface resident regulators/cofactors, and receptors for complement activation products comprising altogether more than 40 components (Whaley and Schwaeble, 1997; Carroll and Sim, 2011). Cell surface resident receptors for complement activation products continuously sense the activation state of the

complement system and coordinate cellular responses of both the innate and the adaptive immune system. As such, complement activation is involved in the initiation and maintenance of numerous inflammatory reactions and inappropriate control of complement activation can predispose to a wide spectrum of infectious or inflammatory pathologies.

Although the bactericidal or hemolytic activity of complement elicited through the formation of MACs is the most popular and widely known function of complement, it is only effective against some bacterial species, while complement-mediated opsonization which targets bacteria, viruses, yeast, host cellular and bacterial debris and eukaryotic parasites for phagocytosis and elimination through the various phagocytes of the reticulo-endothelial system (via their receptors either for C3b, iC3b, C3d, C4b, or C1q/MBL/ficolins). The cellular receptors on phagocytes responsible for the enhanced uptake of opsonized particles and cells include complement receptors type 1 (CR1 also known as CD35), type 3 (CR3, alias of CD11b/CD18), and type 4 (CR4 CD11c/CD18) (Wagner and Frank, 2010). Phagocytes are directed to the location of complement activation by chemotaxis sensing the release of the potent complement chemotactic factor and anaphylatoxin C5a and the anaphylatoxin C3a, through the receptors C3aR and C5aR (alias CD88) (Van Beek et al., 2003; Wallis, 2007). Complement anaphylatoxins C3a and C5a can also increase vascular permeability aiding the transmigration and extravasation of leukocytes into tissue (Williams, 1983). Various complement deficiencies result in a defective recruitment of leukocytes to the site of damage or infection.

Complement activation products also facilitate transport of antigens to the lymphoid follicles and critical interactions between follicular dendritic cells and B cells in order to promote both B-cell memory and the production of specific antibodies (Barrington et al., 2002; Le Fric and Kemper, 2009; Gonzalez et al., 2010). Moreover, complement activation also modulates T-cell responses by coordinating the necessary interactions between antigen-presenting cells and T cells (Zhou et al., 2006; Le Fric and Kemper, 2009; Kwan et al., 2012). The complement system is activated via three activation pathways which all converge through the formation of C3 and C5 convertase complexes and the subsequent formation of the MAC.

## The Classical Pathway

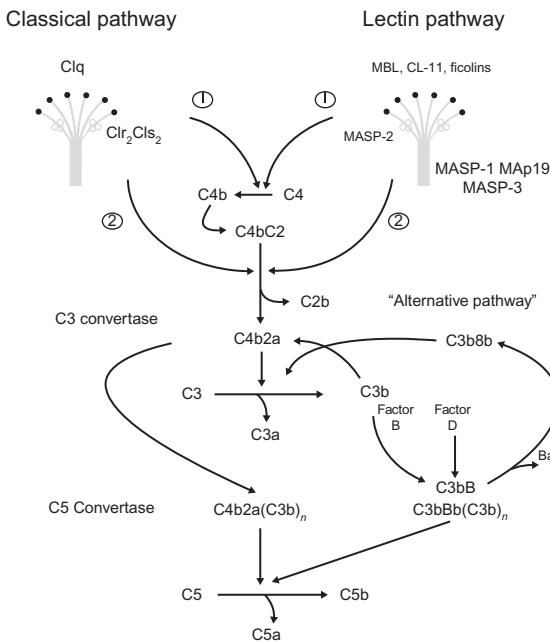

The first component of the complement C1 is composed of a multimolecular initiation complex that triggers complement activation.

The 790 kDa C1 complex consists of a recognition protein, C1q, and a heterotetramer of C1r and C1s zymogens to form the C1q:C1s:C1r2:C1s complex (Fig. 14.1). C1q is composed of six identical subunits joined together through their collagen-like stalks that end in globular heads. Each subunit consists of three homologous polypeptide chains (Arlaud et al., 2002). Classical pathway activation is initiated either by direct binding of C1q to a target (e.g., bacterial) surface or indirectly by binding of C1q to antibodies deposited on the target (immune complexes). IgM, IgG1, IgG2, and IgG3 bind C1q (Arlaud et al., 2002). Binding of C1q to complement activators leads to a conformational change in the collagenous region of C1q which in turn leads to the autoactivation of C1r, which cleaves its only substrate, C1s. C1s in turn cleaves C4 into C4a and C4b and then cleaves C2 bound to the C4b, resulting in the formation of the classical pathway C3 convertase (C4b2a) (Arlaud et al., 2002; Carroll and Sim, 2011).

C4b2a is a protease which activates C3 to form C3a and C3b. C3b, like C4b, can bind covalently to the complement activator, and hundreds of molecules of C3b can be deposited in close proximity to the C3 convertase complex. C3b can bind directly to C4b2a, forming the classical pathway C5 convertaseC4b2a3b, in which C4b and C3b form a binding site for C5, orienting it for cleavage by C2a.

## The Lectin Pathway

In evolutionary terms the lectin pathway (LP) of complement activation seems to be the oldest of the three (Dodds, 2002; Wallis, 2007). The LP is initiated by the binding of a multimolecular LP activation complex, similar in structure to the classical pathway C1, to pathogen-associated molecular patterns, mainly carbohydrate structures present on microorganisms, or damage-associated molecular patterns on damaged host tissue. The LP recognition molecules are mannose-binding lectin (MBL), an MBL-like collectin (CL) called CL-11, and ficolins. Like C1q, they are made up of subunits with globular heads and collagenous stalks. Activation is initiated by the binding of the globular heads to carbohydrate structures present on microorganisms or aberrant glycocalyx patterns on apoptotic, necrotic, malignant, or oxygen-deprived cells (Fujita, 2002; Schwaebel et al., 2002).

**FIGURE 14.1** Flow diagram of the three activation pathways of complement. Activation step 1 depicts the C1s and MASP-2-mediated cleavage of complement C4 to C4a and C4b, activation step 2 depicts the subsequent C1s and MASP-2-mediated cleavage of C4bC2 to form the C3 convertase of the classical and lectin pathway C4b2a. With the conversion of C5 into C5a and C5b, all enzymatic steps of complement activation are completed. Both the classical as well as the alternative pathways are thought to correspond with the alternative pathway activation loop through provision of C3b.

Rodents have at least four circulating LP recognition molecules, with differing, but overlapping, carbohydrate specificities; two mannan-binding lectins (MBL-A and MBL-C), CL-11, and ficolin A (Fnca) (Schwaebel et al., 2011; Ali et al. 2012). A second murine ficolin, Fnrb, associated with monocyte and macrophage cell surfaces does not activate complement in mice but may act as an LP recognition molecule in rats (Girija et al., 2011). Humans have a single MBL (the product of *MBL2*; *MBL1* is a pseudogene), CL-11 (CL kidney 1, CL-K1), and three ficolins, FCN1 (M-ficolin), FCN2 (L-ficolin), and FCN3 (H-ficolin) (Fujita, 2002; Liu et al., 2005; Hansen et al., 2010). These recognition molecules form complexes with the serine proteases called MASP-1, -2, and -3 (MBL-associated serine proteases 1, 2, and 3). These are homologous to C1r and C1s, and form homodimers (and perhaps some heterodimers). The serine proteases in the CP and LP activation complexes all interact with a highly conserved binding motif within the collagenous region of the recognition subunit, that is, C1q for the CP and MBL, ficolins or CL-11 for the LP (Wallis et al., 2004). Each recognition molecule can bind one protease dimer. The recognition molecules also interact with MAp19 and MAp44 (alias MBL/ficolin-associated protein 1), which are nonenzymatic, truncated alternative splice products of the *MASP2* and *MASP1/3* genes, respectively. Both truncated gene products lack the serine protease domain and may regulate LP activation by competing for the binding of MASPs to the carbohydrate recognition molecules (Thiel et al., 1997; Stover et al., 1999; Takahashi et al., 1999; Schwaebel et al., 2002; Iwaki et al., 2006; Degn et al., 2009; Skjoedt et al., 2010). Of the three MASPs, only MASP-2 is required and essential to form the LP C3 and C5 convertases (C4b2a and C4b2a3b) (Thiel et al., 1997; Vorup-Jensen et al., 2000; Rossi et al., 2001; Schwaebel et al., 2011).

Like C1s, activated MASP-2 cleaves C4 and C4b-bound C2, generating C4b2a. Neither MASP-1 nor MASP-3 can cleave C4 (Schwaebel et al., 2011). The function of MASP-1 is still uncertain. It may facilitate LP activation by either direct cleavage of complex-bound MASP-2 or cleavage of C4b-bound C2 (Takahashi et al., 2008; Kocsis et al., 2010; Schwaebel et al., 2011). Recent work demonstrated that MASP-1 (and possibly MASP-3) plays a key role in the maturation and initiation of the alternative activation pathway (Takahashi et al., 2008; Iwaki et al., 2011). The LP is probably mainly activated by charge-neutral sugar structures and clusters of acetyl moieties, whereas in the classical pathway, C1q recognizes mainly charge clusters. The LP can also respond to immunoglobulins deposited on targets, by binding to glycans on some human IgG, IgA glycoforms, and to the glycans on mouse (but not human) IgM (Carroll and Sim, 2011).

## The Alternative Pathway

Factor B, factor D, and properdin (factor P) are specific components of the alternative pathway of complement activation. Unlike the classical and LP (which are initiated via specific recognition proteins such as C1q or MBL), the alternative pathway is initiated through a spontaneous steady-state hydrolysis of C3 to form C3 ( $H_2O$ ) which in turn binds to factor B to form a  $C3(H_2O)B$  zymogen complex. In this complex, factor B is cleaved by factor D releasing a Ba fragment while Bb remains attached to the complex. The newly formed complex  $C3(H_2O)Bb$  is a C3 convertase enzyme and cleaves C3 into C3a and C3b. Once C3b is generated, it will bind covalently to the surface of pathogens where it can bind to another molecule of factor B and form a new alternative pathway C3 convertase  $C3bBb$  (Carroll and Sim, 2011). The alternative pathway also acts as an amplification loop where C3b generated by either the classical or the LP binds to factor B to generate the convertase  $C3bBb$  (Schwaebel and Reid, 1999). The  $C3bBb$  is homologous to C4b2a (C3 is a homolog of C4, and factor B of C2) and like C4b2a will switch its substrate specificity from cleaving C3 to cleaving C5 upon binding of C3b to the convertase, forming  $C3bBb3b$ , the C5 convertase.

## The Membrane Attack Complex

The C5 convertases C4b2a3b and  $C3bBb3b$  cleave C5 into C5b and C5a. C5b then binds to C6, C7, and C8 to form a C5b-8 complex that can bind to cell surfaces and initiate cell lysis by inserting into the lipid bilayer. Multiple C9 molecules can bind to C5b-8, accelerating lysis and forming the MAC, or C5b-9 (Podack et al., 1982).

## CONTROL OF COMPLEMENT ACTIVATION

The complement system is tightly regulated to avoid run-away activation of the enzymatic cascade that would otherwise lead to excess host tissue damage and inflammation. Key events at the center of the cascade are carefully controlled by five closely related complement control proteins, all of which are encoded by genes located in the regulator of complement activation cluster on chromosome 1q32 in man. Complement regulatory components include membrane-bound regulators and fluid phase regulators (Kirschfink and Mollnes, 2003; Carroll and Sim, 2011).

Two host membrane proteins, CR1 and membrane cofactor protein (MCP or CD46), and two fluid-phase regulators, factor H and C4-binding protein (C4bp), act as cofactors for factor I, which inactivates C3b and C4b, preventing formation of the C3 and C5 convertases. C4bp also shortens the half-life of the classical pathway C3 and C5 convertases, while factor H has the same effect on the alternative pathway C3 and C5 convertases. CR1 and another host membrane protein, decay accelerating factor (DAF), act on both the classical, and alternative pathway convertases. A truncated splice variant of factor H, factor H-like protein 1, is also found in serum and has regulatory activity similar to that of factor H (Schwaebel et al., 1987). Prevention of factor H binding results in an increased half-life of C3b containing convertase complexes and overshooting activation of the alternative pathway leading to FHR-C3 glomerulopathies (C3GN) (Ramaglia et al., 2012).

## Fluid Phase Regulators

C1 inhibitor, also known as Serpin G1, is a serine protease inhibitor which irreversibly inhibits C1r, C1s, MASP-1, and MASP-2 by forming a covalent complex with the protease active site (Chen et al., 1998; Presanis et al., 2004; Cicardi et al., 2005). Besides complement regulation Serpin G1 can also inactivate serine proteases of the coagulation cascade (FXIa and FXIIa), and of the contact system (kallikrein) (Cicardi et al., 2005; Wagner and Frank, 2010).

Factor I is a protease and a fluid phase regulator of all three pathways. It converts hemolytically active C3b into hemolytically inactive iC3b, in a cofactor-dependent manner. In the fluid phase, factor H, an abundant plasma component, binds to free and complex-bound C3b to allow factor I to convert C3b to iC3b. A further conversion of iC3b to C3c and C3dg by factor I is also cofactor dependent. In a similar fashion, factor I inactivates C4b in the presence of the cofactor C4-binding protein (C4BP) (Seya et al., 1995). Binding of C4BP to C4b inhibits C4b-C2a binding, preventing the formation of the C3 convertase (Blom et al., 2004). Subsequent factor I-dependent conversion of C4b generates the fragments iC4b, C4c, and C4d. Conversion of C3b to iC3b is

important in another function: iC3b is a powerful opsonin, recognized by CR3 and CR4, while C3b is a less effective opsonin, recognized by CR1.

Factor H is an important alternative pathway regulator, the main activity of which, besides mediating C3b inactivation by factor I, is to destabilize and also accelerate the decay of the alternative pathway C3 convertase (C3bBb) and C5 convertase (C3bBb3b) (Whaley and Ruddy, 1976; Weiler et al., 1976). Factor H destabilizes the C3 convertase by competitive binding to C3b, which dislodges Bb from the convertase (C3bBb). Factor H is important for the discrimination of self from nonself-cells and therefore preventing autoimmunity. Binding of factor H, for example on sialic acid or glycosaminoglycans of host cells, inhibits alternative pathway activation on the surface of host cells (Pangburn et al., 2000). Carboxypeptidase N is an inactivating regulator of the C3a and C5a anaphylatoxins (Bokisch and Muller-Eberhard, 1970). Clusterin and S protein are regulators for the terminal activation cascade of complement. They bind to C5b-7 complex and prevent the insertion of C8 and C9 leading to the inhibition of the MAC formation (Jenne and Tschopp, 1989; Wagner and Frank, 2010).

Properdin is the only known and essential positive regulator of the complement system. It is essential for alternative pathway activation as properdin-depleted sera lack the ability to activate the alternative pathway (Schwaebel and Reid, 1999). Properdin is produced by monocytes/macrophages, peripheral T lymphocytes, and granulocytes (i.e., neutrophils) (Wirthmueller et al., 1997) and acts as a positive regulator by stabilizing the alternative pathway C3 and C5 convertases (Schwaebel and Reid, 1999; Stover et al., 2008).

## Membrane-Bound Regulators

Complement activation is also controlled by at least four characterized membrane-bound proteins or receptors, which protect host cells from attack by complement. These comprise the decay-accelerating factor (DAF, also known as CD55), the CR1 (also known as CD35), the MCP (also known as CD46), and CD59 (also known as protectin) (Wagner and Frank, 2010). Like factor H, DAF regulates complement activation by accelerating the decay (dissociation of the convertases) of the C3 convertases (C3b2a and C3bBb) (Lublin and Atkinson, 1989). CR1 and MCP act as cofactors for the cleavage of C3b and C4b by factor I (Wagner and Frank, 2010). CD59 is a regulator of the MAC complex. CD59 binds the nascent MAC complex (C5b-8) inhibiting C9 polymerization and subsequent pore formation on the surface of a cell (Lehto et al., 1997; Farkas et al., 2002). DAF, MCP, and CD59 are found on most cell types, but CR1 has more restricted distribution (erythrocytes, lymphocytes, dendritic cells, and kidney podocytes).

## THE BIOLOGICAL EFFECTS OF COMPLEMENT ACTIVATION

Complement activation leads to a multitude of biological activities including opsonization, initiation of a proinflammatory response, immune complex clearance, and direct killing of cells via the MAC. Opsonization of pathogens is mediated by the major opsonin C3b or iC3b and C4b to a lesser extent. C3b coats the surface of microorganisms and enhances their phagocytosis by leukocyte via binding to CR1. iC3b binds to CR3 and CR4. L-Ficolin, MBL, and C1q have been reported to initiate phagocytosis directly by binding to pathogens and enhancing phagocytosis by binding to CL receptors on the surface of the phagocytes (Jack et al., 2001; Aoyagi et al., 2005). In other instances, complement can mediate direct killing of bacteria, especially Gram-negative bacteria via the formation of the MAC which form pores in the cell membrane leading to cell lysis (Nauta et al., 2004). During complement activation, proinflammatory cleavage products anaphylatoxins C4a, C5a, and C3a are released. The release of anaphylatoxins increases vascular permeability and formation of inflammatory exudates. These inflammatory exudates enhance the recruitment of inflammatory mediators and inflammatory cells to the site of injury and efficient elimination of invading pathogens or other inflammatory factors. Increased vascular permeability leads to extravasation of leukocytes to the site of inflammation, which helps in clearing invading pathogens. C5a acts as a potent chemotactic factor that stimulates leukocyte migration. In addition, C5a was found to increase the synthesis of other chemotactic agents such as eicosanoids and chemokines. Schindler et al. (1990) reported that C5a stimulates the expression of interleukin-1 and tumor necrosis factor. Complement also plays a major role in the clearance of apoptotic and necrotic cells in addition to immune complexes and microorganisms. The globular head of C1q binds to the surface of apoptotic cells and facilitates the uptake of the cells by macrophages (Taylor et al., 2000). In addition, opsonization of apoptotic cells with iC3b leads to recognition of

these cells by CR3 and CR4 on the surface of phagocytes with subsequent engulfment of these cells (Mevorach et al., 1998).

Complement also inhibits the precipitation of immune complexes and enhances their solubility by binding of C1q, C3b, and C4b. This binding inhibits further increase in the aggregation of the immune complex. These complexes bind to CR1 on the surface of erythrocytes which transfer them into the liver and the spleen where they are cleared from the circulation by the resident macrophages (Manderson et al., 2004).

## COMPLEMENT INVOLVEMENT IN THE PATHOPHYSIOLOGY OF DIVERSE AUTOIMMUNE DISEASES

As a powerful effector system of both the innate and the adaptive immune response, uncontrolled complement activation can lead to the loss of antimicrobial immune protection, but can also initiate, feed, and perpetuate inflammatory conditions leading to tissue destruction and autoimmune disease. Uncontrolled, dysregulated complement activation can be caused by inherited or acquired deficiencies of complement components as well as through gain of function or loss of function mutations in complement genes or genes encoding enzymes that further process complement components. An example for the latter is the X-linked phosphatidylinositol glycan class A (PIG-A) gene encoding an enzyme necessary for the synthesis of *N*-acetylglucosaminyl-phosphatidol, an intermediate required for the membrane anchoring of the membrane protective complement regulatory components DAF (i.e., DAF or CD55) and protectin (i.e., CD59) which are attached to the outer cell surface through glycosyl-phosphatidylinositol anchoring. A rare inherited or acquired deficiency of the PIG-A leads to the loss of the membrane localization of CD55 and CD59, which in turn renders in particular erythrocytes susceptible to autologous complement lysis cells and presents as a hematological disorder named paroxysmal nocturnal hemoglobinuria (PNH) or Marchiafava–Micheli syndrome. In most cases, PNH is a consequence of a nonmalignant clonal expansion of one or more hematopoietic stem cells with an acquired somatic mutation in the PIG-A gene. PNH clinically presents as a chronic hemolytic anemia with both intravascular and extravascular lysis of erythrocytes leading to hemoglobin in the urine and a predisposition of thrombosis. The severity of disease is predicted by the degree of loss of CD55 and CD59 anchoring on blood cells, which can vary between partial loss (PNH type II) and total loss (PNH type III). The condition is potentially life-threatening due to the high risk of thrombotic disease and is presently treated with high-dose applications of a recombinant humanized anti-C5 monoclonal antibody, eculizumab, which prevents C5 activation and MAC formation (Risitano, 2013). This treatment effectively reduces the intravascular lysis, but anemia with the need for blood transfusion persists due to the continuous opsonization of PNH erythrocytes by complement C3 activation products, which makes these erythrocytes susceptible to opsonophagocytosis and extravascular hemolysis. A more effective treatment would be to block complement activation further upstream to avoid C3 deposition. In PNH plasma the direct antiglobulin test (or direct Coombs' test) is usually negative, as the hemolysis of PNH is not caused by antibodies. This sets PNH apart from another autoimmune disorder, called autoimmune hemolytic anemia (AIHA), where antibody-mediated complement activation lyses erythrocytes. In most cases of AIHA the autoantibody is of the IgM class. Treating AIHA with red blood cell transfusions is often ineffective, since the autoantibodies attach to recipient and donor cells alike. Therapeutic application of C1-esterase inhibitor concentrate was recently shown to protect from complement-induced red blood cell destruction and may offer a safe and effective treatment of AIHA (Wouters et al., 2013).

An extremely strong association has been established between deficiencies of the classical pathway of complement activation and systemic lupus erythematosus (SLE).

The first description of an acquired deficiency of the first component of complement in the serum of an SLE patient was published more than 40 years ago showing the presence of anti-C1q autoantibodies by gel diffusion chromatography (Agnello et al., 1971). The hereditary deficiency of C1q and the predisposition for autoimmune SLE or SLE-like disease represents one of the most powerful associations with over 90% of C1q-deficient individuals developing severe SLE. The disease manifestations such as rash, glomerulonephritis, and central nervous system (CNS) disease can vary, but the severity of disease invariably progresses and requires extensive medical care (Walport et al., 1998). A recent report described the successful long-term replacement of C1q through fresh frozen plasma infusions in a young C1q-deficient patient for over 9 years (Mehta et al., 2010). Bone-marrow transplantation was successfully conducted replacing the bone marrow of a C1q-deficient mouse with bone marrow of a syngenic WT mouse (Cortes-Hernandez et al., 2004), restoring normal C1q levels. Interestingly, both

inherited or acquired deficiency of each of the classical pathway components C1, C4, C2, and C3 predisposes to lupus-like autoimmune disease (Carroll, 2004; Pradhan et al., 2012).

This strongly implies a critical role of the classical pathway in the maintenance of immune tolerance and prevention of autoimmune disease. The present understanding points to the conclusion that the classical pathway fulfills an important scavenger function in removing immune complexes as well as cellular debris and that in the absence of this scavenger system the clearance of debris is significantly impaired which in turn results in continuous presentation of autoantigens (Arlaud et al., 2002).

A rare but invariably severe autoimmune pathology is caused by an IgG autoantibody directed against the alternative pathway C3, convertase C3bBb. This autoantibody binds to C3bBb and protects this complex from decay by factor H and subsequent inactivation by factor I and thereby increases the half-life of the alternative pathway C3 convertase leading to a continuous activation of the alternative pathway and secondary hypocomplementemia. This perpetual activation of the alternative pathway clinically presents as a form of membranoproliferative glomerulonephritis (i.e., mesangiocapillary glomerulonephritis type II), which earned this autoantibody the name nephritic factor (NeF). Patients suffering from this rare autoimmune disease frequently show abnormalities in the distribution of their adipose tissue, named partial lipodystrophy. A recent report provided a plausible explanation showing that NeF can also stabilize the C3 convertase on the surface of fat cells and lyse fat cells through perpetual generation of MACs (Mathieson et al., 1993). An even rarer variant of NeF presents as an autoantibody directed against the classical/LP C3 convertase (i.e., C4b2a), called C4 NeF, which stabilizes this convertase causing hypocomplementemia by continuous consumption of C3 (Miller et al., 2012). The majority of the C4-NeF cases were identified in a cohort of lupus nephritis patients. Dysregulated alternative pathway activation caused by deficiencies of the alternative pathway regulators factor H, factor I, MCP, and the factor H-related genes (FHR5 and FHR1) predisposes to C3GN. The predisposing mutations in the factor H-related genes lead to the formation of FHR dimers which effectively bind and compete with factor H for the binding to C3b. Prevention of factor H binding results in an increased half-life of C3b-containing convertase complexes and overshooting activation of the alternative pathway (Ramaglia et al., 2012).

The commonest cause of C3GN is complement factor H-related 5 (CFHR5) nephropathy, which is endemic in Greek Cypriots. Other C3GNs include membranoproliferative glomerulonephritis 1 (MPGN1), fMPGN3, and dense deposit disease, a rare form of glomerulonephritis characterized by the presence of electron dense deposits within the glomerular basement membrane with intense deposition of C3 fragments (De Cordoba et al., 2012).

Hemolytic uremic syndrome (HUS) is a life-threatening condition often following infections with Shiga toxin-producing *Escherichia coli* strains (STEC-HUS; EHEC-HUS). It presents as Coombs' test-negative microangiopathic anemia with severe diarrhea. An atypical form of HUS (aHUS) does not present with diarrhea. It has a poor long-term prognosis as it is recurrent and results in a fatality rate of up to 30%. aHUS can develop in individuals with inherited or acquired predispositions for poorly controlled complement activation, either through mutations in the complement regulatory components factor H, or MCP, factor I or through gain-of-function mutations in factor B and complement C3 (Goicoechea de Jorge et al., 2007), or have autoantibodies against factor H or disease promoting mutations in factor H-related proteins CFHR1 and CFHR5 (see above). Another thrombotic microangiopathy called thrombotic thrombocytopenic purpura (TTP) is pathologically very similar to HUS as it presents with an autoantibody-induced consumption of complement and thrombi in the microcirculation of many organs, including kidney, brain, heart, lung, liver, and gut (Noris et al., 2012). A majority of TTP patients present with acquired autoantibodies that inhibit a plasma metalloprotease called ADAMTS13 that cleave von Willebrand factor. Inherited forms of TTP are caused by ADAMTS13 gene deficiencies.

In 2005 several independent reports identified a loss-of-function mutation (CHFY402H) in the complement regulatory component factor H to be a major predisposing factor for age-related macular degeneration (AMD), a degenerative disorder of the retinal pigment epithelium (RPE) and the most common cause of blindness in the Western world (Klein et al., 2005). Interestingly, retinal drusen, the hallmark of AMD, stain positive for complement activation products, indicating that complement activation is involved in drusen formation. In vitro models of complement activation on retinal pigmented epithelial monolayers have demonstrated that oxidative stress significantly induced complement activation on the surface of these cells and initiated complement activation in a LP-dependent fashion (Joseph et al., 2013). The sublytic deposition of complement on RPE required the presence of MASP-2 to initiate complement activation, while reduced functional activity of alternative pathway regulators may be critical for the disease process to establish and therefore predispose for the severity and the time of onset of AMD pathology. Most recent work also identified that the loss-of-function mutation (CHFY402H) of factor H also as a high risk polymorphism for other diseases with autoimmune characteristics such as ocular sarcoidosis, atherosclerosis, and a subgroup of Alzheimer patients (i.e., ApoE4 risk allele carriers) (Thompson et al., 2013).

Complement has also been identified as a critical player in the pathophysiology of diverse autoimmune diseases of the CNS caused by autoantibody-mediated destruction of cells where activation of complement by either the classical or the LP plays a critical role. These diseases include myasthenia gravis (MG) (Romi et al., 2005), Guillain Barré syndrome (GBS) (Kaida and Kusunoki, 2009), and neuromyelitis optica (NMO) (Asgari et al., 2013). MG is caused by an autoantibody directed against the acetylcholine receptor, which strongly activates complement and blocks signal transduction at the motor neuron synapse to muscle cells causing muscle weakness and loss of muscle control. In an animal model of MG, experimental autoimmune MG was shown that complement activation is required for the disease to develop, since the disease cannot be induced in absence of C3, C4, or C5, and the application of complement inhibitors ameliorates the severity of established disease (Tuzun and Christadoss 2013). In GBS, antiganglioside autoantibodies trigger complement activation leading to a complement-dependent disruption of voltage-gated sodium channel clusters, while in NMO, antiaquaporin-4 autoantibodies trigger complement activation through the classical and/or the lectin activation pathway.

In other autoimmune pathologies of the CNS, such as multiple sclerosis (MS) (a condition caused by autoimmune destruction of the myelin sheets around the axon of neurons), motor neuron disease (MND) (describing a group of neurological disorders selectively affecting motor neurons), and Alzheimer's disease (AD) [which was recently defined as an autoimmune disorder triggered by herpes simplex (Wozniak et al., 2007)]; the involvement of complement in the pathophysiology is somewhat more complex. In experimental autoimmune encephalomyelitis (EAE) a mouse model for MS, the alternative complement activation pathway is essential for the priming of microglial cells. Mice deficient in the C3 convertase regulator complement receptor 1-related protein y (Crry) show an accelerated onset of EAE signs and early microglial priming, but no disease develops in mice deficient in both Crry and C3 and Crry and factor B (Donev et al., 2013). Classical pathway deficiency, however, does not protect from developing EAE. Therapeutic inhibition of factor B in a mouse model does not prevent the onset of EAE but ameliorates the severity of disease once it is established (Hu et al., 2013). In MND, local complement biosynthesis is increased and therapeutic inhibition of the complement anaphylatoxin C5a reduces inflammatory pathology and survival in a rat model of amyotrophic lateral sclerosis, but at present too little is known to define a definite role of complement in this devastating autoimmune pathology (Woodruff et al., 2008).

In AD the classical pathway recognition component C1q colocalizes with the amyloid- $\beta$  depositions in the disease lesion areas. In a mouse model of AD, C1q-deficient mice show a faster progression of AD neurodegeneration, and most recent work demonstrated that C1q is neuroprotective against amyloid- $\beta$  toxicity (Benoit et al., 2013).

Rheumatoid arthritis (RA) is a highly disabling systemic autoimmune disease characterized by a persistent inflammation of the synovial membrane lining the joint, with associated infiltration of macrophages, granulocytes, T cells, and B cells. Local complement activation is critically involved in the onset and maintenance of this inflammatory disease with a preponderant role of the alternative activation pathway in a mouse model (Dimitrova et al., 2012). Deficiencies of C5 and C6 also protect from RA indicating that the terminal activation cascade essentially contributes to the severity of disease while deficiency of an early component such as C2 is a predisposing factor (Jonsson et al., 2005).

Complement-mediated cytotoxicity plays a critical role in the pathophysiology of vitiligo, a common depigmenting autoimmune disorder. Autoimmune antibodies lyse melanocytes through both complement activation and antibody-dependent cellular cytotoxicity (Norris et al., 1988).

Pernicious anemia (PA) is the most common cause of vitamin B12 deficiency. PA patients have complement activating autoantibodies against parietal cells in serum and gastric fluid, but since the antigen H<sup>+</sup>/K<sup>+</sup>-ATPase is not expressed on the surface of the target cell, cytotoxicity in PA is unlikely to be complement mediated (De Aizpurua et al., 1983).

Complement does not appear to be involved in the pathophysiology of primary Sjögren's syndrome. It is likely that complement consumption in Sjögren's syndrome patients is caused by concomitant and secondary systemic disease (Lindgren et al., 1993).

Hashimoto's thyroiditis (HT) and Graves' disease (GD) share many common features including the presence of autoantibodies against thyroperoxidase and thyroid stimulating hormone (TSH) receptor. In GD a subset of TSH receptor antibodies stimulates this receptor and causes the phenotype of hyperthyroidism, the hallmark of GD. The role of the other autoantibodies, however, remains unclear. In HT, immune complexes on the thyroid follicular membrane are often associated with complement deposition indicating a role of complement in the tissue destruction. Previous studies claim that thyrocytes are usually resistant to direct complement lysis as these cells are expressing high levels of membrane-associated complement regulators such as CD59 (Tandon et al., 1992). Nonlytic activation of complement generates soluble MACs during the acute phase of HT

(Weetman et al., 1989). A more recent study claims that thyroperoxidase on the surface of thyrocytes can also initiate complement activation through the binding of C4 and C4b to a complement control module in the ectodomain of thyroperoxidase leading to direct complement-mediated killing of thyrocytes in vitro (Blanchin et al., 2003). This proposed activation mechanism, however, has not been confirmed.

Ischemia/reperfusion injury (IRI) is a complement-mediated postinflammatory condition leading to major tissue loss. IRI was first thought to be mediated through the classical pathway, since it is less pronounced in IgM deficiency, but more recent work identified that it is predominantly driven by the LP of complement in a MASP-2-dependent fashion (Schwaeble et al., 2011). In experimental models of stroke and myocardial infarction, therapeutic inhibition of MASP-2 reduces infarct sizes by up to 40% and may offer a promising new avenue of treatment to reduce morbidity and mortality in these major ischemic pathologies.

Noninterferon Members	283		

## HISTORICAL PERSPECTIVE

Although cytokines are the intermediary intercellular protein signals of the immune system, overproduction of proinflammatory cytokines or deficient production of immunosuppressive cytokine mediators can be a direct cause of autoimmune conditions. Cytokines have been the focus of research for over 70 years, and over 650,000 articles have reported on cytokines. This chapter will highlight in brief only those cytokines contributing to autoimmune and autoinflammatory diseases. Fortunately, there are only 38,000 plus references to autoimmunity and only about 9000 relating cytokines to autoimmunity.

The history of cytokine studies was initiated by the report of Menkin (1944) who was the first to propose that "soluble pyrexins" might be responsible for fever by purifying them from inflammatory exudates. However, these pyrexins survived boiling and were contaminated by pyrogenic bacterial endotoxins. Bennett and Beeson (1953) were the first to extract endotoxin-free endogenous pyrogens from peripheral blood leukocytes. At the same time, nerve-growth factors were discovered (Levimontalcini and Hamburger, 1953). Thereafter, interferons with antiviral activities were distinguished from antibodies (Isaacs and Lindenmann, 1957).

Several reports initiated the studies of lymphocyte-derived factors. Mitogenic factors for lymphocytes were first detected in the supernatants of antigen or alloantigen-stimulated mixed leukocyte cultures

([Kasakura and Lowenstein, 1965](#)). This was rapidly followed by the detection of immunologically nonspecific macrophage migration inhibitory factors (MIF) in such supernatants ([Bloom and Bennett, 1966](#)). The MIF activity was subsequently also found to have macrophage activating activity ([Nathan et al., 1971](#)) that was subsequently attributed to interferon gamma (IFN $\gamma$ ). The historic MIF activity is distinct from the more recently discovered MIF, which is produced by the anterior pituitary and is present at detectable levels in normal human serum. This MIF is hormone-like and counters the immunosuppressive effects of corticosteroids as reviewed by [Santos et al. \(2001\)](#). These lymphocyte-derived factors were termed lymphokines ([Dumonde et al., 1969](#)). Subsequently, it was shown that nonlymphocytes such as macrophages could also produce a thymocyte and lymphocyte activating factor ([Gery et al., 1971](#)). It was subsequently observed that even fibroblast cell lines could produce factors promoting inflammatory reactions and the term “cytokines” was coined ([Cohen et al., 1974](#)). Cytokines serve as signals between every nucleated cell type and regulate the survival, growth, activation, differentiation, and suppression of both innate and adaptive immune responses involved in host defense and restoration of homeostasis. Although by 1978 over 100 cytokine activities had been reported, in 1979 at a meeting of “cytokinologists,” it was decided to call all monocyte/macrophage-derived cytokines interleukin-1 (IL-1) and the lymphocyte-derived ones interleukin-2 (IL-2) ([Mizel and Farrar, 1979](#)). This was based on the simplistic presumption that all the activities could be attributed to these two molecules. Today we are up to interleukin 38, and there are many more cytokines with idiosyncratic names. For example, over 40 chemotactic cytokines called “chemokines” have been discovered that promote the directional migration of many cell types.

Immunologists at the time were enamored of specific antibodies and initially considered these nonspecific factors to be “lymphodrek” and to have little merit. However, the advent of the molecular age led to the identification of these molecules as gene products with distinct functions, forever changing immunology research. The first cytokine to be cloned was IFN $\beta$ 1 ([Taniguchi et al., 1980](#)), followed by IFN $\alpha$ 1 ([Nagata et al., 1980](#)) and IFN $\gamma$  ([Gray et al., 1982](#)). IL-2 was the first interleukin to be cloned ([Taniguchi et al., 1983](#)). The era of “receptorology” was initiated when the first of the three chains of the receptor for IL-2 (IL-2 R $\alpha$ ) was identified and cloned ([Leonard et al., 1984](#)). We now have hundreds of cloned cytokines.

Thus, cytokines, such as hormones, are intercellular regulators of immune cell reactions, but unlike hormones, they are more prominent at local inflammatory sites rather than in the serum. Unlike hormones which are usually produced by glands, cytokines are produced at lower (nanomolar) concentrations by a great variety of cells and tissues. Cytokines, such as hormones, also interact with selective cell receptors inducing an intracellular signal transduction cascade culminating in gene activation. Cytokines usually have localized “paracrine” effects on neighboring cells or “autocrine” effects on the producing cells but less often have “endocrine” systemic effects of hormones. The appearance of elevated levels of cytokines in the serum actually has systemic effects such as pyrexia, hypotension, muscle aches and pains, and malaise and is responsible for the systemic symptoms of infections and injury. In the most severe inflammatory states, as in sepsis, this is called a “cytokine storm,” which can be lethal.

Development of technology to delete or modify gene expression yielded “knockout” mice lacking selected cytokine gene activities. This revealed surprising *in vivo* roles and redefined the functions of a number of cytokines. For example, tumor necrosis factor (TNF), which had cytotoxic antitumor activity in tissue culture ([Carswell et al., 1975](#)), was identified as a key proinflammatory host defense cytokine ([Nedospasov et al., 2003](#)). IL-2 based on its *in vitro* effects was considered a mitogenic factor, but knockout mice often developed lymphoproliferative autoimmune syndromes based on the absence of the stimulating effects of IL-2 on immunosuppressive T regulatory cells (Tregs) ([Hunig and Schimpl, 2003](#)). Thus, studies of knockout mice often revealed specialized and unique roles for many cytokines. Ironically, the advent of knockout mice highlighted the primacy of “*in vivo veritas*” and drove immunologists and molecular biologists from tissue culture studies back to investigating *in vivo* models.

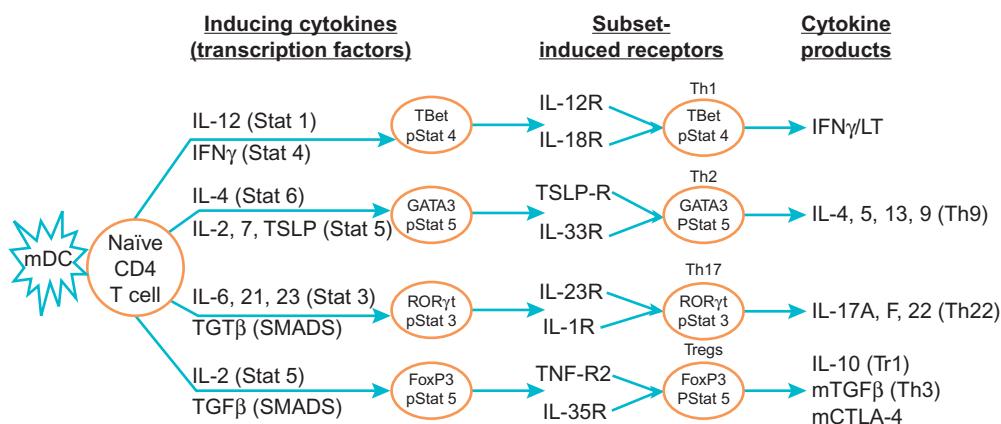

Today we are confronted by a plethora of cytokines, with apparent overlapping redundant activities, in part based on the sharing of receptors. The close interrelationship and apparent overlap in cytokine activities is accentuated by their capacity to induce one another and by their receptors to cross-talk and thus to “transactivate” each other. Thus, cytokines and their receptors operate in a linked network, and inhibition of one often downregulates the effects of other cytokines. It has become apparent over the past two decades that many cytokines mediate inflammatory responses aimed at eliminating invasive organisms and eliminating tissue debris generated by traumatic injuries. However, the identification of Tregs and their immunosuppressive mediators IL-10, transforming growth factor  $\beta$  (TGF $\beta$ ) and CTLA4 have identified a number of antiinflammatory cytokines that aim to restore homeostasis and mediate tissue repair. Thus, cytokines mediate the immunological balancing act between pro- and antiinflammatory reactions to pathogenic organisms and tissue damage. They also mediate the discrimination between self and nonself and can enhance or suppress inappropriate reactions to self.

## CYTOKINES AND IMMUNITY

The initial “innate” immune responses of cells are preprogrammed in the genome and are based on the induction of proinflammatory cytokine and chemokine production. These signals result in recruiting a rapid inflammatory response to invasive pathogenic organisms or tissue injury by phagocytic neutrophils followed by monocytes, macrophages, and dendritic cells (DCs). This cytokine-driven innate immune response is initiated by the interaction of exogenous “pathogen-associated molecular patterns” (PAMPs) or so-called stored endogenous “alarmins” with Toll-like receptors (TLRs), nucleotide-binding oligomerization domain 2 (NOD2), retinoic acid inducible gene (RIG)-like helicases, DNA sensors absent in melanoma2, or cell surface c-type lectin receptors present on or in many somatic cell types including inflammatory cells. These pattern recognition receptors enable host cells to respond to PAMPs and damaged self-proteins as reviewed in [Bellanti et al. \(2012\)](#).

The receptors on phagocytic DC internalize, digest, and process the antigens derived from PAMPs yielding peptide fragments that are then presented in conjunction with major histocompatibility complex (MHC) cell surface molecules on antigen presenting cells (APCs) to T lymphocytes. The presented MHC peptide complexes activate CD4 T cells that express the appropriate receptors to divide, multiply, and produce lymphokines, thus initiating the adaptive immune response with the capacity to mount specific reactions to invasive organisms and/or damaged cell products. The nature of the stimulant and cytokine response is crucial in determining the type of adaptive response that is generated. The activated CD41 T cells differentiate into subsets that exhibit Th1, Th2, Th17, or Treg cell responses as reviewed by [Zhu et al. \(2010\)](#). As shown in Fig. 15.1 ([O’Shea and Paul, 2010](#)), the Th1 lymphocytes producing IFN $\gamma$  favor the production of cellular immune delayed hypersensitivity reactions. Th2 lymphocyte-derived cytokines such as IL-4, 5, 9, and 13 favor humoral antibody-mediated immunity to parasites and allergic reactions. Furthermore, these cytokines reciprocally downregulate the other subset. Thus, IFN $\gamma$  suppresses the Th2 pathway and IL-4 and IL-13 suppress the Th1 pathway. The lymphocyte-derived Th17 type of cytokines (IL-17, IL-22, IL-23) favor acute inflammatory and autoimmune reactions. Treg cells consist of four subsets known as Th3, cell contact-dependent natural or induced Tregs, or Tr1 subsets which mediate their suppressive effects by expressing cell-associated TGF $\beta$ , CTLA4, and secreting IL-10, respectively. They are all engaged as feedback downregulators of inflammation and adaptive immunity and function to promote tissue repair by reducing inflammation and maintaining tolerance.

Lymphocyte subsets also express lineage-specific transcription factors called “master regulators,” such as Tbet, GATA3, ROR $\gamma$ t, and FoxP3 for Th 1, 2, 17, and Tregs, respectively, that are responsible for the production of the characteristic cytokines. The CD41 T cell commitment to the production of those cytokines in the case of Th1 and Th2 subsets is largely stable, but the Th17 and Treg subsets do show considerable plasticity and interconvertibility. Despite the fact that cytokines are mediators or “intermediaries,” they can play pivotal direct or indirect roles in the capacity of the immune system to distinguish between self and nonself. Overactivity of cytokines or of their receptors such as members of the IL-17 pathway that play a proinflammatory role can lead to excessive immune responses and decreases in the ability to differentiate between self and nonself. Thus, the IL-17 family of cytokines often mediates autoimmune reactions. Conversely, failure to produce antiinflammatory cytokines or defective

**FIGURE 15.1** Helper T cell “differentiation” and master regulators. Source: Adapted from O’Shea, J.J., Paul, W.E., 2010. Mechanisms underlying lineage commitment and plasticity of helper CD4 + T cells. *Science* 327, 1098–1102.

responses by cytokine receptors such as the IL-10 pathway can also result in autoimmune or autoinflammatory conditions, since this usually also results in upregulation and overproduction of proinflammatory cytokines.

The interaction of activated “matured” DC and naïve CD4 T lymphocytes in various cytokine milieus results in phosphorylation of lineage-specific transcription factors and master regulators as follows: The Th1 subset is induced by DC-derived IL-12, and this is markedly augmented by IL-18 and by a positive feedback loop involving IFN $\gamma$ . IL-4 derived from mast cells and basophils initiates the induction of the Th2 lineage. This can be augmented by IL-33 and thymic stromal-derived lymphopoietin (TSLP). TGF $\beta$  with the help of IL-6 and/or IL-21 induces Th17 lineage cells. This lineage is augmented by IL-1 and maintained by IL-23. TGF $\beta$  converts naïve CD41 cells to induced Tregs. Their survival requires IL-2, and they are expanded in numbers by cytokines such as TNF interacting with TNFR2. The “augmenting” cytokine ligands upregulate expression of selected cytokine receptors on the subsets enabling them to expand and maintain the lineage and its production of additional characteristic cytokine products.

The Th1 and Th2 lineages are largely stable, but the Th17 lineage can develop into dual Tbet and ROR $\gamma$ t expressing cells that produce both IL-17A and IFN $\gamma$ . Some of the Th2 subset can become IL-9 producing cells (Th9), while some of the Th17 cells or naïve CD41 T cells can go on to produce IL-22 and have been termed Th22. Some Tregs secrete the immunosuppressive IL-10 cytokine (Tr1 subset), while others express TGF $\beta$  on their cell membranes (Th3 subset) or membrane-associated CTLA4. The Treg subset is the most plastic and can develop into FoxP3 expressing cells that also express Tbet, GATA3, or ROR $\gamma$ t resulting in effector cells that are no longer suppressive but function as Th1, Th2, or Th17 cells.

Recently, “innate” lymphoid cells (ILCs) were identified that lacked T cell receptors and were therefore unable to participate in adaptive immune responses (Spits et al., 2013; Walker et al., 2013). Although small in numbers, these ILCs play important roles in lymphoid tissue development and the initiation of inflammation and throughout the duration of immune responses by promoting the transition to adaptive immunity and contributing to chronic inflammation based on their strategic location at mucosal barriers and in proximity to epithelial surfaces. The ILCs can be identified as belonging to three distinct groups. ILC1s that express Tbet and predominantly produce IFN $\gamma$  and contribute to cell-mediated Th1 protective immunity. The ILC1s are regulated differently and therefore distinct from cytotoxic natural killer (NK) cells. ILC2s express GATA3 and produce predominantly IL-5, IL-9, and IL-13, but also IL-4 and granulocyte macrophage colony-stimulating factor (GM-CSF). ILC2s not only protect against parasites and fungi but also promote allergic diseases and asthma. ILC3s express ROR $\gamma$ t and are a source of IL-17 and IL-22 and play a role in autoimmune diseases such as psoriasis and multiple sclerosis (MS). Some plasticities of these ILCs have been reported, and ILC3s can become ILC1 IFN $\gamma$  producers. They do not develop into T receptor-expressing T cells.

## CYTOKINE RECEPTOR SUBSETS

### The Common $\gamma$ c Chain Subset

Cytokines can be classified based on their structure, functions, gene locations, cells of origin, or targets, but such groupings lead to difficulties because of their pleomorphic overlapping effects. Although some cytokines exhibit homologous amino acid sequences, they can best be categorized based on their utilization of related members of receptor families which determines their target cells and effects.

The class I (hematopoietin) family of cytokines includes the common  $\gamma$ c utilizing subfamily of cytokines including IL-2, 4, 7, 9, 15, and 21 as well as the TSLP “stepbrother” of IL-7. Mice with defective  $\gamma$  common chain genes develop severe combined immune deficiency (SCID) syndrome and lack T and B cell immune host defenses against infectious agents as reviewed in Liao et al. (2011).

IL-2 was initially discovered as a mitogenic factor for T and B cells but subsequently also figured prominently in mediating the process of apoptosis (activation-induced cell death) of lymphocytes. IL-2 is produced by CD41 T cells and uses a receptor consisting of three chains IL-2R $\alpha$ ,  $\beta$ , and  $\gamma$  as reviewed by Akdis et al. (2011). The development of IL-2 deficient mice unexpectedly results in hyperplastic lymphadenopathy associated with autoimmune hemolytic anemia. This subsequently was attributed to the crucial role of IL-2 in maintaining the survival and expansion of CD251 (IL-2R $\alpha$ ) expressing Tregs. Scurvy mice based on defective Foxp3 genes also lack CD251 Tregs. Consequently, they have hyperactive CD41 T cells and overproduce proinflammatory cytokines. The homologous human autoimmune disease is known as “immune dysregulation, polyendocrinopathy, enteropathy, and X-linked.” Thus, the IL-2 function of supporting Tregs is crucial in preventing autoimmune disease.

IL-15 is structurally homologous to IL-2, but is produced by nonlymphoid cells (Di Sabatino et al., 2011). IL-15 interacts with a heterotrimeric receptor consisting of IL-2 15R $\beta$ ,  $\gamma$ C, and a unique IL-15R $\alpha$  chain. IL-15 is a more effective stimulant of NK cells, but less active in stimulating Treg cells than IL-2. Deletion of IL-15 or IL-15R $\alpha$  results in mice deficient in DC, NK cells, and DC81 memory T cells. Defective IL-15 production in mice has also been associated with increased susceptibility to infectious challenges. Conversely, IL-15 overproduction has been shown to play a crucial pathogenic role in a number of autoimmune diseases. Neutralizing antibodies to IL-15 have been shown to decrease inflammation in mouse models of rheumatoid arthritis (RA), psoriasis, and experimental autoimmune encephalomyelitis (EAE).

Another  $\gamma$ C cytokine is IL-7 which serves to develop and maintain a stable number of T, pre-B lymphocytes, and ILCs. This product of stromal cells thus maintains lymphocyte homeostasis by interacting with a receptor consisting of an IL-7 R $\alpha$  and the  $\gamma$ C chains. The absence of a functional IL-7 ligand or IL-7R $\alpha$  chain in mice and humans also yields a SCID phenotype, since IL-7 is required for the generation as well as maturation and survival of all T and B cells. Human polymorphisms of IL-7R resulting in excessive inflammatory and immune reactions are a risk factor for a variety of autoimmune diseases. Another gain of function mutation of IL-7R is associated with acute lymphoblastic leukemia (Mazzucchelli et al., 2012).

The deletion of IL-7 R $\alpha$  in mice also inhibits the functions of TSLP, which is produced by epithelial cells and uses a heterodimeric receptor consisting of TSLP-R and IL-7R $\alpha$  chains (Ziegler, 2010). TSLP is a potent inducer of Th2 responses and production of proallergic cytokines such as IL-4 and 13 by T and B cells, DC, mast cells, eosinophils, and macrophages. Mutations causing overproduction of TSLP result in mice with severe atopic dermatitis, and TSLP is necessary and sufficient to produce airway inflammatory disease in mice. Although they share a receptor chain, IL-7 functions to maintain the normal level of lymphocytes, while its stepbrother TSLP promotes Th2 immune responses.

IL-21 is a pleiotropic type I cytokine that is a product of CD41 T cells belonging to Th17 and T follicular helper (Tfh) subsets and NK T cells (Spolski and Leonard, 2010). The Tfh subset of cells has been reported to originate from naïve CD4 T cells by stimulation of Stat 5 and to express Bcl-6 as its master regulator. These T cells express CD41 CXCR51 ICOS1 markers and are located in germinal centers of lymph nodes. Tfh cells produce high levels of IL-21 and promote B cell antibody production and exhibit considerable plasticity. IL-21 is a potent inducer of proliferation and differentiation of CD41 and CD81 T cells, NK T cells, B cells, DC, macrophages, and epithelial cells including terminal differentiation and apoptosis. IL-21 interacts with the IL-21 R/ $\gamma$ C heterodimer. IL-21 stimulates a wide variety of target cells and contributes to the development of both innate and adaptive immunity. IL-21 does this in part by priming Th17 cells and by upregulating their IL-23R expression. IL-21 can also have feedback downregulatory effects by inducing Tr1 cells to produce IL-10 and by arresting DC in an immature state.

IL-21 along with TGF $\beta$  and IL-4 may also induce Th9 cells to produce IL-10. IL-21 stimulated B cells also are a rich source of IL-10. Despite these antiinflammatory effects, studies of IL-21 and IL-21R knockout mice show markedly reduced IL-17 production and reduced development and progression of EAE and systemic lupus erythematosus (SLE). Although IL-21 effects may be tempered by IL-10, overall IL-21 is a proinflammatory effector cytokine.

IL-9 is another pleiotropic cytokine that is produced by a distinct subset of T lymphocytes and mast cells and has therefore been termed a selective product of a unique Th9 pathway (Noelle and Nowak, 2010). However, it is unclear whether IL-9 is a product of stably differentiated cells or whether they exhibit plasticity. IL-9 can also be produced by the Th17 subset and can be coexpressed by IL-17A and by "redifferentiated" Tregs. TGF $\beta$  in the presence of IL-4 induces stat 6-dependent IL-9 production by GATA3 rather than by Fox3 expressing cells. The PU.1 transcription factor is also essential for the development of Th9 cells. IL-9 utilizes a heterodimeric receptor with IL-9R and  $\gamma$ C chains. IL-9 behaves like a Th2 cytokine. Mice deficient in IL-9 or IL-9R $\alpha$  are deficient in generating mast cells. In contrast, IL-9 induces mast cells to produce IL-1 $\beta$ , IL-5, IL-6, IL-9, IL-10, and IL-13. IL-9 is associated with allergic inflammation and immunity to extracellular parasites. Furthermore, adoptive transfer of Th9 polarized cells can promote the development of EAE and experimental autoimmune uveitis (EAU). Conversely, IL-9R $\alpha$  deficiency or neutralizing anti-IL-9 partially ameliorates EAE.

## The $\beta$ C Utilizing Subset

Another class I subset of cytokines, including GM-CSF, IL-3, and IL-5, interacts with heterodimeric receptors including a  $\beta$ C chain (Bellanti et al., 2012). In addition, each of these cytokine ligands uses a distinctive receptor chain. GM-CSF is produced not only by T cells and macrophages but also by endothelial cells and fibroblasts.

GM-CSF is a colony-stimulating factor that induces progenitor cells in the bone marrow to differentiate into granulocytic and myelocytic lineage cells. Transgenic mice overproducing GM-CSF developed increases in neutrophils, eosinophils, macrophages, and committed precursors of erythroid and megakaryocytes, which proved lethal because of the excessive inflammatory consequences. In vitro culture of monocytes with GM-CSF results in the development of DC, while in vivo local injections of GM-CSF or of tumor cells transfected to produce GM-CSF results in the in situ accumulation of DC and enhances tumor immunity.

Surprisingly, GM-CSF deficient mice exhibited normal hematopoiesis and myelopoiesis. Only infectious challenge revealed modest defects in granulocyte and macrophage responses. However, GM-CSF deficient mice do develop pulmonary alveolar proteinosis (PAP) and humans with PAP have high titers of anti- $\beta$ c antibodies or anti-GM-CSF. Since treatment with GM-CSF benefits such patients, PAP may be due to GM-CSF deficiency, which results in dysfunctional macrophages that fail to clear and metabolize surfactant lipoproteins. The GM-CSF deficient mice did accumulate lymphoid and mononuclear cells around their airways and pulmonary blood vessels. They also developed T cells deficient in IFN $\gamma$  production and cytotoxicity and decreases in B cell antibody production. GM-CSF knockout mice were resistant to lipopolysaccharide (LPS) challenge and resisted induction of autoimmune arthritis and EAE. Although the hematopoietic effects of GM-CSF appear to be redundant, GM-CSF has considerable proinflammatory cytokine functions.

IL-5, a Th2 cytokine produced by T cells and mast cells, is a critical regulator of eosinophil expansion in the bone marrow and peripheral blood and tissues in response to allergic and parasitic stimuli (Akdis et al., 2011). However, eosinophil migration is regulated by eotaxin (CCL11) and other chemokines and its development by hematopoietic growth factors. IL-5 deficient mice develop reduced numbers of mature functional eosinophils, but there is partial redundancy with other cytokines such as GM-CSF and IL-3.

IL-3 is a product of activated T cells that stimulates the proliferation, differentiation, and activation of multiple hematopoietic progenitor cells, mast cells, basophils, neutrophils, macrophages, eosinophils, and DC. IL-3 thus promotes antigen presentation to T cells and enhances macrophage cytotoxicity. IL-3 deficient mice, however, are normal, and its functions are redundant except for a reduced mast cell production in response to stem cell factor and parasitic challenge. They also produce fewer basophils in response to parasitic infections, and their contact hypersensitivity responses were also diminished.

### The gp130 Utilizing Subset (Interleukin-6 Family)

A third subfamily of class I cytokines utilizes a signal transducing gp130 receptor chain in common with a unique binding chain for each of the nine cytokine ligands in the family. They include IL-6, IL-11, IL-27, IL-31, leukemia inhibiting factor, oncostatin M, ciliary neurotrophic factor, cardiotropin-1, and cardiotropin-like cytokine (Akdis et al., 2011). Although these cytokines share one signaling chain, they have widely divergent functions depending on the cellular location of their unique binding chains.

IL-6 is one of the most important pleomorphic proinflammatory cytokines. IL-6 is produced not only by macrophages and activated T lymphocytes but also by fibroblasts, endothelial cells, and other somatic cells. IL-6 interacts with IL-6R $\alpha$ , which is restricted to certain tissues. However, IL-6R $\alpha$  is frequently shed and available in a soluble form that complexes IL-6. These complexes can trigger the widely expressed gp130 receptor and initiate signal transduction by JAK and STAT transcription factors. This enables IL-6 to activate T and B cells, macrophages, megakaryocytes, hepatocytes, endothelial cells, neuronal cells, and fibroblasts. This can result in local inflammation, but IL-6 often becomes available in the serum resulting in fever and acute phase responses. IL-6 is a potent inducer of B cell proliferation with the potential of developing plasma cell tumors (multiple myeloma) and growth of neuronal cells. Stimulation by the two other major proinflammatory cytokines, IL-1 and TNF, can induce IL-6 production and IL-6 can synergize with these cytokines. Consequently, IL-6 is a major exacerbator of autoimmune inflammatory diseases (Barr et al., 2012). Neutralizing anti-IL-6 antibodies have been used with therapeutic success to treat not only Castleman's disease, a form of plasma cell leukemia but also juvenile idiopathic arthritis and RA. Anti-IL-6 has been used successfully in some RA patients that were unresponsive to inhibitors of TNF.

### Cytokines Sharing Either a p35 or p40 Ligand Chain

The so-called IL-12 cytokine family consists of cytokines with an  $\alpha$  chain (p19, p28, or p35) and a  $\beta$  chain (p40 or EBI3) as follows: IL-12 (p35 and p40), IL-23 (p19 and p40), IL-27 (p28 and EBI3), and IL-35 (EBI3 and p35) (Akdis et al., 2011).

IL-12 is produced mostly not only by myeloid DC and macrophages but also by activated B lymphocytes and neutrophils. IL-12 utilizes a heterodimeric receptor formed by IL-12R $\beta$ 1 and IL-12R $\beta$ 2. IL-12R $\beta$ 2 appears to be the signaling component of the receptor on Th1 lymphocytes and NK cells that become tyrosine phosphorylated and activate Tyk2 and JAK2 and subsequently Stat 4. This enables IL-12 to play a crucial role in promoting Th1-dependent cytotoxicity of T cells and NK cells and their production of IFN $\gamma$ . IL-2 promotes this pathway by enhancing expression of the IL-12R, while IFN $\gamma$  promotes the production of more of the IL-12 cytokine, resulting in a positive loop. IL-12 has antiangiogenic effects by inducing IFN $\gamma$ , which in turn produces an angiostatic chemokine known as IP-10 or CXCL10. Mice defective in IL-12 p40 or IL-12R become much more susceptible to infections by intracellular pathogens such as mycobacteria and even nonpathogenic Bacille Calmette–Guerin organisms. Such knockout mice are much more resistant to the induction of autoimmunity, while administration of IL-12 exacerbates autoimmune conditions (Adorini, 2003). These results point out the important contribution of Th1 immune responses to various autoimmune states including EAE, EAU, RA, autoimmune myasthenia gravis, and autoimmune thyroiditis. Furthermore, an anti-IL-12 antibody has induced clinical responses and remissions in patients with Crohn's disease (Mannon et al., 2004).

IL-23 is a heterodimeric cytokine, which shares a p40 chain with IL-12. Like IL-12, IL-23 is produced by APCs such as DCs and macrophages and synovial fibroblasts. IL-23, however, has unique functions of stimulating committed Th17 memory cells that express the heterodimeric receptor for IL-23 consisting of IL-23R and IL-12 R $\beta$ 1. IL-23 serves to maintain Th17 responses by inducing the production of IL-17A, IL-17F, TNF, IL-6, GM-CSF, IL-22, and some chemokines (CXCL1 and CCL20). Knockout mice with deficiencies in either p19 or IL-23R develop less severe autoimmune inflammatory bowel disease (IBD) and EAE. This presumably is based on the reduced production of Th17 cytokines, which are important contributors to autoimmune inflammatory states. An anti-p40 antibody, which inhibits both IL-12 and IL-23, has therapeutic efficacy in psoriasis (Krueger et al., 2007).

IL-27 is reported to be a product of DC and macrophages as well as epithelial cells that interact with a receptor consisting of an IL-27R and the gp130 chains. Consequently, IL-27 belongs to both IL-6 and IL-12 subfamilies. IL-27 synergizes with IL-12 in activating T cells to produce IFN $\gamma$  with consequent Th1, antiangiogenic, and antitumor effects. IL-27 also suppresses the development of Th17 cells and can induce considerable IL-10 production by Tregs with antiinflammatory effects (Pot et al., 2011). IL-27 gene deletion results in mice with hyperreactive Th2 inflammatory responses to challenges with pathogenic parasitic organisms. Oral administration of IL-27 expressing lactococci by inducing mucosal IL-10 production suppresses IBD in mice. IL-27 also upregulates checkpoint expression by Tregs (Do et al., 2016). In addition, IL-27 has been shown to stimulate hematopoietic stem cells to produce myeloid progenitor cells (Hasegawa et al., 2016). Thus, the suppressive functions of IL-27 are more dominant.

IL-35 is reported to be a product of Treg cells and has suppressive effects on Th17 cells and CD4 $^1$  CD25 $^2$  T cells. IL-35 also can convert T cells to become FoxP3 Tregs, and this is known as "infectious tolerance." Furthermore, IL-35 is reported to stimulate the proliferation of Treg cells. IL-35 upregulates expression of multiple checkpoints by Tregs as well (Turnis et al., 2016). IL-35 also expands IL-35 producing B cells and protects from EAU. It is therefore said to be an immunosuppressive product contributing to the effects of Tregs. This cytokine has recently been reported to promote testicular immune privilege. Thus, IL-35 prevents autoimmunity but suppresses antitumor immunity (Hasegawa et al., 2016).

## Th17 Cytokines and Receptors

It was recently recognized that in addition to the Th1 IFN $\gamma$  cytokine, a family of IL-17 cytokines is a major contributor to autoimmune reactions; especially IL-17A and IL-17F, which show 50% homology (Iwakura et al., 2011). IL-17 is induced by the combination of TGF $\beta$  and IL-6 and is maintained by IL-23 and/or IL-1. IL-17 is produced mainly by Th17 CD4 and CD8 T cells, NK cells and by ILC3s. IL-17 activates neutrophils, T cells, APCs, and fibroblasts, endothelial cells, and stromal cells expressing various IL-17 receptors. IL-17A and IL-17F utilize IL-17RA and IL-17RD receptors, respectively, while IL-17B, C, and D use IL-17RB. IL-17 induces many other inflammatory cytokines, chemokines, and prostaglandins. Consequently, IL-17 is important in driving acute inflammatory as well as allergic and autoimmune responses. IL-17 actually has suppressive effects on the Th1 pathway and the production of IFN $\gamma$ . Nevertheless, T cells producing both IL-17 and IFN $\gamma$  have been detected. IL-17 promotes the production of proinflammatory cytokines such as IL-6, GM-CSF, G-CSF, IL-1 $\beta$ , TNF, IL-21, IL-22, IL-26, IL-11 various chemokines, and even TGF $\beta$ . Deletion of IL-17A and/or IL-17F or their receptors results in mice with markedly reduced resistance to infectious challenges. Airway hypersensitivity and T cell-dependent

antibody production are also considerably reduced. These IL-17A and F knockout mice develop less severe collagen-induced arthritis (CIA) and resist induction of EAE. Attempts to suppress autoimmune diseases in mouse models with neutralizing anti-IL-17 antibodies have not met with resounding success, perhaps because multiple redundant Th1 and Th2 cytokines all are involved in exacerbating the inflammation in these diseases. A humanized anti-IL-17 antibody has been effective in the treatment of RA ([Genovese et al., 2010](#)).

IL-25 (IL-17E) is produced by Th2 lymphocytes, mast cells, basophils, eosinophils, and epithelial cells ([Akdis et al., 2011](#)). IL-25 utilizes a receptor consisting of IL-17RA and IL-17RB chains. Receptor deleted mice fail to produce IL-5 or IL-13 in response to IL-25. Consequently, IL-25 is an inducer of Th2 and Th9 responses (IL-4, 5, and 13) and actually suppresses Th1 and IL-17 production. In particular, IL-25 is prominently involved in chronic inflammation of the gastrointestinal (GI) tract, including in IBD. IL-25 knockout mice show reduced eosinophil infiltration in allergic states due to the reduction in Th2 and Th9 responses.

## CLASS II CYTOKINE RECEPTOR FAMILY

The class II receptors are utilized by the interferon family (IFN- $\alpha$ ,  $\beta$ ,  $\gamma$ ) and also by IL-10, 19, 20, 22, 24, 26, 28, 29, and 30. The receptors consist of one ligand binding and one signal transducing chain. The interferons are the major host defense cytokines directed against viruses, bacteria, parasites, and fungi. They include IFN- $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\lambda$  (consisting of IL-28 and IL-29). The other family members have a diversity of functions.

### Type I Interferons $\alpha$ and $\beta$

There are actually 13 subtypes of IFN- $\alpha$  and two subtypes of IFN- $\beta$  ([Huber and Farrar, 2011](#)). IFN $\alpha/\beta$  both interact with the type I IFN receptor, which consists of two subunits, IFNAR1 and IFNAR2, and are widely expressed by all nucleated cells. The type I IFN- $\alpha/\beta$  are induced by a wide variety of exogenous and endogenous proinflammatory stimulants (especially viral infections) in many cell types. Plasmacytoid DCs are major producers of IFN- $\alpha$  and IFN- $\alpha$  is particularly elevated in patients with SLE and psoriasis. The fever and fatigue seen in active SLE are usually associated with high levels of type 1 IFN in the blood. Fibroblasts are a greater source of IFN- $\beta$ . Although many functions have been ascribed to IFN- $\alpha/\beta$ , mice knocked out for IFNAR1 exhibit predominantly reduced antiviral host defenses and some reduction in their responses to LPS and CSF-1. Null mutations of IFNAR genes also reduce SLE-like disease in mouse models ([Saadeh et al., 2016](#)). However, genetic polymorphisms resulting in the elevation of IFN- $\alpha$  predispose to the development of human SLE ([Niewold, 2011](#)). IFN- $\alpha/\beta$  are potent stimulators of the maturation of myeloid DC and thus promote adaptive immunity, but this is a redundant function. IFN- $\alpha$  is used in the treatment of hepatitis B and C. IFN- $\beta$  has been used to treat MS, but the mechanism by which IFN- $\beta$  suppresses symptoms and signs of MS may be based on suppression of IL-17 producing T cells. IFN- $\alpha/\beta$  therapy is associated with unpleasant flu-like side effects similar to those seen in SLE patients with elevated IFN $\alpha$  levels.

### Type II Interferon Gamma

IFN- $\gamma$  actually has minimal antiviral activity and is the major immunoregulatory product and coinducer of the Th1 cytokine pathway. IFN- $\gamma$  enhances autoimmunity ([Akdis et al., 2011](#)). It is selectively produced by T lymphocytes, NK cells, and ILC1 cells. There are reports claiming that IFN- $\gamma$  is also produced by macrophages, neutrophils, and B cells, but their contribution, if any, is minor. IFN- $\gamma$  utilizes a receptor consisting of IFNGR1 and IFNGR2 expressed by NK cells, macrophages, Th1 lymphocytes, CD81 CTL, and B cells. IFN- $\gamma$  has a major role in protecting against intracellular bacteria, based on its macrophage activating effects. Humans with gene defects in the IFN $\gamma$  pathway and mice lacking IFN- $\gamma$  or the IFNGR exhibit markedly reduced resistance to mycobacteria and other intracellular bacterial, fungal, and parasitic infections. Macrophage production of nitric oxide, TNF, IL-1, IL-12, and IL-6 is impaired. Unexpectedly, IFN- $\gamma$  knockout mice were not more resistant to the induction of EAE or uveitis, but more readily developed arthritis. Instead, IFN- $\gamma$  was found to be critical in suppressing chronic inflammation and restoring T cell homeostasis by promoting T cell apoptosis. Administration of IFN- $\gamma$  exacerbates MS. Chronic long-term exposure to low levels of IFN- $\gamma$  leads to a lupus-like autoimmune syndrome in mice ([Hodge et al., 2014](#)). IFN- $\gamma$  is used therapeutically to treat infections in patients with chronic granulomatous disease.

### Type III Interferon Lambda

The recently identified subgroup of IFN-λ 1, 2, and 3 are also termed as IL-29, IL-28A, and IL-28B, respectively ([Donnelly and Kotenko, 2010](#)). These cytokines utilize a heterodimeric receptor consisting of an IL-28R chain and IL-10R2 chain. The IFN-λs have both antiviral and immunostimulatory activities. Since the receptors for the IFN-λ are selectively expressed on epithelial cells, they may have fewer undesirable side effects than IFN-α and have demonstrated initial efficacy in the treatment of hepatitis. IL-28 may also have a protective role in EAE and is being investigated as a therapy for autoimmunity.

### Noninterferon Members

IL-10, another family member, has no antiviral activity but is an active immunomodulatory mediator that uses a heterodimeric receptor consisting of IL-10R1 and IL-10R2 chains ([Saraiva and O'Garra, 2010](#)). IL-10, a homodimeric cytokine, is produced by many cell types including Th1, Th2 lymphocytes, cytotoxic T cells, B lymphocytes, mast cells, monocytes, DCs, and the Tr1 subset of Tregs. IL-10 has many suppressive effects by inhibiting proinflammatory cytokine production and activities of T cells, NK cells, mononuclear phagocytes, and DC. However, IL-10 also has stimulatory effects particularly for B cells and promotes B cell proliferation, differentiation, and antibody production and induces isotype switching. Furthermore, by capturing and sequestering antigens, antibodies may, in turn, suppress cellular immune and inflammatory responses, thus further supporting the antiinflammatory role of IL-10.

Stat 3 is essential for the suppressive effects of IL-10 on cytokines since IL-10 fails to have such an effect on Stat 3 knockout mice. Stat 3 depleted mice become hypersensitive to endotoxic shock and develop chronic enterocolitis (IBD). The suppressive effects of IL-10 also involve the induction of inhibitory SOCS 1 and 3 signal transducers. IL-10 immunosuppressive effects, thus, protect the host from excessive inflammatory responses including allergic reactions. IL-10 knock-out mice show normal lymphocyte development and antibody responses, but they develop runting, anemia, and chronic colitis (IBD) due to excessive production of proinflammatory cytokines in response to enteric bacterial antigens. Polymorphisms reducing the effectiveness of IL-10 have resulted in a variety of human autoimmune diseases. IL-10 has a protective role in autoimmune diseases such as SLE, RA, and type 1 diabetes.

The other members of the class II cytokine receptor family, although members of the IL-10 family, have distinct nonimmunosuppressive functions ([Akdis et al., 2011](#)). These cytokines are also considered members of the IL-20 subfamily of cytokines and include IL-19, 20, 22, 24, and 26. They utilize common receptor subunits on target cells, thereby enhancing innate defense mechanisms and tissue repair processes at epithelial surfaces ([Rutz et al., 2014](#)). This is especially true of IL-22 ([Perusina Lanfranca et al., 2016](#)). IL-22 is usually considered a product of the Th17 pathways, although it is also induced by IL-9. IL-22 interacts with receptors consisting of IL-22R1 and IL-10R2. IL-22 is produced by nonlymphoid cells such as macrophages, fibroblasts, and mast cells. IL-22 is also produced by Th17, NK-22, and ILC22 cells and acts primarily on keratinocytes and epithelial lining cells, which express IL-22R1. IL-22 deficient and IL-22R-deficient mice have increased intestinal epithelial damage and become much more susceptible to *Citrobacter rodentium* infection. Thus, IL-22 plays a major role in the maintenance and repair of epithelial lining tissues. IL-22 levels are elevated in psoriasis and IBD. Prolonged expression of IL-22 can lead to chronic inflammation and cancer.

IL-19 shares the IL-20R receptor with IL-24 and IL-26. Since it augments IL-4, 5, 10, and 13 but decreases IFN $\gamma$  production, IL-19 favors Th2 responses. IL-19 is elevated and IL-19 polymorphisms have been associated with psoriasis. Conversely, IL-19 deficient mice more readily develop IBD with increased levels of Th1 cytokines such as IFN- $\gamma$  and also the elevation of IL-1 $\beta$ , IL-6, IL-12, TNF, and KC ([Leng et al., 2011](#)). Thus, IL-19 behaves as an immunosuppressive cytokine.

IL-20 is also elevated in psoriasis and RA, and IL-20 polymorphisms are associated with psoriasis. IL-20 is produced in particular by monocytes, DC, and synovial fibroblasts ([Leng et al., 2011](#)). IL-20 is proangiogenic and a keratinocyte stimulant. IL-20 can be considered a proinflammatory cytokine.

IL-24 promotes wound healing and is apoptotic for some tumor cells. IL-24 is elevated in melanomas and psoriasis. IL-26 is a proinflammatory cytokine, which is absent in mice and difficult to study. IL-26 is elevated in IBD and polymorphisms of IL-26 are protective of MS and RA.

Overall, this IL-20 subfamily is primarily produced by leukocytes and act on epithelial tissues. The IL-20 subfamily members synergize with other proinflammatory cytokines, thus exacerbating autoimmune and chronic inflammatory conditions. They have unique functions in protecting tissues and promoting regeneration and wound healing ([Rutz et al., 2014](#)).

## TUMOR NECROSIS FACTOR RECEPTOR FAMILY

The TNF family consists of 19 cytokines, which use 29 structurally related receptors that share intracellular signaling pathways (Aggarwal et al., 2012). TNF was discovered as a factor in serum that was cytotoxic for tumors (Carswell et al., 1975). TNF is produced by T and B cells, NK cells, and macrophages. Although it interacts with the widely expressed TNFR1 receptor that contains a death domain, TNF acts on immune, endothelial, and other cell types as a major proinflammatory cytokine that mediates acute and chronic inflammatory responses to bacterial infections. TNF stimulates the hypothalamic–pituitary axis to release numerous hormones, induces liver-derived acute phase proteins, activates endothelial cells to express adhesion molecules, and results in egress of TNF activated leukocytes out of blood vessels. Thus, systemic TNF can cause fever, myalgias, malaise, hypotension, vascular leakage, cachexia, osteoporosis, and other signs of inflammation. Nevertheless, studies of mice with deletion of TNF or TNFR1 receptors showed increased resistance to development of endotoxin shock, resistance to carcinogenesis, reduced resistance to infectious challenges, and partial resistance to induction of EAE. A number of polymorphisms of the human TNF gene resulting in excessive activity have been associated with a variety of autoimmune diseases. TNF promotes inflammation and exacerbates autoimmune disorders such as RA, ankylosing spondylitis, Crohn's disease, and psoriasis. This can be countered by treating patients with these disorders with inhibitors of TNF such as anti-TNF antibodies or soluble receptors for TNF. Such immunotherapies do reduce host resistance and can result in activating latent tuberculosis infections. Despite this TNF, the blockade has benefited millions of autoimmune patients.

The second receptor for TNF, TNFR2, is expressed mostly on T lymphocytes and NK cells. TNFR2 is predominantly expressed on all naturally occurring Tregs and activated-induced Tregs (iTregs). Consequently, ligand-induced signals from TNFR2 provide a major means of downregulating proinflammatory effects of TNF stimulation of TNFR1.

Lymphotoxin (LT) $\alpha$  is the closest relative of TNF and also utilizes TNFR1 and 2. LT $\beta$  also utilizes two other receptors (LT $\beta$ R and HVEM). The LT name also represents a misnomer based on their initial discovery as in vitro cytotoxic activities (Ruddle and Waksman, 1967). LT is produced by activated T cells, NK cells, mast cells, fibroblasts, and endothelial and epithelial cells. Studies of knockout mice yielded the surprising revelation that LT was crucial for the organogenesis and maintenance of peripheral lymphoid tissues. Mice deficient in LT had only rudimentary lymph nodes and Peyer's patches and a disorganized splenic lymphoid architecture. Although LT $\alpha$  also uses TNFR1 and TNFR2, the unique effects of LT are based on the fact that LT $\alpha$  forms heterotrimeric complexes with lymphocyte membrane-associated LT $\beta$ , which then act on LT- $\beta$ R. In contrast, LT $\alpha$  homotrimers by acting on TNFR1 can mimic the effects of TNF. Consequently, double TNF/LT $\alpha$  knockout mice become even more susceptible to bacterial challenge than single knockout mice. Although the antibody responses and immunoglobulin switching by such mice are defective, their cellular immune responses remain fairly intact based on redundant pathways.

LIGHT also binds to LT $\beta$ R as well as HVEM receptors. It is more active in tissue remodeling and protecting epithelium than in autoimmune processes. Although proinflammatory, TWEAK and its receptor Fn-14 when blocked have not as yet been shown to ameliorate any antiimmune conditions (Croft and Siegel, 2017). Some of the other members of the TNF superfamily contribute to autoimmune disorders. Humans with disabling heterozygous mutations in the “fragment apoptosis stimulating” (Fas/CD95) receptor develop a disease called autoimmune lymphoproliferative syndrome with lymphadenopathy, splenomegaly, and the production of autoantibodies (Lobito et al., 2011). This is based on failure to remove long-lived lymphocytes by the usual Fas-dependent apoptotic mechanism (Strasser et al., 2009). The homotrimeric FasL triggers the Fas receptor, which contains a death domain, and results in the elimination of senescent lymphocytes. In the absence of normal Fas or FasL functions, humans and mice develop B cell lymphomas and autoimmune syndromes based on the accumulation of senescent and defective lymphocytes.

Another family member, “TNF-related apoptosis-inducing ligand” (TRAIL), similarly acts on death domain expressing DR4 and DR5 receptors. In addition to mediating antitumor effects, mice with deletion of TRAIL or its receptors develop autoimmune diseases. Analogous to Fas deletion, the absence of TRAIL results in failure to eliminate senescent and defective lymphocytes by apoptosis.

A number of the TNF family of cytokines are potent stimulants of B cells and have been implicated in causing or exacerbating SLE. This is true of the B cell activating factor member of the TNF family known as BAFF or BLYS or BLVS (Vincent et al., 2012). BAFF is a product of activated T cells, macrophages, and DCs. BAFF

interacts with two receptors known as TACI and BR3 expressed by B and T cells. In addition, BAFF heterotrimerizes with another TNF family member known as APRIL, which interacts with TACI and BCMA receptors (Cancro et al., 2009). Mice with deletion of a functional BAFF show impaired development of B cells, while mice with defective APRIL expression show impaired development of more mature plasma cells. Conversely, transgenic mice that overexpress BAFF have B cell hyperplasia and develop a lupus-like phenotype. Both BAFF and APRIL are elevated in SLE patients and other autoimmune diseases. A monoclonal anti-BAFF antibody that depletes B cells and shows therapeutic benefit has therefore been approved for use in SLE.

In the 1990s, mice deficient in CD40, CD40L, and wild-type mice treated with blocking reagents were shown to have markedly reduced inflammatory reactions despite being subjected to CIA and prone to lupus-like disease (Croft and Siegel, 2017). Furthermore, patients with genetic polymorphisms resulting in overproduction of CD40L and CD40 have increased susceptibility to a number of autoimmune disorders. Unfortunately, therapies with antagonistic antibodies have had serious thromboembolic effects and other antagonists are being developed.

TL1A is the ligand for death receptor 3 (DR3) and their interactions have proinflammatory consequences and may contribute to rheumatic diseases. Their inhibition can benefit arthritic patients and perhaps other autoimmune conditions (Croft and Siegel, 2017). Glucocorticoid-induced TNF-related ligand and its interaction with the GITR receptor stimulate T and B cells and DCs and can contribute to arthritis. GITR deficient mice display a reduction in CIA.

The CD70 ligand on DC and B cells interacts with CD27 receptors on T lymphocytes. Blocking of these interactions with anti-CD70 reduces bone and cartilage erosion in mice subjected to CIA. CD70 and/or CD27 are elevated in a variety of autoimmune diseases. In contrast, stimulation of 4-1BB (TNFSR9) with a receptor agonist results in marked suppression of joint inflammation and bone resorption in CIA mice. Further 4-1BB deficiency exacerbates lupus-prone MRL/lpr mice. Thus, 4-1BB and its ligand 4-1BBL act as suppressors of inflammation.

## THE INTERLEUKIN-1/TOLL-LIKE RECEPTOR FAMILY OF RECEPTORS

The IL-1 family has expanded to 11 members, but the three initial members have been most thoroughly studied (Sims and Smith, 2010). They consist of agonistic IL-1 $\alpha$ , which is usually cell membrane associated, the soluble IL-1 $\beta$ , and the soluble IL-1 receptor antagonist (IL-1RA). These ligands interact with the ubiquitously expressed type I IL-1R, which transduces signals that result in proinflammatory effects similar to those of TNF, except they do not induce apoptosis. IL-1RA acts as an antagonist of IL-1 $\alpha$  and IL-1 $\beta$  by binding tightly to type I IL-1R and competes with the agonist ligands for this receptor. The type II IL-1R also binds IL-1 $\beta$  and IL-1 $\alpha$  with high affinity but fails to signal and is therefore considered a “decoy” receptor, which traps the ligands. Thus, IL-1 is downregulated by these two mechanisms plus the inhibitory effect of shed type II IL-1R that can also capture IL-1 $\alpha$  and IL-1 $\beta$ . Furthermore, IL-1 $\alpha$  and  $\beta$  are generated with prodomains. IL-1 $\beta$  and IL-18 are generally, but not always, cleaved by caspase-1. This enzyme is generated by the “inflammasome” pathway, which is activated by microbial-derived ligands that interact with NOD-like receptors. This provides another means of regulating the activity of IL-1 $\beta$  as evidenced by the fact that genetically heritable gain of function mutations in the inflammasome pathway result in autoinflammatory periodic fever syndromes such as Muckle–Wells syndrome, familial Mediterranean fever, hyper-IgD syndrome, familial cold autoinflammatory syndrome, and others (e.g., NOMID, CINCA). IL-1 $\alpha$  is usually cleaved by calpain and other enzymes, rather than by inflammasome-derived caspase-1. IL-1RA contains a classical signal peptide and is secreted by the endoplasmic reticulum and Golgi apparatus like most other cytokines. The other IL-1 family members all are biologically active as full-length molecules, but enzymatic processing at their N-terminal ends increases their activities. The IL-1 family members all interact with closely related receptors containing extracellular immunoglobulin domains, and they signal through cytoplasmic Toll/IL-1R domains using the MyD88 signal transduction pathway, similar to that of the TLR.

There is another IL-1 family inhibitory receptor, SIGIRR, expressed largely on epithelial cells that decrease the inflammatory responses to IL-1, IL-18, IL-33, IL-36 $\alpha$ ,  $\beta$ ,  $\gamma$ , and to TLR ligands. This is based on observations showing that SIGIRR deficient mice have enhanced responses to these ligands and develop more severe IBD, asthma, and colon cancer. Thus, SIGIRR also downregulates responses to most of the IL-1 family members.

Despite the plethora of IL-1 activities, deletion of IL-1 $\alpha$  and/or  $\beta$  or of the type I IL-1R has limited deleterious effects on mice with only a modest decrease in cellular and humoral immune responses and decreased resistance to infectious challenges. IL-1/IL-1R deleted mice exhibit greater resistance to the induction of autoimmune

diseases. In contrast, deletion of IL-1-RA yielded dramatic phenotypic effects with hyperinflammatory reactions due to overproduction of inflammatory cytokines, enhanced delayed-type hypersensitivity, humoral immunity, increased resistance to infection, and enhanced induction of autoimmune states including spontaneous development of arthritis. These findings have led to the development of IL-1RA (anakinra) and other inhibitors of L-1 as therapeutics. These antagonists are having dramatic benefits in patients with autoinflammatory diseases. They are also benefiting patients with gain of function mutations in TNFR1 (TRAPS syndrome), Behcet's syndrome, gout, and are being investigated for their utility in type 2 diabetes, congestive heart failure, and other conditions (Dinarello, 2011).

IL-18 also is a member of the IL-1 family that is expressed by a wide range of cell types as an inactive precursor that requires cleavage by caspase-1 generated by the inflammasome pathway. IL-18 interacts with widely expressed heterodimeric IL-18R in which the  $\alpha$  chain binds and the  $\beta$  chain signals in response to IL-18. The IL-18 ligand by itself is a weak stimulant of IFN $\gamma$  (Th1) or IL-13 (Th2) responses, but IL-18 synergizes with IL-12 to produce high levels of IFN $\gamma$  or with IL-2 to produce more IL-13. A neutralizing IL-18 binding protein (IL-18BP) has been isolated from the urine of Italian nuns, which binds and inhibits IL-18 with high affinity. IFN $\gamma$  is a potent inducer of IL-18BP, thus it functions as a negative feedback inhibitor.

IL-18 promotes the development of Th1 responses and functions of NK cells in host defense against bacterial infections. Consequently, IL-18 deficient mice show reduced resistance to parasitic, viral, and bacterial infections. IL-18 is usually elevated in autoimmune diseases and IL-18 deficient mice develop less severe CIA and resist induction of IBD. Moreover, polymorphisms in the promoter regions of the human IL-18 gene have been associated with RA.

IL-33 functions as a nuclear binding transcriptional factor as well as an extracellular cytokine, like IL-1 $\alpha$ . Full-length IL-33, like IL-1 $\alpha$ , is also active, but it can be cleaved by caspase-1 from a 30 kDa to an active 18 kDa cytokine. IL-33 interacts with the ST2 receptor expressed on T helper cells, DCs, and mast cells. Although initially reported as a potent inducer of Th2 responses, more recent data indicated that IL-33 also can be a potent inducer of Th1 polarized cytotoxic CD8 T cells, ILC2 cells, NK cells, and Tregs. A soluble shed form of ST2 has the capacity to bind and inhibit IL-33. Thus, administration of sST2 reduces inflammation in an asthma model in mice and IL-33 as well as sST2 levels are elevated in autoimmune disorders such as SLE, IBD, and RA. Mice with defective ST2 receptors have reduced Th2 responses, increased sensitivity to endotoxin challenge, and increased susceptibility to streptozotocin-induced diabetes (Liew et al., 2016).

The newest IL-1 family members IL-36 $\alpha$ ,  $\beta$ ,  $\gamma$ , IL-36Ra and the antagonist IL-38 all bind to IL-36Ra. Binding of the agonists results in the production of proinflammatory mediators, whereas the antagonistic IL-36Ra and IL-38 prevent the signaling via MyD88 and IRAK4 of NF- $\kappa$ B and mitogen-activated protein kinases (Hahn et al., 2017). In contrast, IL-37 is an inhibitory cytokine that belongs to the IL-18 subfamily and binds to IL-18R. IL-36, IL-37, and IL-38 are products of epithelial cells and infiltrating mononuclear cells. These cytokines are all involved in psoriasis, inflammatory arthritis, lupus, and IBD. In addition, IL-37 may play an important role in the suppression of allergic asthma by suppressing mast cells (Conti et al., 2017).

## IMMUNOSUPPRESSIVE CYTOKINES/GROWTH FACTORS

We have already discussed immunosuppressive cytokines that play pivotal roles in preventing exuberant inflammatory reactions against nonself and self-antigens such as IL-10, IL-25, IL-27, IL-35, and IL-37. The other cytokine that plays a major suppressive role is TGF $\beta$ . TGF $\beta$  belongs to a family of over 40 cytokines that utilize serine threonine kinase receptors. Tregs and the subset of Th3 cells, as well as platelets, macrophages, NK cells, epithelial cells, and glial cells are major sources of TGF $\beta$ . It is usually classified as a growth factor because it promotes wound healing and fibrosis. Concomitantly, TGF $\beta$  has antiproliferative and suppressive effects on T and B cells, macrophages, endothelial cells, hematopoiesis, and suppresses inflammatory reactions which interfere with wound healing. Tumor cells often produce considerable TGF $\beta$  and thus have antiinflammatory and antiimmune effects.

Deletion of TGF $\beta$  in mice is lethal for neonatal mice. They exhibit uncontrolled T cell activation with excessive production of cytokines and die of a "cytokine storm" resembling the effects of "septic endotoxic shock." Conversely, overexpression of TGF $\beta$  results in renal fibrosis and diabetes. TGF $\beta$  is crucial in the generation of Treg cells from naïve T cells and in preventing the maturation of DC, which are crucial in preventing the development of autoimmunity. We will not discuss the other growth factors because they are not known to have direct effects on autoimmune responses.

## CHEMOKINES

There are over 40 chemoattractant cytokines (chemokines) that interact with over 20 different Gi protein-coupled receptors (GiPCR). These chemokines play a major role in the trafficking of inflammatory and non-inflammatory cells and are responsible for organogenesis of lymphoid and other tissues. Chemokines generally have minimal immune cell activating effects. Deletion of various chemokine or chemokine receptor genes have diverse effects depending on the distribution of their receptors. Although elevated in autoimmune diseases, chemokines are not directly responsible for any autoimmune disorders. Nevertheless, as key mediators in the pathogenesis of inflammatory, autoimmune, and neoplastic disorders, polymorphisms of various chemokine genes have been associated with a variety of diseases (Colobran et al., 2007). For example, SDF1/CXCL-12 and IL-8/CXCL-8 polymorphisms have been associated with SLE (Sandling et al., 2011; Wu et al., 2012), while defective CCR5 expression has a protective effect on RA.

## ALARMINs

There are a number of preformed constitutively available molecules residing in cell granules, cytoplasm, or binding to chromatin that are released by cellular degranulation or necrotic cell death (Yang et al., 2009). These “alarmins” have chemotactic/recruiting activity and also activating effects on mononuclear phagocytes and on DCs resulting in cytokine production and promotion of antigen presentation and adaptive immunity. Thus, alarmins are proinflammatory and enhance both innate and adaptive immunity. Alarmins are produced by a wide variety of leukocytes and nonleukocytes and interact with some GiPCR as well as TLR to yield chemotactic and activating effects, respectively. Some alarmins such as histamine, IL-33, and eosinophil-derived neurotoxin polarize Th2 responses, while others such as HMGB1 and HMGN1 are potent polarizers of Th1 responses. Most other alarmins such as defensins, cathelicidins, IL-1 $\alpha$ , and granulysin promote both Th1 and Th2 responses. IL-1 $\alpha$  and IL-33 as well as HMGB1 and HMGN1 are dual function alarmins because they act as nuclear binding proteins as well as cytokines with proinflammatory recruiting and activating effects. Many of these alarmins have been experimentally deleted in mice. Deletion of various antimicrobial defensins and cathelicidin results in reduced resistance to bacterial challenges. Defects in NOD2 with consequent defensin deficiency are associated with enhanced susceptibility to IBD in humans. This NOD2 defect results in overreactive inflammatory responses to GI flora in the microbiome. Deletion of HMGB1 has embryonic lethal effects, while deletion of HMGN1 results in immunodeficient mice with reduced tumor immunity.

Studies of the role of alarmins in autoimmunity are limited. HMGB1 is released passively by necrotic or damaged cells or actively by immune cell activation. Thus, IFN $\gamma$ , TNF, IL-1, the inflammasome pathway, and endotoxin stimulate macrophages to release HMGB1. HMGB1 activates TLR4-MD-2 chain directly and by complexing to other molecules such as RNA, DNA, IL-1 $\beta$ , CXCL-12, and TIM-3 can activate a wide variety of receptors and signal transduction pathways. HMGB1 is, therefore, a very potent immune stimulant, which is fortunately inactivated by ROS resulting in oxidation of its cysteine groups at sites of inflammation. HMGB1 has been associated with the development of RA and is elevated in their synovial fluid (Bertheloot and Latz, 2017). The levels of HMGB1 have been found to be elevated in a number of autoimmune conditions and are correlated with the degree of inflammation. HMGB1 is present in the nucleosomes of SLE serum and autoantibodies to HMGB1 have been detected in SLE sera.

The S100 family of proteins has 25 members that like other alarmins lack a leader sequence and can therefore not be secreted but are released by cells. The calgranulins S100A8/A9 are largely present in the cytosol of neutrophils and monocytes and upon release can interact with RAGE and TLR4 to induce inflammatory and immune responses. They are found in joints inflamed by RA and in psoriatic lesions. Other family members such as S100A4, S100B, and S100A12 also contribute to RA. Despite all these observations, alarmins have not been implicated as directly causative of autoimmune disorders.

## CONCLUSION

Cytokines play important roles as either mediators or suppressors of inflammation in autoimmunity. They can, therefore, be targeted therapeutically with beneficial, although noncurative effects. This brief chapter is of necessity incomplete based on our ignorance and on the enormity of the topic. More cytokines and receptors

remain to be discovered, and some may play central roles in autoimmune processes. More detailed information concerning the role of cytokines in various autoimmune diseases is to be found in many of the chapters in this textbook.

## Acknowledgments

I am grateful to Drs. Scott Durum, Howard Young, and Dennis Klinman for their helpful constructive comments and for the secretarial help of Ms. Sharon Livingstone.

## APOPTOSIS

*Historical.* In 400 BC Hippocrates used the word “apoptosis” in the book of Mochlicon to describe the gangrene resulting from the treatment of fractures with bandages (Andre, 2003). Two millennia elapsed until the mid-19th century description of cell death by Vogt. Shortly after, Virchow and Flemming reported two types of cell death and demonstrated that they were consequences of mechanical or chemical damage (Diamantis et al., 2008). In the early 20th century, the seminal work in embryology of Perez and Glucksmann, among others, led to a detailed histological description of cellular death (Diamantis et al., 2008). In 1972, Kerr coined the word “apoptosis” independently from Hippocrates after a suggestion from a professor of Greek (Kerr et al., 1972). Kerr, Wyllie, and Currie described “shrinkage necrosis” as a defined pattern and sequence of events during cell death, leading to the recognition of apoptosis as an integral part of biological processes such as mitosis (Kerr et al., 1972). In the late 1970s, Sulston and Horvitz used *Caenorhabditis elegans*, a nematode in which a fixed percentage of somatic cells die predictably (Sulston and Horvitz, 1977), to dissect the pathways to cell death and to clone several genes named *CED* (*C. elegans* death). The *CED* genes were eventually shown to be highly preserved in mammals (Lockshin and Zakeri, 2001). Today, apoptosis and necrosis are considered fundamental parts of many physiological and pathological processes. Further understanding of the mechanisms of these processes is likely to lead to new targets for medical intervention.

*What do apoptotic cells look like?* Once apoptosis has been triggered, the cell starts to round up, mostly due to retraction of pseudopods and reduction of cellular and nuclear volume (pyknosis), accompanied by modification of cytoplasmic organelles and plasma membrane blebbing (Mills et al., 1999). There is preservation of plasma membrane integrity and exposure of phospholipids, a fundamental “eat-me” signal (Martin et al., 1995; Darzynkiewicz et al., 1992). The terminal (“executioner”) phase is characterized by nuclear fragmentation (karyorrhexis) and the cell’s disintegration into micronuclei surrounded by plasma membrane, known as apoptotic bodies and microparticles (Nagata, 2005). An important last step is the engulfment of the apoptotic cell by resident phagocytes (Wang et al., 2003).

*Molecular pathways leading to apoptosis.* Cells undergoing apoptosis utilize a programmed molecular cascade [reviewed by Kroemer et al. (2009) and Galluzzi et al. (2012)]. The process may be triggered via an engagement of cell surface death receptors by ligands in their external milieu (extrinsic apoptosis) or through biochemical changes within the cell itself (intrinsic apoptosis) (Riedl and Salvesen, 2007).

Initiation of *extrinsic apoptosis* involves the triggering of a *trans*-membrane receptor. In the presence of their ligands, such as FasL (CD178), TNF- $\alpha$ , or TNF-related apoptosis-inducing ligand (TRAIL) (Takahashi et al., 1994; Wiley et al., 1995), these death receptors [FAS (CD95), TNFR1 (CD120a), and TRAILR 1 and 2 (CD261 and CD262)] trimerize to form the “death-inducing signaling complex” (DISC) (Lavrik and Krammer, 2011). DISC formation depends on a conserved death domain (DD), which can recruit receptor-interacting protein (RIP) kinase 1 (Varfolomeev et al., 2005), FAS-associated protein with a DD (FADD) (Chinnaiyan et al., 1995), multiple isoforms of FADD-like IL-1 $\beta$ -converting enzyme)-inhibitory protein (c-FLIP), and procaspase-8. The triggering of TNFR1 may also lead to activation of NF $\kappa$ B or to necrotic death (see Necrotic Death, below). Once the DISC is formed, the activation of caspase-8 ensues (Scaffidi et al., 1999).

In apoptotic lymphocytes (also called type I cells) (Barnhart et al., 2003), caspase-8 activates caspase-3, which initiates the proteolytic cleavage of cytoplasmic and nuclear proteins, and the activation of caspase-activated DNase, an enzyme that cleaves internucleosomal chromatin (Enari et al., 1998).

*Intrinsic apoptosis* can be triggered by DNA damage, reactive oxygen species (ROS), and the accumulation of unfolded proteins in the endoplasmic reticulum (Galluzzi et al., 2012). The pathways that lead to cellular demise share mechanisms intrinsic to mitochondria. Antiapoptotic pathways (principally involving the *bcl-2* family of proteins) are simultaneously engaged, and the fate of a cell depends on which pathway prevails. In intrinsic apoptosis, membrane outer membrane polarization (MOMP) dramatically reduces ATP synthesis, thereby boosting ROS production (Aon et al., 2006). MOMP also triggers the release of cytochrome c (CYTC), diablo IAP binding mitochondrial protein (DIABLO), apoptosis-inducing factor (AIF), and endonuclease G (ENDOG) (Leibowitz and Yu, 2010). The assembly of the protein complex known as the apoptosome leads to the activation of caspase-9 and cleavage of caspase-3, with subsequent cytoplasmic demise and nuclear fragmentation (Bratton et al., 2001). In some circumstances, AIF and ENDOG translocate to the nucleus and initiate chromatin fragmentation in a caspase-independent manner (Lartigue et al., 2009). Therefore the mandatory involvement of mitochondria, the dispensable role of caspases and the bioenergetics, and metabolic catastrophe are major characteristics of this form of apoptosis.

There is cross talk between extrinsic and intrinsic pathways. For example, in apoptotic hepatocytes (also referred as type II cells) there is involvement of the mitochondrial pathway and caspase-8, instead of activating caspase-3, cleaves BH3-interacting domain death agonist, inducing MOMP and reduction of the transmembrane potential ( $\Delta\psi_m$ ) (Kroemer et al., 2007). The resulting release of CYTC triggers assembly of the apoptosome (CYTC, the cytoplasmic adaptor protein APAF1 and dATP), activation of caspase-9, and finally the initiation of the executioner phase by cleavage of caspase-3 (Bratton et al., 2001; Mills et al., 1999; Martin et al., 1995; Darzynkiewicz et al., 1992; Nagata, 2005; Wang et al., 2003).

## APOPTOSIS IN AUTOIMMUNITY

Abnormalities in the apoptotic process have been linked to a variety of autoimmune diseases both systemic such as systemic lupus erythematosus (SLE) and organ specific such as primary biliary cirrhosis (PBC).

### Defective Apoptosis

The inability to control the immune response via cell death can result in autoimmunity; for example, defects in the extrinsic pathway, such as the lack of *Fas* in MRL/lpr mice, render lymphocytes resistant to cell death with marked lymphadenopathy and lupus-like disease (Cohen and Eisenberg, 1991). MRL/lpr mice succumb

prematurely to severe lupus-like disease and accumulate large numbers of lymphocytes, mostly unusual T cells but also B cells (Kono and Theofilopoulos, 2000). Interestingly, the lack of Fas (or caspase-8) in dendritic cells also leads to lupus-like autoimmunity (Stranges et al., 2007; Chen et al., 2006). Human autoimmune lymphoproliferative syndrome, caused by mutations in the Fas death pathway, is a parallel condition (Drappa et al., 1996; Oliveira et al., 2010). The abnormal expression of apoptotic genes in the intrinsic pathway also results in autoimmunity. Overexpression of the antiapoptotic *bcl-2* gene or deletion of the proapoptotic *Bim* gene leads to accelerated autoimmunity, due to uncontrolled T and B-cell proliferation (Tischner et al., 2011; Strasser et al., 1991; Hutcheson et al., 2008). These findings demonstrate the tight control of autoimmunity by cell death.

## Excessive Apoptosis and Apoptotic Cells as Sources of Autoantigen

Apoptotic cell excess can result in systemic autoimmunity or in flares of preexisting disease, presumably by supplying immunogenic nuclear antigens. Injection of UV-irradiated apoptotic cells induces a rise in antinuclear antibodies in normal mice without glomerulonephritis (Mevorach et al., 1998). Injection of dendritic cells that had phagocytosed apoptotic cells accelerates disease onset in lupus-prone mice while inducing transient expression of autoantibodies in normal mice (Bondanza et al., 2003). These and other studies suggest that apoptotic cells may serve as a source of autoantigens.

Generally, an apoptotic cell is noninflammatory and induces tolerance; nevertheless, there are circumstances during which this type of cell death triggers inflammation and amplifies autoimmune response (Green et al., 2009). For example, the redistribution of nuclear contents into membrane blebs and microparticles allows opsonization by autoantibodies. Uptake via proinflammatory Fc receptors and autoantigen presentation may in turn amplify the autoimmune response (Frisoni et al., 2005). Further, during conditions of excessive apoptosis, dying cells may progress into secondary necrosis due to delayed clearance (Munoz et al., 2009). Secondary necrosis allows the release of proinflammatory “danger signals” (Wu et al., 2001).

Autoimmunity toward nuclear components such as chromatin and ribonucleoprotein complexes is a striking feature of SLE (Rahman and Isenberg, 2008). Yet, these autoantigens are generally protected by the nuclear and the cytoplasm membrane, which shield them from the adaptive immune system. Apoptotic cells redistribute their nuclear material into membrane blebs (Casciola-Rosen et al., 1994; Radic et al., 2004), and these apoptotic cell autoantigens, when engulfed by dendritic cells, may be presented to T lymphocytes (Frisoni et al., 2005).

The cellular components released from dead cells, notably nucleic acids, may further stimulate the autoimmune reaction (see anti-inflammatory effects of apoprotic cells, below). Indeed, lack of Toll-like receptors (TLR) 7 or TLR9, receptors for ssRNA and dsDNA, abolishes the production of autoantibodies in several models of lupus-like autoimmunity (Green and Marshak-Rothstein, 2011).

## Apoptoses

Modifications of antigens on apoptotic cells such as cleavage and posttranslational modifications (Rosen and Casciola-Rosen, 1997; Utz et al., 1997) lead to the generation of “apoptoses,” a term used to designate epitopes displayed on the surface of early or late apoptotic cells and derived from the translocation of intracellular autoantigens (Reed et al., 2007). Apoptoses are recognized by specific autoantibodies, leading to the formation of pathogenic immune complexes such as IgG-apoptotic cells (Cocca et al., 2002), IgG-blebs (Frisoni et al., 2005), or IgG-microparticles (Beyer and Pisetsky, 2010). The recognition of apoptoses by autoimmune IgG can also impair clearance of apoptotic cells by neighboring cells (Reed et al., 2008). PBC, Sjögren syndrome, neonatal lupus (NL), and SLE are major autoimmune diseases in which this concept has been demonstrated. In PBC, the E2 component of the pyruvate dehydrogenase complex (PDC-E2) is considered a major autoantigen, and biliary epithelial cells display PDC-E2 as an apoptote on blebs during cell death (Lleo et al., 2011). Importantly, PDC-E2 maintains its antigenicity after it translocates to the cell membrane and is recognized by antimitochondrial antibodies. Subsequently, these complexes activate the innate immune system in multiple ways, resulting in increased TNF- $\alpha$  production and autoantigen presentation (Lleo et al., 2009). Apoptoses have been also demonstrated in NL, a condition in which the passive transfer of anti-SS-A/SS-B (anti-Ro/anti-La) from the mother to the fetus induces congenital heart block (Buyon et al., 2009). Fetal cardiomyocytes expose these antigens during early and late phases of apoptosis, and they are recognized by anti-SS-A/SS-B, inducing further apoptosis (Tran et al., 2002). The apoptote of SS-A is normally masked by cytoplasmic Y RNAs, but during apoptosis, Y RNA is cleaved, and SS-A translocates to blebs and can be recognized by autoantibodies (Reed et al., 2010).

Lupus autoimmunity is arguably the most diverse; nevertheless, autoantibodies are usually directed toward chromatin and its individual components (i.e., DNA and histones), making the nucleosome, the basic unit of chromatin, the most frequent target (Arbuckle et al., 2003).

During apoptosis, the chromatin undergoes dramatic changes, with fragmentation into the nucleosomes and polynucleosomes (Nagata et al., 2003). These apoptope-bearing fragments also redistribute to the cell membrane into blebs and microparticles and may form complexes with antinuclear antibodies (Frisoni et al., 2005; Radic et al., 2004). These complexes may induce and sustain the autoimmune response and may activate TLR, the best known receptors that activate innate immunity (Marshak-Rothstein and Rifkin, 2007). Apoptotic blebbing requires Rho-associated coil-containing protein kinase 1 (ROCK1) (Orlando et al., 2006). Inhibition of ROCK1 inhibits the redistribution of nucleosomes and the binding of autoantibodies (Frisoni et al., 2005). Inhibition of apoptotic nuclear and chromatin fragmentation leads to milder lupus-like disease in inducible models but to worsened autoimmunity in genetically predisposed ones (Jog et al., 2012; Frisoni et al., 2007). The results suggest that apoptotic autoantigens might serve both as immunogens but also as tolerogens.

## NETosis

The formation and release of neutrophil extracellular traps (NETs) may play a key role in stimulating systemic autoimmunity [Knight and Kaplan, 2012]; see Chapter 14: The Roles and Contributions of the Complement System in the Pathophysiology of Autoimmune Diseases]. These extracellular structures are made of chromatin, histones, and microbicidal granular proteins, and are triggered in neutrophils in response to lipopolysaccharides, granulocyte–macrophage colony-stimulating factor, and IL-8 (Yousefi et al., 2008). NETosis is caspase-independent and depends on the production of NADPH oxidase and ROS.

NETs are triggered by granulomatous vasculitis-associated antineutrophil cytoplasmic antibodies and contain their target antigens proteinase-3 and myeloperoxidase (Kessenbrock et al., 2009). Excess NETosis may play a role in SLE (Knight and Kaplan, 2012). They contain histones and DNA, two major lupus autoantigens, and also trigger danger signals such as HMGB1 and proinflammatory cytokines such as IL-17 (Garcia-Romo et al., 2011). Moreover LL37, a neutrophil-derived antimicrobial peptide present in NETs, has been found in complexes with anti-DNA and DNA, and its presence triggers type I interferon (IFN-I) production by plasmacytoid dendritic cells (Garcia-Romo et al., 2011). Therefore in SLE, NETs may provide autoantigens and the milieu necessary to amplify the autoimmune response and tissue damage.

## NECROSIS

Swelling of the cytoplasm and intracellular organelles, early loss of membrane integrity, and moderate chromatin condensation are the typical morphological changes of a necrotic cell (Kroemer et al., 2009). Molecular steps regulating this process have led to the term programmed necrosis. Two major examples relevant to autoimmunity are described below.

*Necroptosis.* This necrotic molecular cascade is dependent on the activation of RIP-1 and/or its homologous RIP-3 (Degterev et al., 2008; Feng et al., 2007). The best described trigger of necroptosis is TNFR engagement. Trimerization of TNFR triggers the formation of DISC in which RIP-1/RIP-3 phosphorylation is inhibited by caspase-8; in this setting the molecular cascade proceeds toward apoptosis. In contrast, in the absence or inhibition of FADD or caspase-8, there is reciprocal phosphorylation of RIP-1 and RIP-3, which stimulates oxidative metabolism via activation of NADPH oxidase (NOX1), with production of ROS and consumption of ATP (He et al., 2009). The excess of ROS and decreased availability of ATP lead to energy collapse and necroptosis (Declercq et al., 2009).

### Necroptosis in Autoimmunity

Necroptosis plays a role in sterile inflammation such as ischemia/reperfusion injury and neurological disorders (Rosenbaum et al., 2010). Its inhibition benefits models of stroke, myocardial infarction, and Parkinson's disease (Vandenabeele et al., 2010). Nevertheless, necroptosis causes the release of damage-associated molecular patterns (DAMPs), danger signals derived from dead or damaged cells that activate the innate immune system. Necrotic cells stimulate proinflammatory cytokines in SLE and in inflammatory bowel disease

(Caricchio et al., 2003; Welz et al., 2011). In mice in which caspase-8 was conditionally eliminated, TNF- $\alpha$  induced Crohn's-like lesions with intestinal mucosal destruction and increased expression of RIP-3 kinase (Welz et al., 2011). The lesions were reversed by pretreatment with necrostatin-1, a RIP-1 inhibitor (Gunther et al., 2011). Similar lesions in patients with Crohn's disease, especially in Paneth cells, demonstrate necroptosis features, without caspase-3 activation and with increased RIP-3 expression (Gunther et al., 2011). This death pathway is likely to be relevant in both activating the immune system and inducing tissue damage, for example, in small-vessel vasculitis and glomerulonephritis.

*Parthanatos* {Par [poly(ADP-ribosylation] and *thanatos* (death)}. The poly(ADP-ribosylation) of nuclear proteins is an early response to DNA damage in eukaryotic cells (Schreiber et al., 2006). Upon DNA damage, often induced during inflammation by ROS, PARP-1 is selectively activated and uses NAD<sup>+</sup> to catalyze nuclear protein poly(ribosylation) (Luo and Kraus, 2012). If the repair is completed, cells survive, while if DNA damage is extensive, PARP-1 is overactivated, resulting in excessive consumption of NAD<sup>+</sup>. As the cell attempts to resynthesize this substrate, it depletes available ATP, resulting in a sudden reduction of cellular energy and necrosis (Bouchard et al., 2003). PARP-1 also induces a forward-loop by poly(ribosylation) of AIF which translocates to the nucleus and induces DNA damage and further PARP-1 activation (Moubarak et al., 2007). Interestingly, PARP-1 is also part of necroptosis and contributes to the energy collapse (Jouan-Lanhouet et al., 2012).

## Parthanatos in Autoimmunity

Parthanatos is characterized by the release of DAMPs, including HMGB1 (Ditsworth et al., 2007). PARP-1 activation and consequent necrosis participate in the pathogenesis of acute and chronic inflammation by facilitating NF $\kappa$ B activation and production of TNF- $\alpha$ , IL-6, and iNOS (Krishnakumar and Kraus, 2010). If PARP-1 is absent or inhibited, there is reduced NF $\kappa$ B activation and disease severity during septic shock, ischemia/reperfusion injury, or collagen-induced arthritis (Eliasson et al., 1997; Gonzalez-Rey et al., 2007; Soriano et al., 2002). Because necrotic lesions are often a key feature of immune-mediated nephropathies, parthanatos may be important in inducing tissue damage. The absence of PARP-1 protects from spontaneous and inducible mouse models of lupus nephritis by decreasing necrotic cell death and in situ production of TNF- $\alpha$ . As the protection only applies to males, females may use a different necrotic pathway, which does not require RIPK3 (Jog et al., 2009; Corradetti et al., 2016).

## CLEARANCE OF DEAD CELLS

One of the most important tasks of the immune system is the removal of the large number of cells that die every day (Ravichandran, 2011). Efferocytosis (DeCathelineau and Henson, 2003), from the latin root *effero* for "take to the grave," is the process of phagocytosis and digestion of dying cells that most cell types can perform, including epithelial cells and fibroblasts, although in mammals efferocytosis is also a primary function of "professional" phagocytes, such as macrophages. Efferocytosis removes apoptotic cells before they release harmful intracellular components and stimulates antiinflammatory factors to preserve a healthy noninflammatory environment (Erwig and Henson, 2007). Apoptotic cells are normally cleared with extreme efficiency and rapidity, so their detection *in vivo* is usually possible only when there are defects in their clearance (Scott et al., 2001). Failure to remove dead cells promptly has been shown to predispose to inflammation and autoimmunity in a variety of models and in human lupus, where uningested apoptotic cells are evident in lymphoid tissue (Baumann et al., 2002; Cohen and Caricchio, 2004). Deficient phagocytosis may lead to autoimmunity by allowing the apoptotic cells to undergo secondary necrosis and to release autoantigens and DAMPs-activating innate immune cells (Ren et al., 2003). In order to accomplish efficient efferocytosis, phagocytes need to be in close proximity to apoptotic cells and to be able to distinguish apoptotic cells from live or necrotic cells. These two functions are promoted by the find-me signals and the eat-me signals, respectively.

### Find-Me Signals

Macrophages and dendritic cells are recruited by "find-me" signals released by apoptotic cells that promote the directional migration of phagocytes by establishing a chemical gradient (Ravichandran, 2011; Nagata et al., 2010). Lysophosphatidylcholine (LPC) is released by dying cells upon activation of phospholipase A2 in a caspase-3-dependent way. LPC binds the G protein-coupled receptor G2A on phagocytes; mice lacking G2A

develop late-onset autoimmunity (Lauber et al., 2003). Another find-me signal is sphingosine 1-phosphate (S1P), an important sphingolipid involved in several biological processes, from lymphocyte trafficking to immunity and cancer (Orr Gandy and Obeid, 2012). S1P is released by apoptotic cells, and its inhibitor FTY720 is attracting interest in various autoimmune diseases such as multiple sclerosis and thyroiditis.

Another chemotactic factor is the soluble fragment of the chemokine fractalkine (CX3CL1), which is cleaved in a caspase-dependent way from the plasma membranes of apoptotic cells. Mice lacking fractalkine receptor CX3CR1 have defective migration of macrophages in germinal centers, where many B cells undergo apoptosis (Truman et al., 2008). The latest molecules proposed as find-me signals are ATP and UTP. These nucleotides are released by early apoptotic cells and recruit monocytes upon triggering P2Y2 receptors (Elliott et al., 2009); mice enzymatically depleted of nucleotides or lacking P2Y2 receptors show deficient phagocytosis and uncleared apoptotic cells. Early apoptotic cells employ the pannexin family of plasma membrane channels to secrete about 2% of the cellular content of ATP and UTP as a find-me signal, much less than the fraction of these nucleotides released by necrotic cells as DAMP upon the loss of plasma membrane integrity. Thus nucleotides either attract noninflammatory phagocytes or recruit neutrophils and activate dendritic cells, depending on the amount released. Apoptotic cells may also release “keep-out” signals, such as lactoferrin, to avoid the recruitment of proinflammatory cells (Bournazou et al., 2009).

## Eat-Me Signals and Their Receptors

*Phosphatidylserine.* Phagocytes engulf apoptotic cells because they can recognize specific “eat-me” signals expressed by the apoptotic cells. The anionic phospholipid phosphatidylserine is the best known eat-me signal (Fadok et al., 1992). Healthy cells maintain phosphatidylserine hidden in the inner leaflet of the plasma membrane, while apoptotic cells flip the phospholipid content of their membrane through the inhibition of translocases (flippases) and the activation of scramblases, and thereby expose phosphatidylserine in the outer leaflet (Nagata et al., 2010). Professional phagocytes and neighboring cells can recognize phosphatidylserine through a number of receptors and engage in phagocytosis. The exposure of phosphatidylserine in the outer membrane is a universal marker of early apoptosis, occurring within 1–2 hours from the apoptotic insult and is detected experimentally by staining with the soluble molecule annexin V (Ravichandran, 2011). The insertion of phosphatidylserine into the plasma membrane of erythrocytes leads to their phagocytosis by macrophages (Tanaka and Schroit, 1983), and the masking of phosphatidylserine with specific antibodies impairs the clearance of apoptotic cells in vitro and in vivo (Asano et al., 2004). It is still debated whether phosphatidylserine is per se sufficient to induce phagocytosis: indeed, contrary to what was observed in erythrocytes, living cells artificially exposing phosphatidylserine are not efficiently phagocytosed, suggesting that either other still unknown eat-me signals are necessary or that “don’t eat-me” signals, such as CD31 and CD47, protect living cells from removal (Ravichandran, 2011; Devitt and Marshall, 2011). Moreover, phosphatidylserine can be chemically modified during apoptosis, and indeed, some phosphatidylserine receptors preferentially bind oxidized molecules.

The binding of phagocytes to apoptotic cells requires cooperation with adhesion molecules for firmer binding, a process defined as “tethering and tickling” (Henson et al., 2001); this has been compared to the immunological synapse and therefore termed the “phagocytic synapse” (Devitt and Marshall, 2011). The molecules able to recognize phosphatidylserine can be divided into two categories: receptors on the plasma membrane of the phagocytes that directly recognize phosphatidylserine and those that instead recognize a bridge, that is, a soluble molecule that opsonizes apoptotic cells. The first category includes the members of the T-cell immunoglobulin and mucin (TIM) family. TIM4 is expressed by macrophages and dendritic cells, while Tim3 is expressed in the spleen by CD8a+ dendritic cells that are antigen presenting cells specialized in cross-priming. TIM receptors may allow dendritic cells to engulf dead cells and present their antigens for immunity. TIM4 deficient mice show the persistence of apoptotic bodies, hyperactivated T and B cells, and systemic autoimmunity (Rodriguez-Manzanet et al., 2010). Other possible direct phosphatidylserine receptors are the brain angiogenesis inhibitor 1, expressed in neurons, and Stabilin-2, expressed by endothelial cells in lymphoid organs (Nagata et al., 2010).

The second category of receptors for phosphatidylserine includes receptors that recognize soluble molecules bridging phagocytes and apoptotic cells. Milk fat globule EGF factor 8 (MFG-E8) is expressed by most phagocytes including tingible-body macrophages, by follicular dendritic cells in germinal centers, and by epidermal Langerhans cells. MFG-E8 binds phosphatidylserine on the apoptotic cells using its two factor-VIII-homologous

C-terminal C1 and C2 domains and to the integrins  $\alpha_v\beta_3$  or  $\alpha_v\beta_5$  on the phagocytes using an N-terminal EGF domain carrying an RGD motif (Arg–Gly–Asp) (Nagata et al., 2010). During an immune response, the mice deficient for MFG-E8 show accumulation of uncleared apoptotic cells in germinal centers, indicating a nonredundant role for MFG-E8 in the removal of apoptotic cells by tingible-body macrophages in vivo. MFG-E8-deficient mice also develop spontaneous lupus-like autoimmune disease, with anti-dsDNA and glomerulonephritis (Hanayama et al., 2004).

Gas-6 and protein S are two other examples of molecular bridges that opsonize apoptotic cells by recognizing phosphatidylserine and promote their phagocytosis. Gas-6 and protein S bind to members of the TAM family of tyrosine kinases: Tyro3, Axl, and Mer on phagocytes (Rothlin and Lemke, 2010). These kinases are involved in phagocytosis and in the modulation of the immune function of the phagocytes. Mer is expressed by macrophages, dendritic cells, natural killer (NK) cells, and NK T cells (Behrens et al., 2003). *Mer*-deficient mice show an accumulation of apoptotic cells upon a strong apoptotic stimulus and spontaneously develop SLE-like autoimmunity, characterized by anti-DNA, antichromatin, antiphospholipid antibodies, and a mild glomerulonephritis (Cohen et al., 2002). This autoimmune phenotype is more severe in mice lacking all three members of the TAMs, with more intense macrophage activation, swollen joints, and glomerular immune complex deposition (Lu and Lemke, 2001; Cohen and Caricchio, 2004). As seen in MFG-E8-deficient mice and other knockout mice (Cohen and Caricchio, 2004), *Mer*-deficient mice develop severe autoimmunity in the genetic background of the strain 129, while the phenotype is less striking on the C57BL/6 background, presumably reflecting the allelic polymorphisms carried by the strain 129 that promotes autoimmunity (Heidari et al., 2006).

*Other eat-me signals.* Many receptors, such as CD14, CD36, CD68, the LDL-receptor-related protein, the oxidized low-density lipoprotein recognizing receptors, and the scavenger receptors, bind dead cells independently from phosphatidylserine (Ravichandran, 2011). Natural IgM antibodies can bind phosphatidylcholine exposed by apoptotic cells and enhance the uptake of apoptotic cells by phagocytes by recruiting C1q and mannose-binding lectin. Studies suggest that these natural IgMs protect against autoimmunity and atherosclerosis by promoting the clearance of apoptotic cells and regulating immune activation (Gronwall et al., 2012). Some receptors for apoptotic cells are organ specific, such as surfactant A and D, which may be important in the lung: surfactant D-deficient mice spontaneously develop emphysema, possibly because the accumulation of intrapulmonary apoptotic cells promotes inflammation and destruction of the pulmonary parenchyma (Vandivier et al., 2002).

## Receptors for Necrotic Cells

The C-type lectins are a large family of proteins, and some of them are expressed by innate immune cells and recognize damaged and necrotic cells and pathogens (Sancho and Reis e Sousa, 2012). DNGR-1 is a C-type lectin that is expressed by CD8a<sup>+</sup> dendritic cells and binds a self-protein, the F-actin component of the cellular cytoskeleton that, such as phosphatidylserine, is normally hidden in the cytoplasm of healthy cells and is exposed extracellularly upon necrotic death. Triggering of DNGR-1 marks the phagocytosed cargo as necrotic and shuttles it for cross-presentation (Sancho and Reis e Sousa, 2012).

LOX-1 is another C-type lectin that recognizes molecules from injured or dead cells such as modified LDL and heat shock proteins and also facilitates other dead cell recognition receptors such as C-reactive protein (CRP) and C1q. LOX-1-deficient mice show delayed atherosclerosis and reduced ischemia-induced organ damage, possibly because of decreased inflammation (Sawamura et al., 2012).

Complement is an important player in the recognition of necrotic cells. C1q binds to cells in the late stage of apoptosis and possibly to primary necrotic cells and C1q-deficient mice develop a lupus-like disease, with anti-DNA and immune complex-dependent renal disease on the 129 genetic background (Mitchell et al., 2002). Furthermore, C1q deficiency in humans leads to lupus-like disease in nearly all homozygous individuals. Autoantibodies against C1q may also cause a functional deficiency of C1q and may block its binding to dead cells and thus exacerbate SLE disease (Cohen and Caricchio, 2004).

Another class of receptors involved in the recognition of dead cells, either apoptotic or necrotic, is the pentraxins (Bottazzi et al., 2010). The short pentraxins, CRP and serum amyloid P (SAP), are acute phase proteins induced by IL-6 in hepatocytes during inflammation, while the long pentraxin PTX3 is expressed by macrophages, myeloid dendritic cells, neutrophils, and some nonimmune cells in response to inflammatory cytokines and TLR ligands. CRP, SAP, and PTX3 bind pathogens and dead cells and promote their complement-mediated killing and phagocytosis. Mice deficient in pentraxins show defective clearance of dead cells and develop lupus (Muñoz et al., 2010).

## ANTIINFLAMMATORY EFFECTS OF APOPTOTIC CELLS

Apoptotic cells are normally considered antiinflammatory not only because they preserve their membrane integrity and so do not release DAMPs but also because they actively provide antiinflammatory signals to the phagocytes (Erwig and Henson, 2007). Apoptotic cells inhibit phagocyte production of proinflammatory cytokines such as TNF- $\alpha$  and IL-12 and increase the production of the antiinflammatory cytokines IL-10 (Voll et al., 1997), TGF-beta, prostaglandin E2, and platelet-activating factor (Fadok et al., 1998). Phagocytosis of the apoptotic cells polarizes macrophages toward the “alternatively activated” M2 differentiation state, which is reparative and nonphlogistic, through the production of the antiinflammatory cytokines TGF-beta and IL-10 (Sica and Mantovani, 2012). Many receptors may mediate this antiinflammatory effect of apoptotic cells.

Indeed, ligation of Mer by apoptotic cells can suppress the response of the innate immune cells to TLR stimulation and proinflammatory cytokines, through the autocrine production of IFNs-I and the induction of suppressors of cytokine signaling molecules, dampening the innate and adaptive immune response (Rothlin et al., 2007). Therefore the autoimmunity in *Mer*-deficient mice could be ascribed to an excess of autoantigens because of their impaired clearance, with these being presented immunogenically because of the DAMPs released by secondary necrotic cells and also because of the absence of the antiinflammatory function of Mer on innate immune cells (Rothlin and Lemke, 2010).

CR3, also known as CD11b or Mac-1, is expressed by macrophages and myeloid dendritic cells and, upon binding apoptotic cells opsonized by the complement component iC3b, it signals antiinflammatory effects in phagocytes (Behrens et al., 2007). CR3-deficient mice have neither defects in apoptotic cell clearance nor autoimmunity possibly due to the redundancy of antiinflammatory signals from apoptotic cells.

Some forms of apoptotic cells are instead proinflammatory, such as those killed by ultraviolet irradiation: such cells express IL-1 $\alpha$  (Caricchio et al., 2003) and activate dendritic cells (Rovere et al., 1998).

## IMMUNOSTIMULATORY EFFECTS OF NECROTIC CELLS

Necrotic cells activate dendritic cells and stimulate immune responses in vitro and in vivo (Gallucci et al., 1999; Matzinger, 2002) through release of endogenous “danger signals” or DAMPs (Miyake and Yamasaki, 2012). Among these signals, nucleic acids are crucial in lupus pathogenesis because they are important self-antigens, and, either in immune complexes with autoantibodies (Leadbetter et al., 2002) or carried by other chaperones (heat shock proteins, HMGB1 etc.), they activate innate immunity through TLR7 and TLR9 stimulation (Marshak-Rothstein and Rifkin, 2007).

The mechanisms whereby nucleic acids enter cells and trigger immune activation have attracted much attention (Gallucci and Maffei, 2017). It is clear that anti-DNA antibodies can form immune complexes with nucleic acids and subsequently bind to the activating Fc gamma receptor (Fc $\gamma$ RIIA, CD32), leading to their uptake and binding to TLR, provoking production of IFNs-I and cytokines (Bave et al., 2000).

Intracellular RNA, usually of viral origin, binds to cytosolic RNA receptors retinoic acid-inducible gene I and MDA5. After undergoing activation, these proteins bind to mitochondrial-associated adaptor protein (MAVS), which presents in high molecular aggregates in peripheral blood mononuclear cells of SLE patients, a form that provokes the stimulation of IFNs and other inflammatory cytokines and leads to inflammation and autoimmunity (Shao et al., 2016). Intracellular DNA is also recognized by sensor proteins, causing production of IFNs and other cytokines. The best studied is cGAS, which undergoes a conformational change after binding to double-stranded DNA with subsequent production of cyclic 2'-5' cGAMP. This molecule binds to stimulator of interferon genes (STING), with subsequent production of IFN-beta (Cai et al., 2014). Children with activating STING mutations develop a severe inflammatory and autoimmune syndrome (Jeremiah et al., 2014).

An important source of potentially inflammatory DNA is mitochondrial DNA (mtDNA), which can be released in the extracellular compartment by necrotic cells and during NETosis, and triggers immune activation by binding TLR9, or release in the cytoplasm to activate cGAS-STING, promoting autoimmunity (Lood et al., 2016). MtDNA may also be resistant to the action of TREX-1, an endonuclease that degrades single and double-stranded DNA (Gallucci and Maffei, 2017). Mutations of TREX-1 have been shown to result in a severe childhood autoimmune disease (Aicardi-Goutières disease), with antinuclear antibodies, chilblain-like skin lesions, and a variety of profound neurological defects (Crow and Manel, 2015). In this regard, the proinflammatory effects of

free nucleic acids released from dead and dying cells are counteracted by several nucleases (DNase I, RNase1L3, RNase1) that degrade RNA and DNA (Sisirak et al., 2016).

Necrotic cells also release the DAMPs heat shock proteins, uric acid, and degradation products of the extracellular matrix (ECM). These ECM products, such as hyaluronic acid, fibrinogen, and tenascin-C, are upregulated after tissue injury. Their levels are increased in rheumatoid arthritis (RA) tissues, and their administration induces joint inflammation in mice. Mice deficient in tenascin-C show rapid resolution of inflammation (Goh and Midwood, 2011), suggesting a pathogenetic role for ECM molecules in RA.

Finally, HMGB1 is a DNA-binding protein that stabilizes the nucleosome and regulates transcription (Andersson and Tracey, 2011). It is released by necrotic cells and activates innate immune cells by triggering RAGE, TLR2, and TLR4. Necrotic cells lacking HMGB1 are less stimulatory, and neutralizing antibodies ameliorate inflammation (Bianchi and Manfredi, 2007). HMGB1 may be involved in the pathogenesis of RA, SLE, experimental autoimmune encephalomyelitis, and autoimmune diabetes in nonobese diabetic (NOD) mice (Andersson and Tracey, 2011). Inhibition of HMGB1 ameliorates arthritis in animals, while its administration into the joints induces arthritis (Kokkola et al., 2003). In RA patients HMGB1 levels are increased in serum and synovial fluid and decreased with therapies that ameliorate joint inflammation (Zetterstrom et al., 2008). SLE patients have anti-HMGB1 autoantibodies, and their levels of serum HMGB1 correlate with disease activity; in animals the injection of HMGB1-nucleosome complexes induces lupus-like autoantibodies.

## A GLIMPSE INTO THE FUTURE

The last 20 years have been pivotal in the investigation of the role of apoptosis and the clearance of apoptotic cells in the pathogenesis of autoimmune diseases, while only very recently has necrosis been considered a form of programmed cell death with relevance to autoimmunity. Next-generation deep sequencing studies will indicate the genetic links between novel forms of cell death and disease and identify the subgroups of patients in the affected human population. An improved understanding of the fine mechanisms of cell death mediated by novel molecular cascades or programs is likely to lead to new therapeutic targets.

### AUTOPHAGY PATHWAYS

The term autophagy, derived from the Greek and meaning “eating of self,” was first coined by Christian de Duve in 1963 (de Reuck and Cameron, 1963; Klionsky, 2014), to explain earlier electron microscopic observations of mitochondrial degradation in double-membrane vesicles, a process that had been termed autolysis (Ashford and Porter, 1962), and finally, in 2016, the Nobel Prize in Physiology or Medicine was awarded to Yoshinori Ohsumi for his groundbreaking work in identifying the first set of autophagy-related genes in baker’s yeast (*Saccharomyces cerevisiae*) (Tsukada and Ohsumi, 1993), a discovery that ultimately led to a tremendous spark in the field of autophagy research. The identification of an evergrowing number of autophagy-related proteins (ATGs) in recent years has led to the characterization of several discrete autophagy pathways that all serve distinct objectives. Autophagy pathways may be subdivided into canonical and noncanonical pathways with canonical autophagy comprising macroautophagy (MA), microautophagy (MI), and chaperone-mediated autophagy (CMA) (Codogno et al., 2011). Here, we focus on MA, the most extensively studied among all autophagy pathways (Fig. 17.1). This pathway is highly conserved from yeast to mammalian cells and comprises a series of tightly regulated membrane reorganization events under the control of several ATGs ultimately leading to the formation of a double-membrane organelle called the autophagosome. De novo synthesis of this hallmark organelle is an exclusive morphological feature of MA and does not take place during MI and CMA. Three defined sequential processes pave the way to autophagogenesis: induction/nucleation, elongation, and closing/maturation. During the process of closing, the autophagosome sequesters and engulfs neighboring cytoplasmic content. These steps are then followed by fusion of the vesicle with the endolysosomal system and subsequent degradation of its cargo (Mizushima et al., 2011, 2002; Feng et al., 2014). The targeting of cytoplasmic MA substrates may be both unspecific or highly selective (e.g., mitophagy), mediated via several adaptor molecules and ATGs (Galluzzi et al., 2017; Farré and Subramani, 2016). Many mammalian tissues execute MA on a constitutive level at varying degrees and depending on the cell type, macroautophagic activity may be induced and/or modulated by

**FIGURE 17.1** Different autophagy pathways fusing with the endolysosomal compartment. (A) The preinitiation complex (ULK complex) is (among others) under the control of multisite phosphorylation through the two kinases mTOR and AMPK and activates the downstream initiation complex (PI3K complex) which is itself negatively and positively regulated by others. (B) The subsequent elongation reaction is highly dependent on two ubiquitin-like protein conjugation systems. (C) MA: the phagophore stems from PI3P-rich membrane sources. Cytoplasmic cargo is engulfed after recruitment of LC3 to the outer and inner leaflet of the arising autophagosome, and LC3 is removed from the outer membrane as the vesicle is closed. The completed autophagosome then fuses with endosomes and/or lysosomes. Also CMA, MI, and LAP may converge into the endolysosomal system. AMPK, 5' AMP-activated protein kinase; CMA, chaperone-mediated autophagy; LAP, LC3-associated phagocytosis; MA, macroautophagy; MI, microautophagy; mTOR, mechanistic target of rapamycin; MVB, multivesicular bodies; ULK, unc 51-like kinase.

several means (e.g., nutrient deprivation, transcriptional, and epigenetic regulation). MA is controlled both on a systemic and on a cellular level with the two antagonistic kinases 5' AMP-activated protein kinase and target of rapamycin complex 1 (TORC1) being the most central regulatory units of the cellular MA machinery so far identified (Kim et al., 2011; Egan et al., 2011; Efeyan et al., 2015).

### Molecular Autophagy-Related Proteins Machinery of Macroautophagy

Five functionally distinct, hierarchically organized, protein complexes orchestrate initiation and assembly of the autophagosome: the unc 51-like kinase (ULK) complex (1), the class III phosphatidylinositide 3-kinase (PI3K) complex (2), the ATG2/WD repeat domain phosphoinositide-interacting protein (WIPI) complex and the ATG9 cycling system (3), the ATG12-conjugation system (4), and the microtubule-associated protein 1 light chain 3 (LC3)-conjugation system (5) (Feng et al., 2014; Mizushima et al., 2011; Shibutani and Yoshimori, 2014) (Fig. 17.1). During the induction/nucleation step, a double-membrane structure called phagophore or isolation membrane twines around and sequesters designated parts of the cytoplasm. The subcellular source, which provides

membrane material for the phagophore, is still under debate. While some have reported that these parent membranes are predominantly derived from specialized endoplasmic reticulum (ER) domains (Axe et al., 2008; Ylä-Anttila et al., 2009; Hayashi-Nishino et al., 2009), others have suggested contributions from alternative sources such as mitochondria (Hailey et al., 2010), the plasma membrane (Ravikumar et al., 2010), or a novel compartment comprised ATG9<sup>+</sup> vesicles and tubules (Mari et al., 2010).

The ULK multiprotein complex consists of ULK1/2, focal adhesion kinase family–interacting protein of 200 kDa (FIP200), ATG13 and ATG101, is assembled upon an appropriate stimulus and then translocates to autophagosomal initiation sites on tubulovesicular areas consisting of ER and ATG9<sup>+</sup> vesicles (Ganley et al., 2009; Karanasios et al., 2016). Vacuolar protein sorting protein (Vps)34, Vps15 (also called p150), Beclin 1 (ortholog of Atg6), and Atg14L build the tetrameric core of the class III PI3K complex whose major function is to produce PI3P (Suzuki et al., 2016). Recruitment of the complex to autophagosomal initiation sites is mediated via the upstream ULK complex and ATG9. Downstream PI3P-binding partners can now be recruited to the newly generated PI3P-enriched membranes (Matsunaga et al., 2010; Itakura and Mizushima, 2010). These PI3P-enriched membrane sites that are generated via the PI3PK complex attract binding partners that are essential for the further assembly of the autophagosome such as WIPI1/2 and ATG2 (Itakura and Mizushima, 2010; Obara et al., 2008; Velikkakath et al., 2012). At the autophagosomal initiation site, the WIPI/ATG2 complex both facilitates recruitment of lipidated LC3 and prevents its ATG4-mediated deconjugation (Nair et al., 2010). ATG12, ATG7, ATG10, ATG5, and ATG16L1 are all members of the ubiquitin-like ATG12-conjugation system (Mizushima et al., 2011). The E1-like enzyme ATG7 activates ATG12, which is then transferred to E2-like enzyme ATG10. Next, ATG10 catalyzes the covalent conjugation of ATG12 to ATG5 and ATG16L1 can now bind to ATG5 to complete the complex (Geng and Klionsky, 2008). The ATG5–ATG12–ATG16L1 complex is recruited to the autophagosomal initiation site by WIPI2 (Dooley et al., 2014) and FIP200 (Nishimura et al., 2013) in an ATG16L1-dependent manner where it executes its function as an E3-like enzyme for the LC3-conjugation system. In addition, the ATG5–ATG12–ATG16L1 complex guides and determines LC3 to its subcellular destination (Fujita et al., 2008b). Although present on the outer membrane of the nascent phagophore, the ATG5–ATG12–ATG16L1 complex swiftly dissociates from there upon autophagosome closure (Mizushima et al., 2001). Members of the second conjugation system include the ubiquitin-like LC3, the hydrolase ATG4, E1-like ATG7, and E2-like ATG3. ATG4 cleaves off five C-terminal amino acids of the LC3 precursor form to expose a glycine residue (G120) (Hemelaar et al., 2003; Kabeya et al., 2004). The resulting LC3-I is lipidated with phosphatidylethanolamine at the previously exposed glycine residue by the concerted actions of ATG3, ATG7 (Kabeya et al., 2000; Ichimura et al., 2000; Tanida et al., 2004), and E3-like activity via ATG5–ATG12 conjugates (Geng and Klionsky, 2008; Fujita et al., 2008b). Lipidated LC3-II is initially present on the outer and inner membrane of the assembling autophagosome (Kabeya et al., 2000, 2004; Kimura et al., 2007). There it appears to facilitate the elongation of the phagophore as well as coordinate tethering and hemifusion of its membranes and the closing of the phagophore to the completed autophagosome (Nakatogawa et al., 2007; Fujita et al., 2008a; Weidberg et al., 2010; Sou et al., 2008). While LC3-II is recycled from the outer membrane after completion of the autophagosome by ATG4, LC3-II that is coupled to the inner membrane stays associated with the autophagosome and is degraded with this membrane by lysosomal hydrolysis.

## Noncanonical Autophagy Pathways

There are autophagy pathways that result in autophagosome formation but omit the usage of essential elements of the classical MA machinery; other autophagy modes may be autophagosome independent but utilize key components of the MA network. These and other entities may be categorized as noncanonical autophagy pathways (Codogno et al., 2011; Münz, 2015). Some recently characterized members of this group include LC3-associated phagocytosis (LAP), Beclin 1–independent autophagy, autophagy-associated unconventional protein secretion, and defective ribosomal products–containing autophagosome-rich blebs. Due to its strong link to antigen presentation and its reported function in the development of autoimmune disease phenotypes, we will confine ourselves to discussing LAP.

LAP is a process that links both phagocytosis of extracellular constituents and the autophagy molecular core machinery. While some key elements of the MA machinery are essential for LAP (e.g., ATG5, ATG7, LC3, Beclin 1), others are fully dispensable (e.g., the ULK complex including ULK1/2, FIP200, ATG13, ATG101). This pathway features a unique organelle, a single membrane LC3-decorated phagosome (also called LAPosome) and is initiated by ligation of a variety of extracellular receptors including Toll-like receptors (TLRs), fragment

crystallizable (Fc) receptors, C-type lectins, and phosphatidylserine (Ptd-L-Ser)-binding receptors (Romao et al., 2013; Sanjuan et al., 2007; Ma et al., 2012; Martinez et al., 2011; Henault et al., 2012). After binding of LAP-triggering surface receptors, a PI3PK complex, slightly different from the one active during MA, associates with the cytosolic membrane of the arising phagosome and generates PI3P, which, in concert with other factors such as Rubicon, mediates recruitment, stabilization, and activation of the NADPH oxidase (NOX)2 (Martinez et al., 2015). NOX2-derived reactive oxygen species together with LAPosomal PI3P then launch recruitment and activation of the two canonical MA conjugation systems for Atg12 and LC3 (see earlier), resulting in the deposition of lipidated LC3 on the outer LAPosomal membrane (Martinez et al., 2015). While several questions remain with regards to the differential fate of LAPosomes compared to conventional phagosomes, there is ample evidence that LAP in professional antigen-presenting cells (APCs) such as dendritic cells (DCs) enables the cell to retain antigenic material for sustained and more efficient major histocompatibility complex (MHC) class II antigen presentation (Lee et al., 2010; Romao et al., 2013; Ma et al., 2012).

## AUTOPHAGY IN T- AND B-CELL DEVELOPMENT AND ACTIVATION

Aside from its pivotal function in energy housekeeping, autophagy is increasingly recognized for actively participating in the development and maintenance of immune cells (Shibutani et al., 2015). Most of these immune cells originate from hematopoietic progenitor cells (HPCs) and this precursor cell population has been shown to be highly dependent on MA for its survival (Mortensen et al., 2011; Salemi et al., 2012). Not only were progenitors of multiple lineages reduced upon targeted deletion of the essential MA gene *Atg7* in HPCs but also severe myeloproliferation was observed in the affected mice (*Vav-Atg7<sup>-/-</sup>*) in vivo (Mortensen et al., 2011). Moreover, *Atg7*-deficient HPCs depicted defective mitochondrial quality control leading to accumulation of mitochondria with high membrane potential, increased production, and subsequent oxidative damage. These findings were corroborated by a report that shows that T cells lacking ATG5 and ATG7 are critically impaired in their mitochondrial maintenance (Stephenson et al., 2009). Again focusing on T lymphocytes, another study found that *Atg5*-deficient CD4<sup>+</sup> and CD8<sup>+</sup> T cells show normal initial development in the thymus. However, due to increased cell death and the incapacity to undergo efficient proliferation after T-cell receptor (TCR) stimulation in absence of the essential MA gene *Atg5*, these populations later on fail to repopulate the periphery (Pua et al., 2007). In mice with Beclin 1 deficiency in the hematopoietic lineage, T- and B-cell precursors are diminished in thymus and bone marrow, respectively, while peripheral T- and B-cell compartments are largely normal (Arsov et al., 2011). The susceptibility of lymphocyte precursors may result from the biphasic expression of Beclin 1 and, therefore, resulting macroautophagic activity during development, while nonactivated T and B cells seem to have low MA levels (Arsov et al., 2008). Upon activation, MA is upregulated in peripheral lymphocytes, including T cells (Arsov et al., 2008; Pua et al., 2007). T cell-specific conditional knockout of Beclin 1 (CD4-Cre Beclin 1<sup>f/f</sup>) also confirmed that cell-intrinsic absence of MA precludes peripheral homeostasis of T lymphocytes due to increased susceptibility to cell death upon activation (Kovacs et al., 2012). The requirement during T-cell activation, however, results at least in part from impaired Ca<sup>2+</sup> mobilization upon TCR engagement (Jia et al., 2011). While the Ca<sup>2+</sup> storing ER is enlarged, influx of this second messenger upon T-cell activation is impaired, resulting in reduced immune responses. Signal transmission from the TCR to NF-κB is in part mediated by the adaptor protein B-cell lymphoma/leukemia 10 (Bcl10), which is reflected by the failure of T cells to proliferate upon TCR ligation in absence of Bcl10 (Ruland et al., 2001). Targeted degradation of Bcl10 via selective MA has been identified as a feedback mechanism to avoid excessive TCR signaling and to limit NF-κB-dependent effector responses thereby broadening the concept of autophagy-mediated T-cell functions beyond survival fitness (Paul et al., 2012). Targeted deletion of yet another protein essential for MA, ATG16L1, in T cells leads to expansion of IL-13-secreting Th2 subsets and diminished numbers of intestinal T-regulatory cells (TREGs) resulting in the spontaneous development of intestinal inflammation (Kabat et al., 2016). Foxp<sup>+</sup>CD4<sup>+</sup> TREGs are specialized lymphocytes whose major function is to control and limit immune responses mounted against self- and foreign antigens in order to retain self-tolerance (Josefowicz et al., 2012). TREG-specific deletion of ATG5 and ATG7 results in lower frequencies and survival of this subset (Wei et al., 2016). TORC1 activity in TREGs has been reported to be crucial for integrating immunological signals from the TCR and IL-2 to functional fitness (Zeng et al., 2013). TREGs, which depict a higher autophagic activity as compared to naïve T cells, seem to utilize autophagy to restrain TCR-triggered TORC1 which leads to increased c-Myc expression and exuberant glycolytic metabolism in autophagy-deficient TREGs entailing compromised self-tolerance (Wei et al., 2016). A critical role has also been attributed to autophagy proteins during CD8<sup>+</sup> memory T-cell homeostasis. Targeted deletion of ATG7 in T

lymphocytes engenders weakened CD8<sup>+</sup> T cell–dependent recall responses upon infection with influenza and murine cytomegalovirus (MCMV) (Puleston et al., 2014). The age-related decline of CD8<sup>+</sup> T-cell memory function has been linked to reduced efficacy of vaccination in the elderly (Haq and McElhaney, 2014). In line with this, CD8<sup>+</sup> cells isolated from aged mice show lower levels of autophagic activity as compared to younger controls. By contrast, systemic pharmacological induction of autophagy partly restored memory CD8<sup>+</sup> T-cell function (Puleston et al., 2014). While in part contradicting previous findings (Pua et al., 2007), Xu et al. illustrate a more dynamic course of autophagic activity in T cells in that CD8<sup>+</sup> T lymphocytes initially downregulate autophagy following TCR ligation and during proliferation, followed by another upregulation of the process before the contraction phase. Mechanistically, loss of autophagy proteins in CD8<sup>+</sup> T cells results in dysfunctional mitochondrial fatty acid oxidation at the transition to the memory phase (Xu et al., 2014). Interestingly, there seems to be a differential requirement for autophagy pathways dependent on the T-cell subset (Kovacs et al., 2012). It is known that mice that lack the E3 ubiquitin ligase itchy E3 ubiquitin protein ligase (ITCH) are prone to develop hyperactive T cell–driven systemic autoimmunity (Fang et al., 2002). CMA has been reported to regulate the outcome of T-lymphocyte activation to the extent that regulators of calcineurin 1 and ITCH, both negative regulators of TCR signaling, serve as substrates for this autophagy pathway. CD4<sup>+</sup> T cells devoid of the essential CMA component LAMP-2A, exhibit a strong reduction in activation-induced proliferation showing that CMA-mediated degradation actively participates in the calibration of T-cell responses similar to MA-dependent clearance of Bcl10 (Valdor et al., 2014; Paul et al., 2012).

Invariant natural killer T cells (iNKT) comprise a conserved subset of unconventional T lymphocytes with a memory-like phenotype that recognizes glycolipids presented by CD1d molecules and in crosstalk with professional APCs, they facilitate and boost coordinated stimulation of innate and adaptive immune responses (Godfrey et al., 2015). During their thymic development and differentiation, iNKT cells upregulate autophagy in order to keep mitostasis. Consequently and in line with what has been described for other hematopoietic cells, the absence of ATG7 in iNKT cells leads to amassment of mitochondria and excessive generation of mitochondrial superoxide species followed by apoptosis. Hence, lack of autophagy in iNKT cells leads to an early arrest in thymic development accounting for the complete absence of mature iNKT cell in peripheral lymphoid organs (Salio et al., 2014). Similar to T-cell development, B cells require autophagy both during development and maintenance in the periphery. While in developing B cells the transition from pro- to pre-B cells is affected by the loss of MA (Arsov et al., 2011; Miller et al., 2008), among mature B cells, only the mostly innate B-1a subset is affected (Miller et al., 2008).

These data show that lymphocyte development, their activation, and effector functions are compromised upon disruption of autophagy pathways. This may for example result from half-live shortening or partial loss-of-function mutations in essential autophagy genes which may preclude affected cell population to efficiently mobilize nutrients, maintain cellular fitness, or adequately integrate extracellular signals. Further studies will be warranted to clarify differential roles of autophagy pathways in distinct lymphocyte subsets particularly in the context of T cell–driven autoimmunity.

## AUTOPHAGY IN INNATE IMMUNITY

As an innate immune response to viral and microbial pathogens, autophagy pathways participate in limiting pathogen replication in host cells. Bacteria and parasites that either escape from endosomes and replicate in the cytosol or condition the phagosome to serve as their replication niche—by preventing fusion with lysosomes—have been found to be delivered for lysosomal degradation via autophagy (Nakagawa et al., 2004; Gutierrez et al., 2004; Singh et al., 2006; Wild et al., 2011). For example, ruptured *Salmonella typhimurium*–containing vacuoles expose host glycans, which serve as ligands for the lectin and cytosolic danger receptor galectin 8. The recognition of these carbohydrate residues by galectin 8 entails recruitment of the autophagy receptor nuclear domain 10 protein 52 and the consecutive initiation of MA, thereby restricting *Salmonella* proliferation (Thurston et al., 2012). Furthermore, autophagy contributes to sealing endosomal membranes upon *S. typhimurium*'s type three secretion system-mediated damage (Kreibich et al., 2015). Some bacteria, such as *Listeria monocytogenes*, *Shigella flexneri*, and *Mycobacterium tuberculosis*, have already developed evasion strategies in order to circumvent autophagy-mediated clearance of pathogens (Ogawa et al., 2005; Yoshikawa et al., 2009; Kim et al., 2015). Innate immune responses to microbial antigens are initiated through stimulation of pattern-recognition receptors (PRRs) which include TLRs, nucleotide-binding and oligomerization domain-like receptors, retinoic acid–inducible gene I–like helicases, and a subset of C-type lectin receptors. These sensor molecules endow cells of the innate

immune system with the ability to recognize a large number of molecular patterns expressed by bacteria, viruses, or fungi. Recent data have revealed an intricate, mutual interplay between PRRs and autophagy pathways, whereby autophagy, on the one hand, facilitates PRR-mediated recognition of cognate ligands by fostering their physical interaction and, on the other, serves as an immune effector mechanism downstream of PRR stimulation. For example, several TLRs function as triggering receptors for initiating the noncanonical LAP pathway thereby linking members of the autophagy core machinery to phagocytosis (Sanjuan et al., 2007). Furthermore, cytosolic viral replication intermediates of single-stranded RNA viruses, recognized by PRRs, are delivered to endosomally located TLR7 through MA, which results in robust type I interferon (IFN)-dependent innate immune responses via plasmacytoid DCs (pDCs) (Lee et al., 2007). Also in pDCs, the LAP pathway has been implicated in channeling TLR9 to IFN regulatory transcription factor 7-signaling compartments upon Fc $\gamma$ R-mediated binding of immune complexes thereby coupling autophagy and pathogenic type I IFN secretion (Henault et al., 2012). During another noncanonical selective autophagy pathway in macrophages, TLR4 ligation leads to the nucleoporin 62 (p62)/sequestosome (SQSTM1)-dependent targeting of aggresome-like induced structures (Fujita et al., 2011). Also downstream of TLR4, p62/SQSTM1-dependent mitophagy restrains exuberant NACHT, leucine rich repeat (LRR), and pyrin domain (PYD) domain-containing protein (NLRP3)-inflammasome activity and consecutive release of proinflammatory mediators (Zhong et al., 2016). Extending previous findings, which highlight the role of autophagy pathways during antibacterial defense, another study using mice that are deficient in intestinal epithelial cell ATG5 shows that autophagy downstream of myeloid differentiation primary response 88 (MyD88)-signaling is crucial for impeding dissemination of *S. typhimurium* in vivo (Benjamin et al., 2013). PRR signaling and T<sub>h</sub>1 cytokines such as IFN $\gamma$  and members of the tumor necrosis factor family can induce or augment MA in several tissues, which might represent a feedback mechanism by which activated T cells augment MA under inflammatory conditions (Xu et al., 2007; Delgado et al., 2008; Orvedahl et al., 2007; Keller et al., 2011). Other groups of molecules such as T<sub>h</sub>2 cytokines (e.g., IL-4, IL-13) or regulatory cytokines (e.g., IL-10) have been shown to downregulate autophagy (Van Grol et al., 2010; Harris et al., 2007). The net effect of the exposure to a given cytokine, however, is likely to be dependent on multiple parameters such as coexposure to other mediators and the respective target tissue. Conversely, autophagy pathways may, through several mechanisms, also contribute to calibrating extracellular levels of cytokines as reported for the proinflammatory protein IL-1 $\beta$  (Dupont et al., 2011; Zhang et al., 2015). This cytokine very well exemplifies the complex reciprocal interrelationship of some soluble signal molecules with the autophagy machinery when keeping in mind that mitophagy limits NLRP3-mediated release of IL-1 $\beta$  (Zhong et al., 2016) or the fact that IL-1 $\beta$  itself may induce autophagy (Pilli et al., 2012).

## AUTOPHAGY PATHWAYS DURING ANTIGEN PRESENTATION

Although the exact molecular underpinnings remain unknown, it is widely accepted that certain genetic variants within the human leukocyte antigen locus render individuals more susceptible to autoimmunity (Matzarakis et al., 2017). In addition to regulating T-cell development and activation, autophagy pathways also participate in shaping of the T-cell repertoire during several antigen processing and presenting routes (Münz, 2016a,b). Conventional T cells recognize proteolytic fragments of proteins that are presented on MHC molecules. MHC class I molecules present primarily proteasomal substrates to CD8 $^{+}$  T cells, while MHC class II molecules present peptide ligands generated in the endolysosomal pathway to CD4 $^{+}$  T cells (Trombetta and Mellman, 2005). Autoimmunity is commonly triggered by a specific adaptive immune response that is mounted against self-antigens. Acknowledged degradation pathways which may facilitate MHC class II presentation of self-antigens include the classical MHC class II pathway, MA, and LAP (Münz, 2016a,b). Early work has already suggested presence of an endogenous MHC class II pathway that allows viral proteins to be presented to CD4 $^{+}$  T cells (Jacobson et al., 1989; Nuchtern et al., 1990) and analysis of the affinity-purified MHC class II peptidome revealed that about 30% of eluted natural ligands stem from endogenous protein sources (Rammensee et al., 1999; Dengjel et al., 2005) which gave rise to the assumption that a yet unidentified endolysosomal route delivers these ligands onto MHC molecules. Eventually, MA was recognized as a novel pathway that conveys endogenous cargo to endosomal MHC class II-containing compartments (MIICs) for subsequent recognition by CD4 $^{+}$  T cells (Nimmerjahn et al., 2003; Paludan et al., 2005; Schmid et al., 2007). In some professional APCs, autophagosomes frequently fuse with MIICs, and experimental delivery of antigens to autophagosomes by targeting the autophagosomal membrane via fusion with LC3 consequently leads to efficient recognition by cognate CD4 $^{+}$  T cells (Schmid et al., 2007; Comber et al., 2011; Aichinger et al., 2013; Jin et al., 2014; Coulon et al., 2016; Fonteneau

et al., 2016). Further evidence came from studies reporting that the two mammalian ATG8 homologs in higher eukaryotes, namely, LC3 and gamma-aminobutyric acid receptor-associated protein, are among the source proteins for natural MHC class II ligands (Dengjel et al., 2005; Suri et al., 2008). MHC class II presentation of endogenous cytosolic and nuclear antigens can be increased by 50% upon starvation, a strong inducer of MA, while starvation leaves loading of ligands from membrane-bound proteins unaffected (Dengjel et al., 2005). Several professional APCs, such as DCs and B cells, carry out MA on a constitutive level (Dengjel et al., 2005; Nimmerjahn et al., 2003; Paludan et al., 2005) and, as discussed previously, the process can be additionally upregulated (and downregulated) following immune stimulation via PRRs such as TLRs or inflammatory cytokines (Lee et al., 2007; Delgado et al., 2008; Xu et al., 2007; Van Grol et al., 2010; Harris et al., 2007). The proficiency to harness autophagy pathways for delivery of endogenous antigens to MHC class II appears differentially relevant depending on the specific APC population (Brazil et al., 1997).

Among the more in-depth characterized endogenous antigens to be delivered via MA to MIICs are the nuclear antigen 1 of the Epstein–Barr virus (EBNA1) and the bacterial transposon-derived neomycin phosphotransferase II (NeoR). EBNA1 is intracellularly processed for MHC class II presentation by Epstein–Barr virus–infected B cells (Munz et al., 2000). This processing is executed within lysosomes because EBNA1 accumulates in cytosolic vesicles upon inhibition of lysosomal proteolysis (Paludan et al., 2005). Furthermore, CD4<sup>+</sup> T-cell recognition of EBNA1 expressing B cells is compromised upon RNA silencing of essential MA genes (Leung et al., 2010; Paludan et al., 2005). Inhibition of nuclear import of EBNA1 increases MA-dependent MHC class II presentation of this antigen (Leung et al., 2010). NeoR, on the other hand, is a cytosolic antigen, whose processing for MHC class II presentation is sensitive to MA inhibition (Nimmerjahn et al., 2003). Vice versa, antigens that are fused to NeoR are more efficiently presented to CD4<sup>+</sup> T cells via MA (Comber et al., 2011). However, in contrast to EBNA1, nuclear import of NeoR does not compromise its presentation on MHC class II molecules after macroautophagic antigen processing (Riedel et al., 2008). Therefore nuclear localization by itself does not necessarily protect antigens from processing for MHC class II presentation via MA, suggesting that the subcompartmentalization of the antigen in the nucleus could dictate, if this antigen gains access to the cytosol after nuclear envelope dissociation during mitosis.

Ample data show that autophagy also contributes to extracellularly derived antigen processing and presentation. ATG5-deficient DCs process and present pulsed antigen less efficiently via MHC class II when compared to their wild-type counterparts (Lee et al., 2010). This defect correlates with decelerated phagosome maturation, possibly due to less efficient fusion with lysosomes. Lee et al. showed that the TLR-dependent phagocytosis of herpes simplex virus (HSV)-2 entails formation of LC3-decorated single-membraned organelles and while pharmacological intervention of MA via inhibition of TORC1 left MHC class II–mediated antigen presentation unperturbed, the targeted deletion of LAP-essential ATG5 in the DC compartment significantly abated HSV-2-specific CD4<sup>+</sup> T-cell responses indicative of a non-MA pathway linking phagocytosis and MHC class II presentation (Lee et al., 2010). While during canonical MA cytoplasmic cargo is sequestered into forming autophagosomes, LAP denotes a process by which extracellular constituents enter the cell through phagocytosis in a single-membraned phagosome that is subsequently decorated by LC3. This hallmark vesicle, also termed LAPosome, may deliver antigenic fragments to the endolysosomal system including MIICs, thereby prompting downstream T-cell responses (Münz, 2015; Martinez et al., 2015; Romao and Münz, 2014). There is evidence that in mouse macrophages, the decoration of phagosomes with LC3 leads to accelerated movement of these vesicles along microtubules and rapid fusion with the lysosomal compartment, which is in keeping with one of the primary tasks of macrophages being quick elimination of phagocytosed microorganisms or damaged cells (Florey et al., 2011; Sanjuan et al., 2007; Martinez et al., 2011; Ma et al., 2014). On the other hand and similar to what has been reported in mouse DCs (Lee et al., 2010), in human professional APCs, LAP is facilitated for sustained MHC class II antigen presentation in that antigenic cargo is retained in the endolysosomal system rather than promoting degradation of antigenic constituents (Romao et al., 2013). Decreased levels of lysosomal proteases and antigenic stabilization and containment are presumed mechanisms via which professional APCs such as DCs calibrate and maintain robust antigen presentation for prolonged stimulation of cognate T cells (Delamarre et al., 2005; Romao et al., 2013; Romao and Münz, 2014). Aside from the previously described role in pDCs, where LAP tunes TLR9-mediated release of IFN $\alpha$  in the context of immune complex binding to Fc $\gamma$ R (Henault et al., 2012), the process has also been implicated in aiding the clearance of *S. cerevisiae* and *Aspergillus fumigatus* (Sanjuan et al., 2007; Martinez et al., 2015).

Autophagy pathways may also participate in the delivery of distinct processing enzymes to phagosomes for increased antigenic peptide formation. In this view, it was reported that peptidylarginine deiminase, which citrullinates endocytosed proteins and thereby gives rise to autoantigens that are recognized in some autoimmune diseases, like rheumatoid arthritis, reaches phagosomes via MA (Ireland and Unanue, 2011). Thus the

support of extracellular antigen processing by the autophagy core machinery could result from LC3-assisted fusion with lysosomes or processing enzyme delivery to phagosomes by autophagosomes.

While an extensive body of evidence points toward a role of autophagy pathways during antigen processing toward MHC class II presentation, an increasing amount of studies also implicates autophagy proteins in MHC class I-mediated antigen presentation toward CD8<sup>+</sup> T cells. Along these lines, late during HSV infection of macrophages, it was observed that autophagosomes engulf viral capsids at the outer nuclear membrane (English et al., 2009). Furthermore, MHC class I presentation of an endogenous human cytomegalovirus latency-associated protein, pUL138, has been found to be facilitated via two distinct modes, one being the conventional transporter associated with antigen processing (TAP)-dependent pathway while the other, independent of TAP, relies on MA (Tey and Khanna, 2012).

The majority of MHC class I presented peptides are derived from the endogenous ligand pool. The term cross-presentation is commonly applied to subsume pathways that deliver exogenous peptides for MHC class I presentation to CD8<sup>+</sup> T cells. Autophagy pathways have so far been reported to modulate antigen cross-presentation in two distinct ways. First, antigen donor cells are capable of packaging antigen and subsequent exocytosis for cross-presentation onto MHC class I molecules more efficiently via MA (Li et al., 2008; Uhl et al., 2009). Second, cross-presenting cell-intrinsic roles for autophagy pathways have been delineated. Hereto, APCs may assemble endosomal cross-presenting compartments with the assistance of autophagy proteins for efficient cross-priming of antifungal CD8<sup>+</sup> T cells (De Luca et al., 2012). Interestingly, Mintern et al. have reported that for effective MHC class I-mediated presentation of exogenous antigen in mice, the autophagy machinery is particularly important in CD8<sup>+</sup> DCs, an APC population that is known for being the prime cross-presenting subset. However, this was only true for soluble antigen but not required for cell-associated or receptor-mediated endocytosed antigen (Mintern et al., 2015).

Nevertheless, the functions of autophagy proteins during antigen presentation to CD8<sup>+</sup> T cells seem to be far from unidirectional. It has been suggested that aggregated proteins are redirected toward proteasomal degradation and MHC class I antigen processing in the absence of MA (Wenger et al., 2012). Several reports document enhanced CD8<sup>+</sup> T-cell responses in the context of DC-inherent autophagy deficiency (Hubbard-Lucey et al., 2014; Lévy et al., 2015; Loi et al., 2016). A recent study broadened the concept of noncanonical autophagy pathways during antigen presentation to the MHC class I pathway by showing that absence of ATG5 in CD11c<sup>+</sup> DCs leads to impaired internalization of MHC class I molecules from the plasma membrane. The failure in internalization was due to reduced recruitment of adaptor-associated kinase 1 to cell surface-bound MHC class I. Persistence of MHC class I molecules on the surface of DCs consequently entailed enhanced CD8<sup>+</sup> T-cell responses upon influenza A and lymphocytic choriomeningitis (LCMV) infections *in vivo* (Loi et al., 2016). Finally, autophagy proteins assist in the recruitment of AP2 to the nonpolymorphic MHC class I-like molecule CD1d. Loss of the essential autophagy protein ATG5 in CD11c<sup>+</sup> DCs hampered clathrin-dependent internalization of CD1d molecules leading to the stabilization of stimulatory CD1d:glycolipid complexes and consecutively boosted iNKT cell activation (Keller et al., 2017). Thus ATGs seem to support antigen presentation of exogenous and endogenous antigens on MHC class II molecules, while they restrict classical and nonclassical MHC class I antigen presentation via enhanced internalization.

## AUTOPHAGY IN TOLERANCE AND AUTOIMMUNITY

The first *in vivo* situation that was identified to involve MA-mediated antigen processing for MHC class II presentation is thymic T cell selection. Recognition of self-antigen-derived epitopes presented by MHC class II molecules on thymic epithelial cells (TECs) is critical for the generation of a functional and self-tolerant CD4<sup>+</sup> T-cell repertoire. TECs shape the T-cell repertoire to recognize self-peptide/MHC complexes with low affinity by a process called positive selection and weed out T cells that react to these self-structures with high affinity by negative selection (Kyewski and Klein, 2006). Even so they express MHC class II molecules to execute these functions for CD4<sup>+</sup> T cells, their endocytic capacity is low, but autophagosomes fuse also in these cells frequently with MIICs (Kasai et al., 2009). Indeed, when positive selection of TCR transgenic T cells through MA-deficient thymi was investigated, only some T-cell specificities were correctly selected, while others were deleted and loss of MA in TECs resulted in severe colitis and multiorgan inflammation (Nedjic et al., 2008). While positive selection of CD8<sup>+</sup> T cells was found to be MA independent (Nedjic et al., 2008), MA in medullary TECs also participates in clonal deletion during thymic-negative selection by facilitating the direct presentation of endogenous self-antigens (Aichinger et al., 2013). These data suggest that MA processes certain self-ligands for MHC class II

presentations that are involved in positive and negative T-cell selection in the thymus and thereby contributes to the generation of a self-tolerant T-cell repertoire.

In addition to its function in central tolerance, MA in DCs has recently been identified as one potential mechanism that underlies  $\text{Foxp3}^+$  TREG-mediated immune suppression (Alissafi et al., 2017). In the aforementioned study,  $\text{Foxp3}^+$  TREGs were shown to impair autophagolysosome formation and antigen presentation capacities in DCs in a CTLA4-dependent manner. Autophagy-deficient DCs exhibited reduced immunogenic potential and failed to prime autoantigen-specific CD4 $^+$  T cells to mediate central nervous system autoimmunity (Alissafi et al., 2017). Along these lines, mice deficient for the essential autophagy protein ATG7 in DCs and other myeloid cells are reported to develop milder experimental autoimmune encephalomyelitis, a CD4 $^+$  T cell–driven autoimmune disease model, compared with control animals (Bhattacharya et al., 2014; Kanayama et al., 2016). These data suggest that the canonical autophagy pathway in DCs is a molecular target of  $\text{Foxp3}^+$  TREG-mediated suppression that can be harnessed to suppress autoimmune responses.

Aside from its function in inducing and maintaining central and peripheral T-cell tolerance, autophagy in myeloid cells has also been linked to autoimmune tissue inflammation through its role in the removal of apoptotic cell corpses. Rapid removal of apoptotic cell material is thought to be crucial for the prevention of tissue inflammation. Efficient elimination of apoptotic bodies during programmed cell death involves exposure of Ptd-L-Ser on the surface and release of lysophosphatidylcholine (LPC) by apoptotic cells. Apoptotic cells, which fail to express ATG5 or Beclin 1 genes, do not expose Ptd-L-Ser at the cell surface and produce lower levels of LPC compared to their wild-type counterpart (Qu et al., 2007). Defective clearance of apoptotic cells has long been suggested to drive autoimmunity in patients with systemic lupus erythematosus (SLE) and other autoimmune diseases (Bratton and Henson, 2005). Absence of LAP in myeloid cells by lysozyme M-Cre-mediated gene deletion, which targets macrophages, monocytes, some neutrophils, and cDCs, was recently shown to lead to development of a systemic autoinflammatory syndrome in mice with increased expression of IFN signature genes, occurrence of antididouble-stranded DNA and nuclear antibodies, and signs of kidney damage, commonly associated with SLE (Martinez et al., 2016). The aforementioned study showed that macrophages deficient in ATG7 or Rubicon, both required for ATG-dependent phagocytosis, did engulf, but not effectively clear, dying cells and produced proinflammatory cytokines, including IL-1 $\beta$  and IL-6, upon challenge with apoptotic cell material (Martinez et al., 2016). An increased propensity of ATG7 $^{-/-}$  macrophages to produce proinflammatory cytokines after engulfment of apoptotic cells has also been described in vitro (Martinez et al., 2011) indicating that defective ATG-dependent phagocytosis in macrophages can result in a failure to digest engulfed dying cells, leading to elevated inflammatory cytokine production and the development of a lupus-like syndrome.

Although the autophagy machinery has been implicated in almost every immunological-driven response, its role in the development of autoimmune diseases is still incompletely understood. Genetic deficiencies of essential autophagy proteins in myeloid cells have been shown to either ameliorate or drive autoimmune responses and disease phenotypes (Alissafi et al., 2017; Martinez et al., 2016). These seemingly contradictory effects suggest that autophagy protein functions are likely cell- and context-dependent. Future research will dissect the involvement of individual autophagy proteins and pathways in human autoimmune diseases and disease models. A clear and comprehensive concept of how the autophagy machinery couples to autoimmune disease development and progression appears to be required to predict the outcome of therapeutic interventions in this pathway.

### INTRODUCTION

In the 1960s pathological reactions produced by an otherwise healthy immune system were subdivided into four groups on the basis of the effector mechanism initiated. More recent advances in our understanding of cellular immunology have led to less prominent use, and critique, of the Gell and Coombs classification system (Rajan, 2003), which cannot be upheld as such in the light of today's knowledge. Nevertheless, it remains a useful introductory way of characterizing some aspects of autoimmune effector mechanisms. Of the four types of "hypersensitivity reactions," type I represented "conventional" allergic and anaphylactic responses, while the other three contribute to *bona fide* autoimmune pathology.

### AUTOANTIBODIES

Autoantibodies are a hallmark of autoimmune disease (Tan, 1991). In fact, their presence is so common in autoimmunity that autoinflammatory disease, which does not involve specific immune recognition, is principally defined by the absence of autoantibodies (Ombrello and Kastner, 2011) (see Chapter 4: Innate and Adaptive Systems of Immunity). In most cases, autoantibodies are important for diagnostic purposes and may not directly influence the outcome of the disease. However, an increasing number of autoantibodies have been directly linked to inflammation, cell death, or functional problems. Antibody-mediated autoimmune disease is distinguished

**TABLE 18.1** Variable Effects of Well-Defined Autoantibodies

Antibody to	Disease	Function of antibody
Acetylcholine receptors	Myasthenia gravis	Receptor blockade
Aquaporin-4	Neuromyelitis optica	Cytotoxicity
Beta-2 glycoprotein I	Antiphospholipid syndrome	Activation of coagulation
Desmogleins	Pemphigus vulgaris	Binding function blocked
Factor VIII	Acquired hemophilia	Coagulation factor removal
Glycoprotein IIb/IIIa	Immune thrombocytopenic purpura	Thrombocyte clearance
Thyrotropin receptor	Graves' disease	Receptor stimulation

into two groups by the Gell Coombs classification system. Type II hypersensitivity reactions are mediated by a direct effect of the antibody binding its target antigen; examples of pathogenic autoantibody effects are listed in **Table 18.1**. By contrast, type III hypersensitivity reactions are mediated by the deposition of immune complexes in affected tissues, which will almost always result in inflammation, as discussed below.

## DIRECT ANTIBODY-MEDIATED DISEASE

Type II hypersensitivity reactions mainly lead to cell death and removal or disturb physiological functions (**Table 18.1**).

Autoantibodies leading to cell death or cell removal include those against erythrocyte membranes in hemolytic anemia, against various, mostly uncharacterized, antigens in the other systemic lupus erythematosus (SLE) cytopenias, or, presumably, against endothelial cell antigens in systemic sclerosis. These autoantibodies follow typical antibody function patterns that include antibody-dependent cell mediated cytotoxicity (ADCC) where the antibody recruits an immune (natural killer, NK) cell to induce cells to kill or phagocytose any target that is marked by an antibody. Alternatively, antibodies may destroy their target by recruiting components of the complement system. Essentially, all these antibodies are of particular IgG subclasses, and the specific IgG subclass is relevant for their properties. For example, IgG1 and IgG3 activate complement, while IgG2 is a poor complement activator, and IgG4 does not activate complement at all ([Daha et al., 2011](#)). The same classes that activate complement, that is, IgG1 and IgG3, also avidly bind the activating Fc receptor Fc $\gamma$ R1 ([Nimmerjahn and Ravetch, 2010](#)) and mediate ADCC.

Blood cells marked by antibodies will be phagocytosed in the spleen (and liver) and cleared ([Cines and Blanchette, 2002](#); [Gehrs and Friedberg, 2002](#)), while immobile cells, such as endothelial cells to which antibodies bind in systemic sclerosis, may be killed by cytotoxic cells ([Sgong et al., 1996](#)). While the former mechanism is usually obvious and can be easily proven, for example by recording clinical improvement following removal of autoantibodies ([American College of Rheumatology Ad Hoc Committee, 2004](#)), ADCC can often not be proven *in vivo* and is even difficult to prove in an *in vitro* situation. Nevertheless, the latter most probably is the more common process.

In addition to marking cells for ADCC or phagocytosis, autoantibodies can also cause significant pathology by functionally disturbing physiological processes. Important examples of this type of autoantibody-induced mechanism are antibodies to proteins and glycoproteins, such as to factor VIII ([Zeitler et al., 2013](#)) in acquired hemophilia or antibodies to  $\beta$ 2-glycoprotein I, which induce thrombotic events in the antiphospholipid antibody syndrome ([Giannakopoulos and Krilis, 2013](#)) (see Chapter 34: Rheumatoid Arthritis and Chapter 51: Multiple Sclerosis). Autoantibodies may engage cell receptors, such as the TSH receptor in Graves' disease ([Dalan and Leow, 2012](#)) triggering their activation and so leading to thyrotoxicosis or neuromuscular acetylcholine receptors in myasthenia gravis ([Levinson, 2013](#)) preventing their activation leading to muscle weakness. They may also target channel proteins, such as aquaporin-4, which is targeted in neuromyelitis optica/Devic's disease (see Chapter 57: Hepatitis and [Papadopoulos and Verkman, 2012](#)). Other examples of antibodies impairing functions are those to desmogleins in the autoimmune blistering disease pemphigus ([Stanley and Amagai, 2006](#)), or those mediating psychosis in SLE ([Fong and Thumboo, 2010](#)).

## IMMUNE COMPLEX DISEASE

Commonly, inflammatory pathology is not induced by IgG monomers, but by immune complexes consisting of autoantigen and autoantibodies resulting in what Gell and Coombs termed a type III hypersensitivity reaction. In this case, antibody classes other than IgG play a major role. In particular, this is relevant to the pentameric IgM and the dimeric IgA, due to their crosslinking capabilities. Immune complexes will strongly activate complement and will be recognized by Fc receptors, thus causing inflammation.

IgM and IgA rheumatoid factors (RFs) are characteristic for active seropositive rheumatoid arthritis. RFs bind to the Fc portion of IgG and in this way induce immune complexes, which likely play a major role in the pathophysiology of rheumatoid arthritis (RA). In fact, the complement system is clearly activated in rheumatic joints (Olmez et al., 1991). Moreover, beyond disease activity, high titer RFs are associated with incurring damage (Aletaha et al., 2012).

Immune complexes also play a major role in organ inflammation in systemic autoimmune diseases, and in SLE in particular. For example, immune complexes of double-stranded DNA (dsDNA) and anti-dsDNA antibodies lead to proliferative glomerulonephritis. These antibodies can directly be detected in glomeruli. However, rather than being deposited from the blood, they may form locally, by antibodies to nucleosomes being caught at the negatively charged glomerular basement membrane (Mjelle et al., 2011; Yung and Chan, 2008).

Similarly, antibodies to the nuclear antigen Ro/SS-A are associated with subacute cutaneous lupus erythematosus (Sontheimer, 2005), where, likewise, immune complexes can be directly detected in the affected skin. While anti-neutrophil cytoplasmic antibodies (ANCA)-associated vasculitides are not immune complex driven, lupus vasculitis is, as are RA vasculitis, cryoglobulinemic vasculitis, IgA vasculitis (Henoch–Schönlein disease), or hypocomplementemic urticarial vasculitis (Jennette et al., 2013).

## COMPLEMENT CASCADES

Immune complexes, as well as most antibodies binding to surfaces, activate the complement cascade via the classical pathway (see Chapter 15: Cytokines, their Receptors and Signals and Daha et al., 2011). Binding occurs via complement component C1, leading to cleavage of C4 and C2 (Walport, 2001). The activated larger cleavage products C4b and C2a form the convertase for C3, the central complement of the downstream complement cascade, which then leads to the activation of C5 and the membrane attack complex consisting of C5b, C6, 7, 8, and 9. In addition to formation of the membrane attack complex, C1q, C3b, and C4b bound to immune complexes facilitate phagocytosis, a process called opsonization. Mannose binding lectins form an initiating event similar to that of C1, which is not known to play a role in autoimmunity.

In contrast, the alternative complement pathway is commonly involved in autoimmune disease. This amplification pathway is started by cleavage of C3, upon which C3b has to bind to a membrane. Membrane bound C3b then binds to factor B, and together they activate the alternative C3 convertase C3bBb. Antibodies stabilizing the C3bBb complex, called nephritic factor, are associated with type II dense deposit membranoproliferative glomerulonephritis as well as with partial lipodystrophy (Walport, 2001).

Cells have mechanisms to defend against occasional deposition of C3b. CD59 (membrane inhibitor of reactive lysis) protects autologous cells against the membrane attack complex, and its deficiency leads to paroxysmal nocturnal hemoglobinuria (Yamashina et al., 1990), where erythrocytes are slowly but continuously destroyed by unrestrained activation of the alternate complement pathway. In addition, the inhibitory plasma protein factor H binds to C3b, leading to its inactivation by factor I (Walport, 2001). Two membrane proteins, namely CD35 (complement receptor type I) and CD46 (membrane cofactor protein), also play a role in complement inactivation. As another option, cells may be able to eject complement bound membrane by forming microparticles, albeit at the risk of inducing immune complex disease elsewhere (Pisetsky, 2012).

The classical complement pathway is checked by C1 inhibitor, the deficiency of which causes angioedema. This is related to yet another function of the complement system: The smaller fragments C3a, C5a, and C4a act as anaphylatoxins, inducing the chemotaxis and activation of leukocytes (Walport, 2001). This may play a role in the kidney disease of ANCA-associated vasculitides, since C5a receptor deficient animals are resistant to this disease (Schreiber et al., 2009).

Finally, complement may play a role in limiting immune complex disease by aiding the clearance of immune complexes—or of apoptotic cells. Inherited deficiencies of C1–C4 are all associated with an increased incidence of SLE (Aringer et al., 2013).

## MACROPHAGES

Monocytes and macrophages are the main cells to deal with immune complexes (see Chapter 11: Dendritic Cells in Autoimmune Disease). They are equipped with both Fc receptors and complement receptors, thus simultaneously recognizing immune complexes and C5a (Karsten and Kohl, 2012). Under such circumstances, removal of immune complexes (and attached particles) becomes a highly inflammatory process. Not only will these M1 macrophages then present antigen but they will also produce a variety of proinflammatory cytokines. Immune complex recognition leads to not only the release of TNF, (Aringer and Smolen, 2012) but also other cytokines, including IL-6, IL-1, IL-8, and GM-CSF (Jarvis et al., 1997). In this way, macrophages link between immune complex deposition and inflammation. Indeed, Fc receptor deficiency was illustrated by uncoupling of immune complex deposition from glomerulonephritis in a lupus mouse model (Clynes et al., 1998). In addition to their role as essential promoters of inflammation in autoimmune complex disease, macrophages are also an important effector in autoimmune thrombocytopenia and hemolytic anemia, where antibody-loaded cells are cleared in spleen and kidney (Cines and Blanchette, 2002; Gehrs and Friedberg, 2002).

## NEUTROPHILS

As the most common leukocytes, neutrophils are prototypical effector cells of the immune system (Amulic et al., 2012). In addition to phagocytosis and degranulation, NETosis has been more recently been investigated. NETosis is a form of “aggressive” neutrophil cell death that constrains and kills pathogens; in the end, it is the physiological background of what has long been known as pus. Neutrophil extracellular traps (NETs) consist of fibrous structures that contain decondensed chromatin, histones, and antimicrobial proteins (Amulic et al., 2012). NETosis may be importantly involved in autoimmune tissue inflammation, such as in SLE (Kaplan, 2011) or in ANCA-associated vasculitides (Kessenbrock et al., 2009). Neutrophils also produce cytokines, including IL-8, IL-1, IL-17, and tumour necrosis factor (TNF), as well as chemokines (Amulic et al., 2012; Hoshino et al., 2008).

Like macrophages, neutrophils carry both Fc and complement receptors and accordingly react to antibodies and immune complexes (Hoshino et al., 2008; Nemeth and Mocsai, 2012). In addition, neutrophils are activated by high concentrations of IL-8, which in lower concentrations acts as a chemoattractant (Amulic et al., 2012). Activated platelets can also activate neutrophils (Caudrillier et al., 2012). In other inflammatory situations, Toll-like and non obese diabetic (NOD)-like receptors recognizing pathogen-associated molecular patterns and danger-associated molecular patterns play a major role (Amulic et al., 2012).

## MAST CELLS

In addition to being the principal players in allergic or type I hypersensitivity reactions, there are indications that mast cells also act as effectors in autoimmune diseases. In addition to histamine and serotonin, mast cells produce the proinflammatory cytokines IL-6 and TNF (Wesolowski and Paumet, 2011). In RA, mast cells have been found within the synovitic joint (Kiener et al., 1998), and mast cell deficient mice are protected against arthritis in the K/BxN mouse model (Lee et al., 2002). Antibodies to citrullinated peptides, which are fairly specific for rheumatoid arthritis, also exist as IgE antibodies, that are associated with mast cell activation and synovial histamine release (Schuerwagh et al., 2010). Mast cells are also activated by IgG immune complexes, a process that is potentiated by the presence of the inflammatory cytokine, IL-33 (Kaieda et al., 2012).

## NATURAL KILLER CELLS AND CYTOTOXIC T CELLS

To protect the organism, virally infected and transformed cells are actively eliminated by NK cells and CD8 + cytotoxic T lymphocytes. Cytotoxicity is principally mediated via membrane bound ligands of death receptors, such as Fas ligand, and granzyme B (Afonina et al., 2010), all of which induce apoptosis in the target cell. Extracellular granzyme B in addition has proinflammatory effects in that it enhances IL-1 $\alpha$  activity by processing this cytokine (Afonina et al., 2011). Conversely, IFN $\gamma$  and TNF made by either cell type increase Fas (CD95) expression on target cells that facilitates their destruction (Bergman and D'Elios, 2010).

Cytotoxic T cells require priming by myeloid cell-dependent antigen presentation in order to be able to kill (Sigal et al., 1999) and recognize specific peptides presented by autologous major histocompatibility complex (MHC) I molecules. These cells are implicated in *Helicobacter pylori*–related gastric autoimmunity (Bergman and D’Elios, 2010), type I diabetes mellitus (Coppieters and von Herrath, 2011), and autoimmune CNS disease (Melzer et al., 2009).

In contrast to cytotoxic T lymphocytes, NK cells need no previous activation. NK cells have receptors that have evolved in parallel with the MHC class I proteins they recognize (Parham and Moffett, 2013). This points to their function in recognizing small changes in MHC class I, which may herald an important safety issue with the afflicted cell. In addition, NK cells kill cells targeted by autoantibodies through ADCC. Whereas circulating cells covered by autoantibodies are removed in spleen and liver, ADCC is the deadly effector pathway of IgG autoantibodies that bind noncirculating cells, such as endothelial cells in systemic sclerosis (Sgouros et al., 1996). This process may thus induce tissue damage anywhere in the body, but this will be difficult to prove *in vivo*.

## EFFECTOR T-HELPER CELL–MEDIATED AUTOIMMUNE DISEASE

Whereas CD8+ cytotoxic T cells act directly to damage target tissues, CD4+ helper T cells (Th cells) drive a specific immune attack by employing a variety of additional mechanisms. For any specific immune reaction, these cells are of the utmost importance and need to be addressed when investigating effector mechanisms in autoimmune disease.

*A priori*, the immune system does not know which kind of pathogens to expect next. Therefore, naïve T cells are entirely flexible. This flexibility changes for determination in the process of activation. Like cytotoxic T cells, naïve Th cells need antigen presentation by myeloid cells in order to be able to mature into effector Th cells. These two groups of T cells mediate delayed type (type IV) hypersensitivity responses; the 24–48-hour delay is due to the required period of antigen presentation. During this process of antigen presentation, the presence of cytokines secreted by the myeloid cell or other nearby immune cell will determine what lineage of effector Th cell will be generated. These include Th1 cells, Th2 cells, and Th17 cells (Reiner, 2007; Tato and O’Shea, 2006).

Th1 cells are important for the clearance of intracellular pathogens (Infante-Duarte and Kamradt, 1999). They are induced by activation in the presence of IL-12 and are characterized by the ability to secrete IFN- $\gamma$  (Table 18.2), which activates macrophages to kill such organisms and activates NK cells and cytotoxic T lymphocytes, as well as the ability to enhance MHC expression.

Th2 cells are essential for defending mucosal and epithelial barriers against worms and parasites (Maizels et al., 2012; Paul and Zhu, 2010). They are induced in the presence of IL-4 and are characterized by the ability to secrete IL-4, IL-13, and IL-5 when activated. IL-4 stimulates IgG class switching to IgG4 and IgE, and together with IL-13 alternatively activates macrophages toward the M2 phenotype. IL-9 mobilizes mast cells, and IL-5

**TABLE 18.2** Characterization of Important Effector Cells by Their Receptors and Their Mediators

Effector cell	Important receptors (receptor chains)	Important cytokines and mediators
Monocyte	Fc $\gamma$ RI, IIa, IIb; CR1, 3, 4, C5aR	TNF, IL-6, IL-8, GM-CSF
Macrophage	Fc $\gamma$ RI, IIa, IIb, RIIIa; CR1, 3, 4, C5aR	TNF, IL-6, IL-8, GM-CSF
Neutrophil	Fc $\gamma$ RI, IIa; CR1, C3aR, C4aR, C5aR	TNF, IL-1, IL-8
Mast cell	Fc $\epsilon$ R, Fc $\gamma$ RIII; C3aR, C4aR, C5aR	Histamine, serotonin, IL-6, TNF
NK cell	NCRs; Fc $\gamma$ RIIIa; CR3, 4; KIRs	IFN- $\gamma$ , TNF, GM-CSF, IL-8, granzyme B
Cytotoxic T cell	TCR; KIRs; CTLA-4	IFN- $\gamma$ , TNF, granzyme B, perforin
Th1	TCR; IL-12R ( $\beta$ 1 + $\beta$ 2), IL-18R	IFN- $\gamma$ , IL-2, TNF
Th2	TCR; IL-4R ( $\alpha$ + $\gamma$ c)	IL-4, IL-5, IL-9, IL-13, IL-25
Th17	TCR; IL-23R (IL-12R $\beta$ 1 + IL-23R)	IL-17, GM-CSF, TGF $\beta$ , TNF

Fc $\gamma$ RI = CD64, Fc $\gamma$ RIIa = CD32, Fc $\gamma$ RIIIa = CD16 activating Fc $\gamma$  receptors, Fc $\gamma$ RIIb inhibitory Fc $\gamma$  receptor; CR1 (complement receptor 1) = CD35, CR2 = CD21, CR3 = CD11b + CD18, CR4 = CD11c + CD18; NCRs, natural cytotoxicity receptors; KIRs, killer cell immunoglobulin-like receptors; TCR, T-cell receptor; NK, natural killer.

plays the same role for eosinophils. Together, IL-4, IL-13, and IL-5 increase mucus secretion, which helps eliminating pathogens such as helminthes and other parasites. The related, newly identified lineage, Th9 cells, mainly produce IL-9 but do not produce IL-4 (Dardalhon et al., 2008). They emerge in situations where both IL-4 and TGF $\beta$  are present.

Th17 cells are highly relevant for the defense against extracellular bacteria, such as *Staphylococcus* or *Klebsiella*, as well as against *Candida* (Annunziato et al., 2009; Peters et al., 2011). They are induced in the presence of TGF $\beta$ , IL-6, and IL-23 and are characterized by the secretion of IL-17 when activated, which leads to increased neutrophil formation via G-CSF and GM-CSF, and to increased neutrophil recruitment via IL-8 and other chemokines (Zuniga et al., 2013). In addition, IL-17 stimulates the production of defensins and other antimicrobial substances. While Th17 cells also produce IL-22 that induces expression of defensin proteins in target cells, there are cells that produce IL-22, but not IL-17, and are therefore termed Th22 cells (Duhen et al., 2009). This subset is particularly prevalent among skin homing cells.

After exposure, since the immune system tries to completely eliminate any foreign invader, this process may become protracted. It is therefore not surprising that the T-helper phenotype is largely stable. This is achieved by combining several mechanisms. First, lineage-specific transcription factors that drive differentiation are stably expressed. For Th1 cells, the critical transcription factor is T-bet, for Th2 cells, it is GATA-3, and for Th17 cells ROR $\gamma$ t.

The Th1 transcription factor T-bet is induced by Stat1 and Stat4 homodimers, activated by IFN $\gamma$  and IL-12, respectively. T-bet in turn promotes IFN $\gamma$  production and represses IL-4 production, among many other effects essential for the maturation of Th1 cells (Miller and Weinmann, 2010). The Th2 transcription factor GATA-3 is induced by homodimers of Stat6, the principal signaling molecule of IL-4 and IL-13. GATA-3 induces IL-4, IL-5, IL-13, and GATA-3 itself (Wei et al., 2011). ROR $\gamma$ t is induced by homodimers of Stat3, the principal signaling molecule of IL-6, IL-21, and IL-23 at the same time T-bet and IFN $\gamma$  production are inhibited, whether by (low concentrations of) TGF $\beta$  or by other means (Hirahara et al., 2010; Peters, Lee, and Kuchroo, 2011). ROR $\gamma$ t in a protein complex that includes STAT3 induces the expression of IL-17 and the IL-23R.

In addition, there is a second level of control, namely epigenetic regulation, whereby chromatin accessibility is regulated further restricting gene expression. Global DNA methylation mapping has demonstrated that the IFN $\gamma$  locus is open in Th1, but not Th2 or Th17 cells, the IL-4 locus exclusively open in Th2 cells, and the IL-17 locus open in Th17 cells only (Wei et al., 2009). Thus epigenetic modifications are one means by which cell differentiation is kept stable during T-cell expansion, or, less fortunately, in autoimmune disease or allergy.

Although there is much experimental evidence for the role of particular lineages of Th cells in protection from infection, the role of each lineage in driving autoimmune disease is less clear. Th2-generated cytokines, such as IL-13, are associated with type I hypersensitivity reactions including asthma in mouse models (Wills-Karp, 2004) and monoclonal antibodies against IL-13 are having some success in early clinical trials. By contrast, inhibition of IFN $\gamma$ , the principle Th1 cytokine, often leads to exacerbation of disease in mouse models of multiple sclerosis (extrinsic autoimmune encephalomyelitis) and acute graft versus host disease (Teng et al., 2015). This may be in part because IFN $\gamma$  is able to inhibit Th17 cell differentiation. Cytokines that drive Th17 differentiation including IL-1, IL-6, and IL-23 are linked with autoimmune disease in mouse models as is IL-17 itself (Teng et al., 2015). Furthermore, inhibitors of all these cytokines have been successful in the treatment of a number of autoimmune diseases.

## INNATE LYMPHOID CELLS

Innate lymphoid cells (ILCs) share many of the functional properties of T lymphocytes but notably lack T-cell receptors. Like T cells they are dependent on the common  $\gamma$  chain family of cytokines for development and survival. They are activated by similar cytokines that drive Th cell lineage polarization and in turn act by expressing cytokines that are associated with Th cell lineages. This activation is not dependent on an antigen receptor and is rapid. Thus ILC “hold the fort” in the initial stages of an infection until a T-cell lineage has expanded to resolve it. For every Th cell lineage, there is an equivalent ILC, with IFN $\gamma$  expressing group 1 ILCs that mirror Th1 cells, IL-4 and IL-13 expressing group 2 ILCs that mirror Th2 cells, and IL-17 and IL-22 expressing group 3 ILCs that mirror Th17 cells (Spits et al., 2013). The contribution of ILCs to autoimmune disease is not clear, although they are capable of recruiting inflammatory cells and driving acute inflammation in the same way as Th cells and any strategy designed to block a specific Th cell lineage will likely affect the equivalent ILC lineage. Elevated numbers of ILC1 and ILC3 cells have been identified in the synovium of patients with RA. ILC2 cells are present in lung tissue and have been linked with atopic disease and inflammatory bowel disease (Shikhagaie et al., 2017).

## EFFECTOR CYTOKINES AND THEIR TARGETS

Essentially, all of the immune cells discussed produce significant amounts of cytokines. These are essential for shaping the immune system at any given time. However, some of these cytokines also have important effects on other tissues (Table 18.3), thereby directly contributing to tissue pathology in autoimmune disease. The importance of individual cytokines is highlighted by the success of anticytokine antibodies in the treatment of a number of autoimmune diseases.

TNF is a particularly well-known example in this regard. TNF is being produced by many immune cells (Table 18.2), and by monocytes and macrophages in particular. Mice transgenic for, and thus overexpressing, human TNF display peripheral and sacroiliac joint pathology indistinguishable from RA and ankylosing spondylitis, respectively (Keffer et al., 1991; Redlich et al., 2004). TNF fosters the development of osteoclast precursors from monocytes and enhances osteoclast activity, which is essential in that osteoclasts are the only cells able to digest bone (Redlich et al., 2002). Conversely, pharmacological TNF blockade blocks radiographic progression in RA even when disease activity is not adequately controlled (Smolen et al., 2006). TNF also activates fibroblasts (Vasiliopoulos et al., 2007) and endothelial cells and leads to vascular leakage (Bradley, 2008).

Since both TNF and IL-1 signal via nuclear factor- $\kappa$ B (NF- $\kappa$ B) and mitogen-activated protein kinases, it is not surprising that IL-1 in part reduplicates and further enhances such effects, leading to pronounced inflammatory reactions (Dinarello et al., 2012). Unchecked IL-1 effects in infants lacking IL-1 receptor antagonist (IL-1RA) lead to a fatal, highly inflammatory disease with pronounced skin and bone involvement, which can be effectively treated with recombinant IL-1RA (Aksentijevich et al., 2009). Acting systemically, IL-1 is essential for inducing fever by switching on cyclooxygenase in hypothalamic cells. Acting locally, IL-1 may also be the key to the death of islet cells in diabetes (Dinarello et al., 2012).

IL-6 is the third highly inflammatory cytokine that is currently targeted in the clinic. While the full IL-6 receptor is only expressed on leukocytes and hepatocytes, all other cells are able to recruit IL-6 bound soluble IL-6 receptor to the gp130 chain they express (Rose-John et al., 2006). This process is termed transsignaling. Although IL-6 signals via STAT3, which is distinct from TNF and IL-1 signaling, its *in vivo* effects are less obviously different (Nishimoto and Kishimoto, 2006). Nevertheless, IL-6 has many unique actions including the induction of C-reactive protein and other acute phase reactants, the inhibition of iron uptake and use via hepcidin. IL-6 is important in the maturation of Th17 cells in both mice and humans. Finally, IL-6 is known to influence sleep and fatigue (Rohleider et al., 2012).

Like IL-1 and IL-6, IL-23 plays a role in Th17 and group 3 ILC differentiation via the activation of STAT3. It is of note that patients with mutations that lead to excessive STAT3 activation are associated with autoimmune disease (Vogel et al., 2015). Inhibition of IL-23 using the monoclonal antibodies ustekinumab and tildrakizumab

**TABLE 18.3** Important Examples of Cytokines Targeting Cells Outside the Immune System

Cytokine (signaling pathways)	Target cell	Effects
TNF (NF- $\kappa$ B, MAPK)	Monocytes	Osteoclast formation
	Osteoclasts	Bone resorption
	Fibroblasts	Activation
IL-1 (NF- $\kappa$ B, MAPK)	Hypothalamic cells	Fever
	Pancreatic islet cells	Cell death, diabetes
IL-6 (Stat3)	Osteoblasts	Reduced bone formation
	Hepatocytes	CRP and hepcidin production
IL-17 (NF- $\kappa$ B)	Epithelial cells	Chemokine production
	Osteoblasts	RANKL expression
TGF $\beta$ (Smads, MAPK)	Fibroblasts	Extracellular matrix deposition
	Podocytes	GBM thickening

*NF- $\kappa$ B*, Nuclear factor- $\kappa$ B; *MAPK*, mitogen-activated protein kinase; *Stat3*, signal transducer and activator of transcription 3; *GBM*, glomerular basement membrane; *CRP*, C-reactive protein.

has been successful in the treatment of psoriasis, psoriatic arthritis, and Crohn's disease. The receptors for both IL-6 and IL-23 require a family of protein tyrosine kinases known as Janus kinases (JAKs) in order to activate their target cells. Two JAK inhibitors, tofacitinib and baricitinib, have been licensed for the treatment of RA and many more are under development.

IL-17 receptors are found on a variety of nonimmune cells, including epithelial cells, endothelial cells, fibroblasts, and adipocytes (Pappu et al., 2011) as well as osteoblasts (Onishi and Gaffen, 2010). Signaling via NF- $\kappa$ B, albeit less effectively than TNF (Sonder et al., 2011), IL-17 induces epithelial cells to secrete chemokines, a process of great importance in psoriasis (Onishi and Gaffen, 2010), psoriatic arthritis, and ankylosing spondylitis, where IL-17 blockade works well (Miossec and Kolls, 2012). On osteoblasts, IL-17 is able to induce the expression of receptor activator of nuclear factor kappa-B ligand (RANKL), which stimulates osteoclast differentiation (Onishi and Gaffen, 2010). IL-17 may also reduce cartilage matrix synthesis by chondrocytes (Hu et al., 2011). By contrast, IL-17 blockade is detrimental in Crohn's disease.

TGF $\beta$  has a complex role, exerting both antiinflammatory and profibrotic effects within the immune system. It is able to inhibit the expression of a number of other inflammatory cytokines and is known to inhibit Th1 and Th2 polarization, and conversely, in the presence of IL-6, it is known to induce Th17 cells in both mice and humans and in the presence of IL-4 can induce IL-9 expressing Th9 cells. Furthermore, it acts on fibroblasts to produce extracellular matrix, and thus tissue fibrosis in many organs (Pohlers et al., 2009). TGF $\beta$  has therefore been suggested as a therapeutic target for systemic sclerosis (Varga and Pasche, 2009). Similarly, TGF $\beta$  may stimulate podocytes to produce extracellular matrix, leading to glomerular basal membrane thickening (Lee, 2012).

## CONCLUSIONS

As to be expected given the time the immune system has had to evolve in an environment where pathogens of various kinds threaten the organism, its effector mechanisms are impressive and have the potential to constrain all current and future pathogens. The adaptive immune system, in particular, has developed highly specialized cells and mechanisms for a differential response. Unfortunately, all of these cells and mechanisms can in some way damage the organism when the immune system makes the error of mistaking self for a dangerous intruder. While our understanding on the mechanisms involved has deepened, and while biologicals and apheresis methods have become more successful in arresting autoimmune disease while preserving immune function, effective nontoxic cures for many autoimmune diseases remain elusive. We hope that further advances in our understanding of the immune system will continue to improve the situation in years to come.

# Diet, the Gut Microbiome, and Autoimmune Diseases

Charles R. Mackay

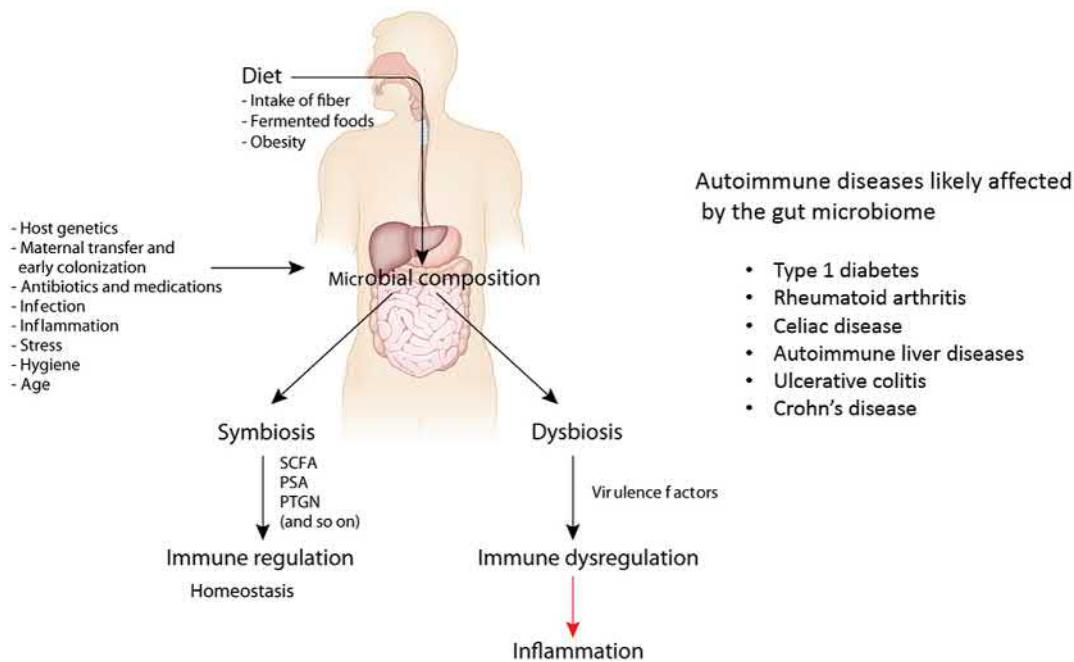

Department of Microbiology, Biomedicine Discovery Institute, Monash University, Clayton, VIC, Australia

## OUTLINE

Introduction	331	Mechanisms for Microbiome-Mediated Gut and Immune Homeostasis Metabolite-Sensing G-Protein Coupled Receptors	336
Evidence That Diet and the Gut Microbiome Associate With Human Autoimmune Diseases	332	Transcriptional and Epigenetic Effects	338
Diet and the Gut Microbiota	333	Other Important Metabolites: Tryptophan Catabolites, ω-3 Fatty Acids	338
Major Products of the Gut Microbiome—Short-Chain Fatty Acids, Mediate Gut Homeostasis, and Immune Tolerance	334	Concluding Remarks	339
Sites Other Than the Gut Where Dietary or Bacterial Metabolites May Influence the Immune Response	336	References	340

## INTRODUCTION

The incidence of many inflammatory conditions has increased dramatically in Western countries over the last decades. This includes not only certain autoimmune diseases, particularly type 1 diabetes (T1D), but also celiac disease, myasthenia gravis, Crohn's disease, and ulcerative colitis (Lerner et al., 2015; Molodecky et al., 2012). Moreover, other "Western lifestyle" diseases such as fatty liver disease, atherosclerosis, hypertension, Alzheimer's disease, and type 2 diabetes have a strong immunological connection, as well as connections to altered gut microbiota composition. The prevailing hypothesis for the increased incidence of inflammatory disease with Western lifestyle has been the hygiene hypothesis (Strachan, 1989, 2000), which proposed that declining family size and improvements in personal hygiene reduced opportunities for cross-infections in families, and this leads to dysregulated immune responses. This hypothesis has evolved, and now disruption of the beneficial gut commensal flora has been suggested as the driver of Western inflammatory diseases (Noverr and Huffnagle, 2004; Rook et al., 2003). In recent years, we have argued for diet and its effect on the microbiome, as an alternative or additional component (summarized in Fig. 19.1). Recent studies highlight the profound effect of diet on gut microbiota composition (Kau et al., 2011; Macia et al., 2015; Turnbaugh et al., 2006). In all likelihood, a variety of Western lifestyle factors combine to adversely affect the gut microbiota composition. This includes antibiotic use (including in the food chain), consumption of processed foods, insufficient intake of dietary fiber, and limited exposure to beneficial microbes, such as those encountered on a farm (Fig. 19.1).

**FIGURE 19.1** Diet, microbial composition, and regulation of the immune system. Diet and other environmental and host factors have a major effect on gut microbial composition. Our model would suggest that balanced microbial composition results in symbiosis; this provides regulation of immune and inflammatory responses through antiinflammatory and/or immunomodulatory products such as short chain fatty acids (SCFAs), polysaccharide A (PSA), and peptidoglycans (PTGN), which helps maintain homeostasis. Dysbiosis can lead to dysregulation of the immune system through lack of beneficial microbial products and changes in gut epithelial integrity, and altered immune tolerance (see below), which could leave the host susceptible to inflammation. Dysbiosis could occur through the consumption of a Western diet (insufficient fiber), as well as through changes induced by factors such as antibiotic use. Source: Adapted from Figure 1 of Maslowski, K.M., Mackay, C.R., 2011. *Diet, gut microbiota and immune responses*. *Nat. Immunol.* 12, 5–9.

Important mechanisms whereby dietary and bacterial metabolites interact with the immune system, or gut biology, and affect inflammation, have been uncovered. Many of the foodstuffs that have traditionally been considered healthy, such as dietary fiber, fish, and elements of the Mediterranean diet, can now be connected to cellular and molecular pathways that promote gut health and immune tolerance. These cellular and molecular studies, combined with epidemiology studies of autoimmune disease, make a compelling case that environment in the West is adding to the incidence of certain autoimmune diseases.

## EVIDENCE THAT DIET AND THE GUT MICROBIOME ASSOCIATE WITH HUMAN AUTOIMMUNE DISEASES

There are now many studies that show that an altered, dysbiosis-related microbiota composition associates with both autoimmune and nonautoimmune inflammatory diseases. Some examples include rheumatoid arthritis (Scher and Abramson, 2011; Van de Wiele et al., 2016), T1D (de Goffau et al., 2013; Endesfelder et al., 2014; Vaarala et al., 2008; Vatanen et al., 2016), Crohn's disease and ulcerative colitis (Huttenhower et al., 2014; Jostins et al., 2012a), celiac disease (Collado et al., 2009), systemic lupus erythematosus (SLE), and others (Vieira et al., 2014). There are considerably more references than those listed here. A central unanswered question is whether certain bacterial species promote disease, or whether the absence of protective commensal species does so. In all likelihood, a combination of these applies.

There have been comprehensive studies on the gut microbiota in human and mouse T1D. Variances in gut microbiota in children diagnosed with T1D, although conflicting, have been widely examined. Children who develop T1D have a less diverse gut microbiota with a decreased presence of *Firmicutes* phylum correlated with decreased fecal butyrate than children with no T1D that presented an increase in *Bacteroidetes* phylum (de Goffau et al., 2013; Giongo et al., 2011). In line with these findings, non-obese diabetic (NOD) mice deficient in the adaptor protein myeloid differentiation factor 88 (MyD88), important for the detection of microbial antigens, fail to

develop T1D under specific pathogen-free (SPF) conditions but in germ-free conditions lead to an exacerbated development of T1D (Wen et al., 2008). In addition, a study by Danska et al. demonstrated the role of the gut microbiota in the marked gender differences that characterize T1D in NOD mice (Markle et al., 2013). Similar to humans, male NOD mice display considerably delayed onset and reduced incidence of T1D. Remarkably, the female cohort gavaged with male gut microbiota were protected from T1D development, in comparison to female cohorts gavaged with a female gut microbiota or untreated, which displayed typical disease incidence (Markle et al., 2013). Treatment of NOD mice with probiotics coincides with the maintenance of  $\beta$ -cell function and prevention of T1D (Calcinaro et al., 2005), and probiotic treatment in genetically susceptible children for the prevention of T1D is currently the focus of the ongoing PRODIA study in Finland (Ljungberg et al., 2006). While these studies provide compelling evidence for the role of gut microbiota in modulating T1D development, the specific metabolites responsible for preventing or ameliorating the diabetic immune response remain to be identified.

## DIET AND THE GUT MICROBIOTA

The average American consumes  $\sim$ 16 g of fiber per day which is well below the recommended daily threshold of 25–38 g/day, and individuals in lower socioeconomic groups consume even less fiber (King et al., 2012). The Mediterranean diet, which is based on high consumption of vegetables, fruits, olive oil, and fish, has now gained scientific credibility, at least in the prevention of cardiovascular diseases, and also asthma (Berthon et al., 2013; Castro-Rodriguez et al., 2008; Estruch et al., 2013; Nagel et al., 2010). A dietary basis for asthma, allergies, and certain autoimmune diseases such as T1D fits with epidemiologic studies (Devereux, 2006; Eder et al., 2006). As a country undergoes development and transformation to the Western lifestyle, there is a rise in the prevalence of asthma and allergy (Eder et al., 2006) and certain autoimmune diseases.

An “obesogenic” diet is characterized by increased consumption of energy-dense, processed foods and reduced consumption of nutrient-rich foods such as fruits and vegetables. If diet does underpin many inflammatory diseases, then metabolites derived directly from the diet, or from commensal bacteria, are certainly involved. The current leading metabolites that likely play protective roles for autoimmune diseases (as well as other inflammatory diseases) are the short-chain fatty acids (SCFAs), omega-3 fatty acids, and tryptophan metabolites. There are well-characterized receptors, transcription factors, and epigenetic mechanisms that account for the anti-inflammatory, protolerogenic actions of bacterial metabolites.

Western diets shape the composition of the gut microbiota (De Filippo et al., 2010; Le Chatelier et al., 2013; Ou et al., 2013; Turnbaugh et al., 2008). The composition of the gut microbiota also relates to human disease (Clemente et al., 2012; Kau et al., 2011; Round and Mazmanian, 2009), through mostly poorly understood mechanisms. However, as stressed throughout this chapter, metabolites such as SCFAs, long-chain fatty acids, or tryptophan catabolites may play a major role in the prevention of inflammatory disease and likely underlie at least some of the microbiota-related associations with human autoimmune diseases. We have argued previously that the major metabolites produced by gut commensal bacteria are SCFAs. It is one of the important symbiotic relationships in vertebrate biology—the use of gut bacteria to digest dietary fiber to produce SCFAs. Vertebrates do not have the enzymes for breakdown of fiber, whereas commensal bacteria in the gut do. The more dietary fiber ingested, the higher the production of SCFAs. The microbiota composition of rural Africans is different to that of African-Americans, with a higher proportion of *Prevotella* (efficient at digesting fiber and producing SCFAs), a lower proportion of *Bacteroides*, and higher production of SCFAs such as butyrate (Ou et al., 2013). In one often quoted study (De Filippo et al., 2010), fecal microbiota of European children and rural African children (from Burkina Faso) were compared. African children showed a higher bacterial richness, and a significant enrichment in bacteria from the genus *Prevotella* and *Xylanibacter*, whereas these bacteria were completely absent from the microbiota from the European children. There were significantly more SCFAs in the feces of African versus European children, attributable to their higher consumption of fiber.

What are the features of the gut microbiota that might promote, or protect against, autoimmune and other diseases? Bacterial “richness” (diversity) is one feature. Individuals with a low bacterial richness ( $\sim$ 23% of the Danish population) tended to adiposity, insulin resistance, and dyslipidemia and a more pronounced inflammatory phenotype, compared with individuals with a high bacterial richness (Le Chatelier et al., 2013). Low bacterial diversity has already been associated with human inflammatory bowel disease (IBD) (Lepage et al., 2011; Manichanh et al., 2006). In our studies in mice, we further observed a close association between gut bacterial diversity and inflammation (colitis, food allergy, autoimmune diabetes). Mice on low-fiber diets produce

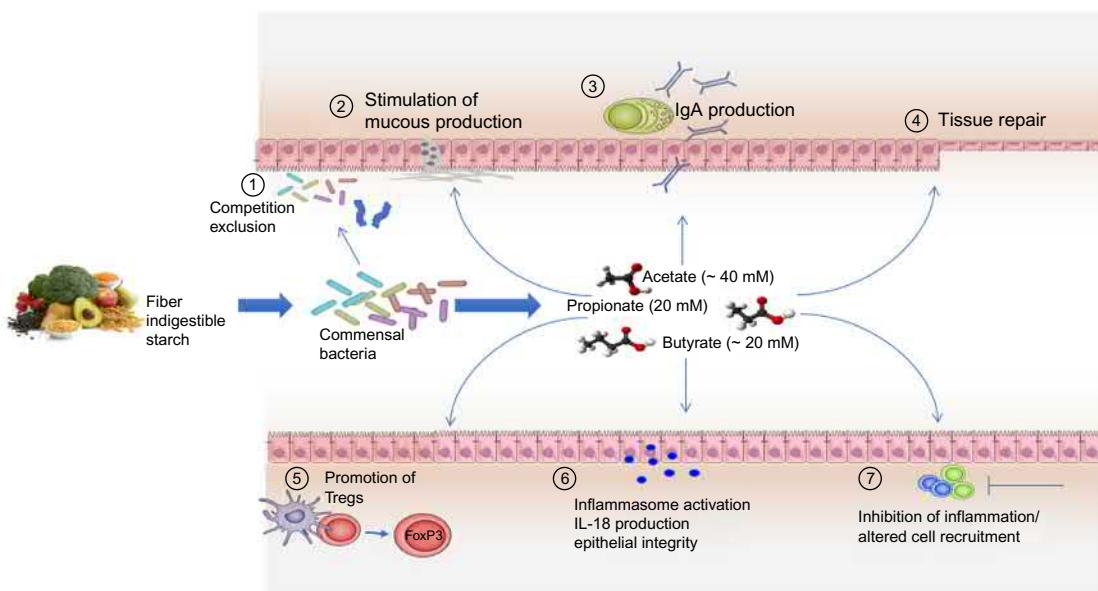

significantly less SCFA in the colon, presumably because of altered bacterial ecology. Such low-fiber fed mice show exacerbated inflammation in models of DSS colitis (Macia et al., 2015), food allergy (Tan et al., 2016), or *Citrobacter rodentium* infection (unpublished). To date, there is little information on the relative ability of different bacterial species to produce various metabolites. In general, *Clostridium* species, particularly clostridial cluster XIVa and IV, are the highest producers of butyrate, and these are also the bacterial species considered necessary for optimal colonic Treg development. All the features of a healthy microbiome have not been fully elucidated, although as discussed throughout this chapter, the capacity to produce SCFAs generally correlates with beneficial bacterial species. However, SCFAs are just one class of metabolite that may promote gut health, for instance, various metabolites associated with tryptophan catabolism promote gut homeostasis (discussed below). Coming years should see vastly improved bioinformatics tools that equate the presence of different bacterial species with enzymatic machinery, and actual capacity, for production of various metabolites.

## MAJOR PRODUCTS OF THE GUT MICROBIOME—SHORT-CHAIN FATTY ACIDS, MEDIATE GUT HOMEOSTASIS, AND IMMUNE TOLERANCE

Numerous metabolites may contribute to gut and immune homeostasis; however, SCFAs are probably the most important. Thus, deficiency of dietary fiber, the foodstuff that yields SCFAs, may underlie poor gut homeostasis and in addition contribute to the development of certain autoimmune diseases as well as asthma, allergies, and even cardiovascular disease and Alzheimer's disease (Maslowski and Mackay, 2011; McKenzie et al., 2017). Disrupted gut homeostasis likely precedes inflammatory conditions. For instance, compromised epithelial integrity may allow translocation of bacteria or their products from the gut lumen to peripheral tissues. Gut "leakiness" may also allow bacterial products such as lipopolysaccharide (LPS) to distribute systemically and potentiate immune cell stimulation. There is considerable evidence that poor gastrointestinal tract integrity plays a role in promoting the pathogenesis of autoimmune T1D (Vaarala et al., 2008). Moreover, obese mice display increased intestinal permeability, and endotoxemia (Cani et al., 2009). An obesogenic diet disrupts gut flora ecology and likely results in lower production of metabolites that maintain epithelial integrity and promote immune tolerance, such as SCFAs. Certain commensal bacteria promote gut epithelial integrity (Fukuda et al., 2011) or Treg function (Arpaia et al., 2013; Furusawa et al., 2013; Smith et al., 2013).

Some of the major mechanisms whereby SCFAs facilitate gut homeostasis and immune tolerance are illustrated in Fig. 19.2. The first relevant mechanism is "competitive exclusion" whereby high-fiber diets expand commensal bacteria, thus limiting access of pathogenic bacteria to gut epithelium. Insufficient intake of fiber or excessive intake of fat or carbohydrate could equally disrupt normal bacterial ecology and compromise competitive exclusion. SCFAs also promote the secretion of mucus by gut epithelial cells (Willemsen et al., 2003). In addition, high acetate-producing bacteria such as *Bacteroides thetaiotaomicron* promote goblet cell differentiation and expression of genes for mucus production (Wrzosek et al., 2013). The mucus barrier is one of the most important elements for physical separation of bacteria from the epithelial surface and is a critical contributor to gut homeostasis, and to immune tolerance (Shan et al., 2013). Interestingly, the inflammasome component Nalp6 is necessary for proper mucus secretion in the gut (Wlodarska et al., 2014), and we suspect that SCFA signaling through metabolite-sensing G-protein coupled receptors (GPCRs) activates Nalp6. In a recent paper, deficiency of dietary fiber had dramatic effects on colitis in the dextran sulfate sodium (DSS) model (Macia et al., 2015). There is evidence that SCFAs promote the secretion of IgA by B cells (Tan et al., 2016). IgA has a key role in maintaining the noninflammatory relationship between the host and the gut microbiota (Peterson et al., 2007) as well as microbiota composition (Round and Mazmanian, 2009). Another point at which SCFAs operate in the gut is in tissue repair (Fig. 19.2, point 3). The gut mucosa is prone to ulceration and like any other tissue relies on tissue repair. This may be particularly important in the GI tract as ulcers, physical damage, or actions of parasites would require constant wound healing processes.

Point 4 of Fig. 19.2 highlights the role of SCFAs in promoting Treg responses in the gut (Atarashi et al., 2013, 2011; Geuking et al., 2011, 2013). SCFAs promote the expansion of Tregs, which presumably facilitates immunological tolerance to food antigens and possibly some commensal bacteria. In one of the first studies, Atarashi et al. (2013) used human fecal samples and applied a sequential methodology to select bacterial species capable of inducing Tregs, when these species were used to colonize germ-free mice. The most potent inducers of Tregs fell within clusters IV, XIVa, and XVIII of *Clostridia*. Simple oral inoculation of *Clostridium* to mice during early life resulted in resistance to colitis and IgE responses (Atarashi et al., 2011), supporting the notion that some inflammatory diseases may have as their basis an unbalanced microbial ecology. The exact properties of

**FIGURE 19.2** Dietary fiber, SCFAs, and mechanisms for gut and immune homeostasis. There is now overwhelming evidence for the positive health benefits of high concentrations of SCFAs in the gut, as well as the high consumption of dietary fiber. Currently, the metabolite-sensor GPCRs responsible for the effects of fiber/SCFAs on gut health and immunity are not fully elucidated, although GPR43 and GPR109A and certain HDACs appear to be particularly important. The current knowledge on precise roles for these molecules is discussed in the main text. The seven major actions for fiber/SCFAs can be summarized as follows: (1) “competitive exclusion” whereby high-fiber diet expands commensal bacteria and limits pathogenic bacteria access to gut epithelium. (2) SCFAs promote the secretion of mucus by gut epithelial cells (Willemse et al., 2003). The mucus barrier is one of the most important elements for the physical separation of bacteria from the epithelial surface. (3) SCFAs promote the secretion of IgA by B cells. IgA has a key role in maintaining a mutualistic relationship between the host and the gut microbiota (Peterson et al., 2007) and SCFAs may influence IgA production. (4) SCFAs promote tissue repair and wound healing. This may be particularly important in the gastrointestinal tract as ulcers, physical damage, or actions of parasites would necessitate constant wound healing processes. (5) SCFAs promote Treg development in the gut, in a process that presumably facilitates immunological tolerance to food antigens and possibly some commensal bacteria (see text). (6) SCFAs (particularly acetate) enhance epithelial integrity (Fukuda et al., 2011) in a process dependent on inflammasome activation and IL-18 production. (7) SCFAs have well-established antiinflammatory effects (Maslowski et al., 2009; Tedelind et al., 2007) particularly inhibition of NF- $\kappa$ b. Source: This figure was adapted from Figure 1 from Thorburn, A.N., Macia, L., Mackay, C.R., 2014. Diet, metabolites, and “western-lifestyle” inflammatory diseases. *Immunity* 40, 833–842.

*Clostridia* that induce Tregs are unclear, although *Clostridia* species are one of the highest producers of the SCFA butyrate, and this may well explain the ability of *Clostridia* to promote Treg numbers. Indeed, recent reports show that SCFAs, particularly butyrate, directly influence numbers and function of inducible Tregs (Arpaia et al., 2013; Furusawa et al., 2013; Smith et al., 2013). Smith et al. (2013) showed that SCFAs delivered to germ-free mice regulated the size and function of the colonic Treg pool.

Point 5 in Fig. 19.2 depicts the effects of SCFAs on epithelial integrity. Acetate produced by a probiotic bacterial species *Bifidobacterium longum* was found to promote epithelial integrity and protect against infection by a pathogenic strain of *Escherichia coli* (Fukuda et al., 2011; Suzuki et al., 2008). However, to date, the best characterized molecular pathway for maintenance of epithelial integrity involves the inflammasome pathway, and production of the inflammasome-related cytokine IL-18 (Dupaul-Chicoine et al., 2010; Elinav et al., 2011; Normand et al., 2011; Zaki et al., 2010). Recently, membrane hyperpolarization, especially mediated by K<sup>+</sup> efflux, or Ca<sup>2+</sup> flux, was found to trigger Nalp3 inflammasome activation (Muñoz-Planillo et al., 2013). GPCR signaling is a common pathway for K<sup>+</sup> efflux, or Ca<sup>2+</sup> flux, and we showed that SCFA signaling through metabolite-sensing GPCRs such as GPR43 and GPR109A activated the Nalp3 inflammasome and production of IL-18 by colonic epithelium (Macia et al., 2015). In addition, we found that diets deficient in fiber, resembling a typical Western diet, enhanced colitis in the DSS model and in a colon cancer model whereas in mice a very high intake of dietary fiber showed a remarkable level of protection in DSS colitis, and colon cancer (Macia et al., 2015).

Point 6 in Fig. 19.2 depicts the antiinflammatory effects of SCFAs, for instance, on inflammatory cytokine production, or on leukocyte recruitment. The antiinflammatory effects of SCFAs have been documented now in a number of animal models of inflammation (Maslowski et al., 2009; Tan et al., 2014). SCFAs have been

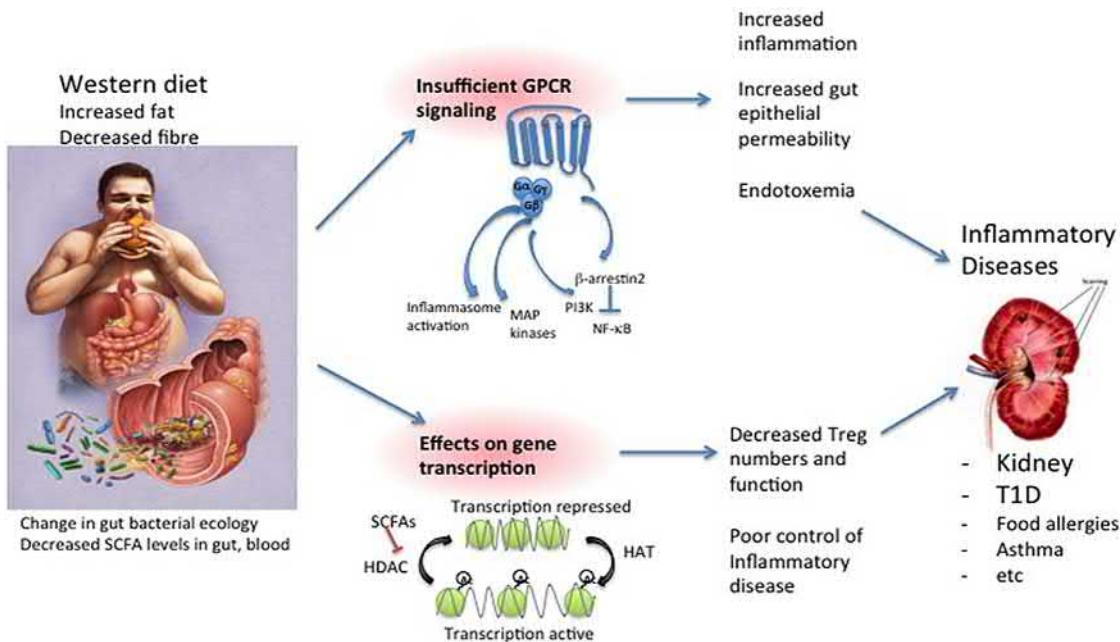

reported to reduce vascular cell adhesion molecule (VCAM) and Intercellular adhesion molecule (ICAM) expression, production of inflammatory chemokines, and inflammatory cytokines, tumor necrosis factor (TNF), Interleukin-6 (IL-6), and Interferon-gamma (IFN- $\gamma$ ) (Vinolo et al., 2011). The ability of SCFAs to inhibit nuclear factor kappa-light-chain-enhancer of activated B cells (NF- $\kappa$ B) is well established, and this may depend on both histone deacetylase (HDAC) inhibition and activation of metabolite-sensing GPCRs, especially signaling through  $\beta$ -Arrestin2 (see below). Thus the actions of SCFAs in the gut shown in Fig. 19.2 are highly relevant to gut health and fit with many years of research that has demonstrated the benefits of either SCFAs or dietary fiber in gut inflammation. In addition to SCFAs, other metabolites show antiinflammatory properties, such as  $\omega$ -3 fatty acids which inhibit TNF or IL-6 production from macrophages (Oh et al., 2010). The antiinflammatory properties of many metabolites presumably reflect the need for constrained immune responses to bacterial or food antigens in the gut. The following sections outline the main molecular mechanisms whereby metabolites influence biological outcomes, which include “metabolite-sensing” GPCRs, and effects on gene transcription through HDAC inhibition, or agonism of specific transcription factors.

## SITES OTHER THAN THE GUT WHERE DIETARY OR BACTERIAL METABOLITES MAY INFLUENCE THE IMMUNE RESPONSE

Originally, the gut was considered the main site where dietary metabolites mediated their effects, such as on gut epithelial integrity, or mucosal immunity. However, several papers show that metabolites (particularly SCFAs) distributed systemically may affect the course of inflammatory responses, lung responses, and macrophage/dendritic cell (DC) differentiation in the bone marrow (Maslowski et al., 2009; Trompette et al., 2014). Nevertheless, the first major point is in the gut, particularly the lower colon, where fiber is fermented by commensal bacteria to produce large quantities of acetate, propionate, and butyrate, ~40, 20, and 20 mM, respectively (Tan et al., 2014). However, acetate is transported across the gut epithelium and reaches relatively high concentrations in the portal venous blood, up to 500  $\mu$ M (Marino et al., 2017). Many immune cells, particularly neutrophils, macrophages, and DCs, express high levels of metabolite-sensing GPCRs (see below). In the periphery, SCFAs influence inflammation through their antiinflammatory effects (Maslowski et al., 2009). The exacerbated inflammatory reactions observed in some germ-free mouse models (Herbst et al., 2011; Maslowski et al., 2009) likely relate to the absence of SCFAs in the gut, blood, or tissues. Another major point at which metabolites may affect biology is through their transport across the placenta to the developing fetus. Acetylation and deacetylation of histones as well as nonhistone proteins such as transcription factors represent one of the main mechanisms for epigenetic control of gene expression. The epigenetic effects of SCFAs in the fetus, acting through HDAC inhibition, represent one likely explanation for dietary links to asthma, and the developmental origin of human disease. For instance, SCFAs profoundly affect the expression and function of FoxP3. Similar considerations also apply to the supply of metabolites through breast milk. To date, the role of breast milk in protecting (or promoting) human disease is inconclusive. High fat feeding of mice during lactation predisposes adult offspring to obesity/and metabolic syndrome diseases (Vogt et al., 2014), and it is possible that quality of breast milk may also influence the development of autoimmune diseases.

## MECHANISMS FOR MICROBIOME-MEDIATED GUT AND IMMUNE HOMEOSTASIS METABOLITE-SENSING G-PROTEIN COUPLED RECEPTORS

Vertebrates have evolved several mechanisms to respond to dietary and bacterial metabolites (see Fig. 19.3). One is metabolite-sensing GPCRs which produce immediate biological responses to specific metabolites. Many of the common dietary and bacterial metabolites have GPCR sensors (Tan et al., 2017; Thorburn et al., 2014). During evolution, these metabolite sensors evolved to recognize metabolites produced either by mutualistic gut bacteria, or by nonbacterial digestion of foodstuffs. The reason why cells of the body, including immune cells, use these receptors to modify function is still uncertain but presumably relates to a need to sense the availability of nutrients. Many of the metabolite sensors were identified as late as the 1990s through large-scale sequencing efforts, and these sensors were deorphaned in the 2000s (reviewed in Macia et al., 2012; Tan et al., 2014). Probably the best characterized metabolite-sensing GPCRs are GPR43, GPR41, and GPR109A, which bind SCFAs. GPR43 and GPR109A appear to be important for gut homeostasis, and both are expressed by colonic epithelium, by inflammatory leukocytes such as neutrophils and macrophages, and by Treg cells. Hence, many of the actions

**FIGURE 19.3** Pathways whereby the gut microbiome may influence autoimmune disease. On the left is the role an altered gut microbiota, produced through poor diet or antibiotic use, may have on gut microbiota composition. Mechanisms are still uncertain but leaky gut and translocation of LPS or bacteria is a likely scenario. On the right are depicted molecular mechanisms whereby gut metabolites may promote gut homeostasis and protect against disease. The first is through immediate responses, mediated by metabolite-sensing GPCRs (top of figure) which signal through a variety of pathways, but in particular  $\beta$ -arrestin2 (which yields antiinflammatory effects), or through G-proteins such as G $\alpha$ i or G $\alpha$ q. The second mechanism whereby SCFAs affect biology is through effects on gene transcription. SCFAs inhibit the activity of HDACs, which deacetylate either histone proteins (bottom). Such inhibition of HDACs is a mechanism for regulation of gene transcription. Another mechanism not listed here is direct agonism of transcription factors such as AhR by certain metabolites.

described above for SCFAs in gut homeostasis can be ascribed to these two receptors. Deletion of either receptor in mice exacerbates DSS colitis (Maslowski et al., 2009; Singh et al., 2014). We have found that the beneficial effects of dietary fiber, in the DSS colitis model, depend on GPR43 and/or GPR109A (Macia et al. 2015). Moreover, the beneficial effect of acetate on epithelial integrity (Fukuda et al., 2011) probably operates through GPR43. In our studies, we see far fewer Th17 $^{+}$  T cells in the colon of *Gpr43* $^{-/-}$  mice during DSS colitis.

Regulation of colonic and possibly peripheral Treg numbers relates to metabolite-sensing receptors, including GPR43 and GPR109A (Singh et al., 2014; Smith et al., 2013). Our studies reveal that high-fiber feeding, or acetate, promotes colonic Treg numbers, whereas *Gpr43* $^{-/-}$  mice show reduced Treg numbers (Marino et al., 2017). Lack of GPR109A, a metabolite sensor for butyrate, was associated with fewer colonic Tregs due to the reduced ability of colonic macrophages and DCs to promote their development (Singh et al., 2014). Regardless of some discrepancies in these recent papers relating to the relative roles of acetate, propionate, and butyrate, SCFAs, the main metabolic products of commensal bacteria, are used as a mechanism for tolerance induction in the gut (Tan et al., 2016).

Other important metabolite-sensing GPCRs include GPR120 which recognizes long-chain fatty acids such as  $\omega$ -3 fatty acids (Oh et al., 2010) derived from foodstuffs including fish and olive oil, GPR91 as a receptor for succinate (a product of the citric acid cycle), GPR84 which is a receptor for medium chain fatty acids derived from milk in certain species, and GPR35 which is a receptor for metabolites of tryptophan catabolism, that is, kynurenic acid. All of the metabolite-sensing GPCRs are expressed by immune cells, and particularly by innate-type cells, although this knowledge has mostly been gleaned from transcript expression analyses. Another defining feature of metabolite-sensing GPCRs is their expression on tissues or cells relevant to metabolism, pancreatic islets, or white adipose tissue. Another common expression pattern is on intestinal epithelium, which probably relates to roles in the maintenance of epithelial integrity. The role of many of these receptors is poorly defined, and tools to study their expression and function await development.

Metabolite-sensing GPCRs have a large bearing on the control of inflammatory responses, particularly inflammatory bowel disease (Maslowski et al., 2009; Oh et al., 2010; Singh et al., 2014; Tan et al., 2016; Trompette et al., 2014). Indeed, most metabolite-sensing GPCRs including GPR43 and SCFAs, GPR120 and  $\omega$ -3 fatty acids,

GPR109A and its ligands, and possibly GPR35 and its ligands facilitate antiinflammatory effects (Tan et al., 2017). Concerning the SCFA receptors, *Gpr43*<sup>-/-</sup> mice showed exacerbated inflammation in models of airway hypersensitivity, DSS-induced colitis, and rheumatoid arthritis (Maslowski et al., 2009). Administration of acetate to mice in the drinking water protected against colitis in wild-type mice but not in *Gpr43*<sup>-/-</sup> mice suggesting that acetate mediates its antiinflammatory effects through GPR43. The antiinflammatory effects of SCFA are not limited to GPR43 as a recent study (Trompette et al., 2014) established a role for propionate and its receptor GPR41 in the generation of macrophage and DC precursors and in the seeding of the lungs by DCs that have high phagocytic capacity, but an impaired ability to promote Th2 cell responses.

An important question is how GPCR signaling by metabolite agonists produces antiinflammatory effects. Metabolite-sensing GPCRs signal in several ways to mediate biological effects, although this aspect remains unclear. There are several possible outcomes following engagement of a metabolite sensor with its agonist, including signaling through regular G-proteins such as G<sub>αi</sub> or G<sub>q</sub>, which usually lead to activation of MAP kinases, PI3 kinases, or mTOR. Interestingly, many metabolite-sensor GPCRs engage an alternative signaling pathway, mediated by β-Arrestin2 (Oh et al., 2010), which generally produces antiinflammatory effects, some of which relate to the inhibition of NF-κB. All of the major metabolite-sensor GPCRs signal through β-Arrestin2, but precise circumstances or cell types that preferentially use β-Arrestin2 have not yet been established. β-Arrestin2 directly interacts with IκBα (an inhibitor of NF-κB), so preventing the phosphorylation and degradation of IκBα (Gao et al., 2004).

## TRANSCRIPTIONAL AND EPIGENETIC EFFECTS

Acetylation and deacetylation of histones, as well as nonhistone proteins such as transcription factors, are a major mechanism for epigenetic regulation of gene expression (Fig. 19.3). Acetylation of histones, by histone acetyltransferases (HATs) or inhibition of HDACs, results in negatively charged histones which, when interacting with negatively charged DNA, loosen the chromatin structure resulting in a transcriptionally active conformation. Acetylation also promotes the activation, nuclear translocation, and DNA binding of transcription factors such as STAT3, NF-κB, FoxP3, N-FAT, and RUNX1. This promotes the expression of multiple genes, including those for proinflammatory cytokines (Wang et al., 2009). Acetylation of transcriptional factors can lead to structural changes that alter transcriptional factor binding to the promoter region, thereby initiating gene expression. In the case of NF-κB, acetylation of the RelA subunit prevents interaction with IκBα and results in poor formation and reduced transcriptional interaction (Chen et al., 2001). HDACs are a class of enzymes that catalyze the removal of acetyl groups from proteins, and ~1750 acetylated proteins have the potential to be affected by HDAC activity (Choudhary et al., 2009). SCFAs are natural inhibitors of HDAC enzymatic activity, and this may affect gut homeostasis, since HDAC3 deleted from intestinal epithelial cells severely disrupted gut homeostasis, in the DSS model (Alenghat et al., 2013). Butyrate is the most potent HDAC inhibitor, and acetate the least. However, SCFAs may also inhibit the transcription of individual HDAC genes, thereby influencing HDAC activity. Synthetic small molecule inhibitors of HDACs attenuate inflammation in animal models of arthritis, inflammatory bowel disease, asthma, diabetes, cardiovascular disease, and multiple sclerosis (Wang et al., 2009). In addition, the broad HDAC inhibitor trichostatin-A increases Treg gene expression and suppressive capacity (Tao et al., 2007) supporting involvement of SCFAs in Treg induction, and illustrating the potential of either natural or synthetic HDAC inhibitors to promote immunological tolerance, or antiinflammatory responses.

## OTHER IMPORTANT METABOLITES: TRYPTOPHAN CATABOLITES, ω-3 FATTY ACIDS

If Western diet and metabolites are related to the increase in incidence of some autoimmune diseases, then how much of this relates to the gut microbiota, versus metabolites derived directly from food digestion, such as ω-3 fatty acids, or tryptophan metabolites. Tryptophan, an essential amino acid, is found in foodstuffs such as red meat and fish, eggs, yogurt, and many vegetables. Tryptophan may be catabolized by microbial species, such as lactobacilli. One tryptophan metabolite produced by lactobacilli, indole-3-aldehyde, is an

Aryl hydrocarbon receptor (AhR) agonist (Zelante et al., 2013). Following agonist binding, AhR translocates to the nucleus, where it forms a heterodimer with AhR nuclear translocator. AhR-dependent gene expression includes genes involved in the production of mediators important for gut homeostasis including IL-22, antimicrobial factors, increased Th17 cell activity, and the maintenance of intraepithelial lymphocytes, and ROR $\gamma$ t<sup>+</sup> innate lymphoid cells (Li et al., 2011; Veldhoen and Brucklacher-Waldert, 2012). The absence of AhR in mice increases the severity of DSS colitis (Li et al., 2011) as well as *C. rodentium* infection (Kiss et al., 2011). However, various other metabolites bind AhR, including flavonoids and glucosinolates, which are abundant in plants. Tryptophan is degraded to kynurenin (an AhR agonist) by the immune-regulatory enzyme indoleamine 2,3-dioxygenase (IDO) and IDO activity is linked to suppression of T-cell responses, promotion of Tregs, and immune tolerance (King and Thomas, 2007). Moreover, a number of tryptophan metabolites including Kynurenic acid and niacin agonize metabolite-sensing GPCRs, such as GPR35 and GPR109A. GPR35 polymorphisms are a genetic risk factor for IBD (Jostins et al., 2012b). Dietary tryptophan can be metabolized by the gut microbiota into AhR agonists and in one study had an effect on astrocytes to limit CNS inflammation in the experimental autoimmune encephalomyelitis (EAE) model. Moreover, in individuals with MS, the circulating levels of AhR agonists were decreased (Rothhammer et al., 2016). Thus multiple elements of tryptophan catabolism may affect gut homeostasis, metabolite levels, and autoimmune disease.

The mere existence of metabolite-sensing GPCRs for dietary factors such as  $\omega$ -3 fatty acids (Oh et al., 2010; Toma et al., 2008) or tryptophan metabolites suggests nonbacterial metabolites are important for regulating immunity. It is possible that the health benefits of the Mediterranean diet relate, in part, to  $\omega$ -3 fatty acids, which show antiinflammatory effects in many animal models, as well as in clinical intervention studies (Simopoulos, 2002).

SCFAs may play a major role in the prevention of autoimmune disease and may underlie at least some microbiota-related associations with human disease. We have shown that SCFAs from the mother cross the placenta and protect against inflammatory asthma in offspring through epigenetic imprinting, mediating changes in gene transcription such as Foxp3 target genes important for tolerance/autoimmunity (Thorburn et al., 2015). SCFAs produced from bacterial fermentation of fiber not only promote Treg number and function in the colon (Furusawa et al., 2013; Smith et al., 2013) but also induce the promotion of extrathymic generation of Treg, via epigenetic effects (Arpaia et al., 2013). This, in turn, allows Treg to better control autoreactive lymphocytes and prevent the development of autoimmune disease (Bridle et al., 2013; Feuerer et al., 2009; Fontenot and Rudensky, 2005; Zhou et al., 2009). For instance, epigenetic alterations such as histone modifications of the FOXP3 locus are important for proper Foxp3 expression and the functional activity of Tregs (Zhang et al., 2013). Foxp3 also epigenetically modulates the transcriptional activity of target gene loci by altering DNA methylation, transcription factor associations, and histone modifications. These include the HATs Tip60 and p300 and the HDAC HDAC7 (Li et al., 2007; Tao et al., 2007). Tregs, driven by the Foxp3 transcription factor, are particularly important for limiting autoimmunity and chronic inflammation (Tao et al., 2007; Vignali et al., 2008).

## CONCLUDING REMARKS

New understanding in gut microbial ecology, metabolite biology, metabolite-sensing GPCRs, and transcriptional regulation by metabolites opens up an attractive new understanding of autoimmune diseases, as well as new avenues to prevent or treat autoimmune diseases—particularly those diseases that have a very strong environmental influence. Increases in the incidence of certain autoimmune disease likely relate to Western diet and lack of dietary fiber. It is also possible that antibiotic use by humans, or antibiotic presence in the food chain, adversely affects gut bacterial ecology which then flows through to higher incidences of some autoimmune diseases. Although it is early days, the implementation of diet and/or gut microbiota as a tool to prevent or treat autoimmune diseases is an exciting prospect that may impact greatly on human health. One of the advantages of a gut microbiota/prebiotic approach to human disease, including autoimmune disease, is that beneficial metabolites operate through numerous cellular and molecular pathways (Marino et al., 2017; Tan et al., 2016), they appear to be highly efficacious in most models tested, and they are natural products. For these reasons, the treatment (or prevention) of autoimmune diseases could undergo a transformation in the coming years.

## INTRODUCTION

Although the mechanisms by which autoimmune diseases develop remain obscure, accumulating evidence suggests that these disorders result from environmental exposures in genetically susceptible individuals (Luppi et al., 1995; Cooper et al., 1999b; Miller, 1999; Gourley and Miller, 2007; Miller et al., 2012b; Pollard et al., 2010). Despite the great progress that has been made in understanding many major histocompatibility complex (MHC) and non-MHC genetic risk factors for autoimmune diseases (see Chapter 26: Genetic Predisposition to Autoimmune Diseases Conferred by the Major Histocompatibility Complex: Utility of Animal Models, and Chapter 28: Autoimmunity in Primary Immunodeficiency Disorders), relatively little information is currently available regarding the role that specific environmental agents play in the development and course of these disorders. This is partly a result of the lack of validated exposure biomarkers and environmental assessment tools, difficulties inherent in defining which of the many environmental exposures are related to autoimmune disease, little formal training in environmental medicine for physicians, environmental effects that are limited to specific genetic backgrounds, difficulty knowing the time frame from exposure to disease onset, the rarity of some autoimmune diseases (making well-powered studies difficult), and the relative lack of resources dedicated to this area. Thus for most autoimmune conditions, specific environmental triggers remain unknown. Just as there are likely to be multiple genes needed to induce autoimmune disease, multiple environmental exposures may occur

in a particular sequence or in tandem to provoke the chronic immune activation that leads to autoimmunity. It is also possible that environmental exposures might influence epigenetic modifications that are controlled by heritable but potentially reversible changes in DNA methylation and/or chromatin structure (Javierre et al., 2011; Meng et al., 2017). In this regard many lessons might be learned from studies of cancers. Like autoimmune diseases, cancers are multifactorial disorders in which multiple genetic and environmental risk factors must interact and may need to do so in a correct sequence, with occasional long latencies, before the development of disease (Sarasin, 2003). Thus in some cases, a change induced by one exposure might be necessary before a subsequent exposure can have its effect. Alternatively, mixtures of exposures, including possible infectious and noninfectious agents, perhaps occurring during critical windows when persons may be more susceptible to them (i.e., in utero, in childhood, during puberty, pregnancy, or lactation) may be necessary in order to overcome tolerance.

Other general principles from cancer research that might be relevant to autoimmunity include the pathogenetic heterogeneity of currently defined disorders, the likely low effect sizes from many environmental exposures, and the possible requirement for inducers, promoters, and sustainers of disease at different points in the pathogenetic process (Cooper et al., 2002b). This is particularly borne out by investigations, suggesting that immune activation and autoantibodies are antigen driven and precede the development of clinical disease by months to years (Dotta and Eisenbarth, 1989; Leslie et al., 2001; Arbuckle et al., 2003; Klareskog et al., 2004; Hirschfield and Gershwin, 2013; Miller et al., 1990). These findings suggest that certain environmental exposures might be necessary for tolerance to be overcome in genetically susceptible individuals, which induces autoantibody formation, while other agents might be necessary to promote the expression of clinical disease. While some environmental factors have a role in disease pathogenesis, other types of environmental factors appear to play a role in disease severity and presentation or alternatively may serve as protective factors (Deane, 2013). There is increasing evidence that some environmental factors, such as exercise, can reduce disease symptoms (Boehler et al., 2017) and potentially decrease inflammation, while other factors such as ultraviolet light may cause disease flares (Mamyrova et al., 2017). Thus the presence of multiple risk factors, combined with the relative absence of preventative factors, might allow for the development of autoimmune diseases.

If one defines environmental agents as everything outside the genome, the many exposures that have been suspected of being involved in the pathogenesis of autoimmunity may be divided into two general categories: infectious and noninfectious agents. This chapter will focus on the evidence for the role of noninfectious environmental agents in the pathogenesis of human autoimmune diseases. Infectious agents are reviewed in Chapter 19, Diet, the Gut Microbiome, and Autoimmune Diseases.

## EVIDENCE SUPPORTING THE ROLE OF ENVIRONMENTAL AGENTS IN AUTOIMMUNE DISEASE

Evidence for the role of environmental agents in autoimmune disease comes from a variety of investigative approaches (Box 20.1). Although many of these methods are indirect, anecdotal, or may be applicable only to single patients, taken together these diverse findings strongly support the contention that most autoimmune diseases have an important environmental component (Cooper et al., 1999a; Smyk et al., 2012). A principal line of evidence for the role of the environment is that for autoimmune diseases studied to date, there is generally less than 50% disease concordance in monozygotic twins (Cooper et al., 1999b; Leslie and Hawa, 1994; Bogdanos et al., 2012). These findings suggest that, if all the genetic risk factors for a given autoimmune disease were identified, without the incorporation of environmental or other factors, it would not be possible to predict disease onset more accurately than flipping a coin.

For certain agents, it can be relatively clear when a given exposure has induced a disease in an individual patient. The definition of an environmental disease in an individual can be accomplished by identifying a new clinical disorder, which develops soon after a novel exposure, resolves when the exposure is removed (dechallenge), and then recurs after reintroduction of the same exposure (rechallenge) (Miller et al., 2012a). This approach is most easily applied in cases of exposure to defined chemical entities, such as drugs, foods, and topical or inhaled toxicants. Unfortunately, many xenobiotics (compounds not naturally found in the body) cannot easily be removed from an organism after exposure; therefore for these agents, this approach is not usually helpful. Exposures in this category include inhaled silica, vaccines, fat-soluble oils, and collagen or silicone implants.

The nonrandom distribution in time and space of some autoimmune illnesses also implies that nongenetic factors are important in disease development (Moroni et al., 2012). Studies on these topics are preliminary and sometimes have not been reproduced, leading critics to posit that referral or other biases might explain some of the

**BOX 20.1****LINES OF EVIDENCE SUPPORTING THE ROLE OF ENVIRONMENTAL AGENTS IN THE DEVELOPMENT OF AUTOIMMUNE DISEASE**

1. Less than 50% disease concordance in monozygotic twins
2. Strong temporal associations between some environmental exposures and disease onset
3. Dechallenge (disease resolution or improvement in an individual after removal of the suspected agent)
4. Rechallenge (disease recurrence or worsening in an individual after reexposure to the suspected agent)
5. Seasonality in birth dates and disease onset
6. Geographic clustering in disease incidence and prevalence
7. Changes in the prevalence or incidence of disease over time and when genetically similar cohorts move to different geographic locations
8. Major genetic risk factors for autoimmune diseases are polymorphic genes that influence responses to environmental exposures
9. Strong biologic plausibility from animal models
10. Epidemiologic associations between particular exposures and certain diseases

findings. Nonetheless, intriguing investigations have suggested that certain autoimmune disorders have a seasonal onset or that there is a seasonal association with subsets of patients based on disease-specific autoantibodies. The diseases reported to have seasonal associations include autoimmune myositis (Leff et al., 1991; Miller, 1993; Sarkar et al., 2005), juvenile rheumatoid arthritis (Feldman et al., 1996), type 1 diabetes (Weinberg et al., 1984; Willis et al., 2002), narcolepsy (Han et al., 2011), antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (Schlesinger and Schlesinger, 2005), systemic lupus erythematosus, inflammatory bowel disease, autoimmune liver disease, and psoriasis (Watad et al., 2017). Furthermore, studies of type 1 diabetes, myositis, thyroid disease, autoimmune Addison's disease, and other diseases have shown significant associations with birth dates (Willis et al., 2002; Ursic-Bratina et al., 2001; Vegosen et al., 2007; Thvilum et al., 2017; Pazderska et al., 2016), implying that certain exposures at certain times of the year may alter the target tissues or immune systems of fetuses or neonates, resulting in later autoimmunity. Although infectious agents are often presumed to be the source of such seasonal or geographic associations, the immune system, like other organ systems, appears to have cyclic or rhythmic patterns (Haus and Smolensky, 1999; Terao et al., 2012), possibly related to light exposure and mediated by melatonin or other neurohormones (Nelson and Drazen, 2000). In addition, many occupational or other exposures are seasonal, including certain pesticides, chemicals in sunscreens, and some air or water pollutants, so it is possible that noninfectious agents could account for some of those data in ways that have not been accounted for. Geographic clustering or gradients in disease prevalence or incidence have also been found for some autoimmune diseases. These investigations have primarily shown associations with latitude, suggesting a role for ultraviolet radiation in (1) inducing disease, as may be the case for dermatomyositis and celiac disease (Okada et al., 2003; Love et al., 2009; Unalp-Arida et al., 2017); (2) altering age at onset, as may be the case for rheumatoid arthritis and multiple sclerosis (Latitude, 2017; Tao et al., 2016); (3) altering mortality, as may be the case in lupus (Grant, 2004); or (4) protecting from disease, as may be the case in multiple sclerosis and type 1 diabetes (Ponsonby et al., 2002). Measurable increases or decreases in the incidence or prevalence of disease over time imply a nongenetic etiology, given the slow rate of genetic change in a population. Although data are limited in this area, and several studies are possibly confounded as a result of improvements in the ability to diagnose some conditions over time, it appears that type 1 diabetes, multiple sclerosis, lupus, and myositis are becoming increasingly prevalent, whereas rheumatoid arthritis in adults and children may be decreasing in prevalence in some populations (Oddis et al., 1990; Onkamo et al., 1999; Uramoto et al., 1999; Cooper and Stroehla, 2003).

Changes in living standards and treatment approaches can also affect disease frequency, as in rheumatic heart disease, which is decreasing in prevalence (Johnson et al., 1975). Some authors believe that as our exposure to microbial agents has decreased in modern urban environments, the development of our immune systems has been altered, resulting in greater frequencies of autoimmune disorders, a concept known as the "hygiene

hypothesis" (Rook, 2012). Studies of genetically similar populations living under different conditions have been illuminating. For example, the incidences of both multiple sclerosis and type 1 diabetes changed as members of a population moved to new regions (Dahlquist, 1998; Noseworthy et al., 2000).

Epidemiologic studies linking specific exposures to autoimmunity are limited and usually consist of relatively small, often underpowered investigations, resulting in low effect sizes and large confidence limits. Much larger, well-designed, multicentered, and sometimes international studies, using appropriate controls and collecting adequate information to minimize confounding, will be needed in the future to more fully define the specific environmental risk factors for disease (Miller, 2012). In some cases it may be useful to assess novel observational study designs such as case crossover studies (Sun et al., 2016).

## IDENTIFYING AND DEFINING ENVIRONMENTALLY ASSOCIATED AUTOIMMUNE DISEASES

One limitation in making progress toward identifying and defining environmental triggers for autoimmune disorders has been the lack of consensus about the necessary and sufficient evidence needed to define a condition that is triggered by an environmental factor. Medical and legal issues that surround many environmental exposures have further complicated this area. A group of experts in the field—members of the American College of Rheumatology Environmentally Associated Rheumatic Disease Study Group—developed consensus on a general approach to overcome this problem (Miller et al., 2000) with revision and expansion based on an expert panel workshop (Miller et al., 2012a,b). In this scheme the overall process, from the identification of the first possible patient who developed a new disease after an exposure, to the refinement of classification criteria for the new disease, is divided into four stages (Table 20.1).

The *first stage* begins by identifying a single case, or a series of cases, suspected to result from a given exposure. Such cases need to meet certain criteria to ensure that a minimum number of attribution elements are present (Miller et al., 2012a). A total of at least four of eight possible attribution elements need to be present, including at least three of five primary elements.

The five primary elements are

1. temporal plausibility (taking into account the pharmacokinetics/pharmacodynamics of the agent, minimum induction time, and maximum latency);
2. exclusion of other likely causes for the syndrome;
3. dechallenge (if possible);
4. rechallenge (if appropriate); and
5. biologic plausibility.

The additional three secondary elements are

1. identification of prior reports of similar cases (analogy);
2. identification of prior reports of nearly identical cases (specificity); and
3. evidence for a dose–response effect.

**TABLE 20.1** Proposed Stages for Identifying and Defining New Environmentally Associated Autoimmune Diseases

Stage	Description	Nomenclature (example)
1. Proposing the association	Case reports, defined by ascertainment criteria, propose a possible association of a specific clinical syndrome with a given exposure	Syndrome following exposure (rheumatoid arthritis following hepatitis B vaccination)
2. Testing the association	After a number of such cases are reported, surveillance criteria are proposed and epidemiologic and laboratory studies test that hypothesis	Cardinal signs, symptoms, and labs but without the putative exposure (EMS)
3. Defining criteria for the condition	If studies above are positive, specific preliminary classification and other criteria are defined for that specific environmental disease	Exposure-associated disorder ( <i>L</i> -tryptophan-associated EMS)
4. Refining criteria for the condition	Criteria are reassessed and refined as additional data are obtained about the disease	Exposure-induced disorder (hydralazine-induced lupus-like disorder)

Modified from Miller, F.W., Pollard, K.M., Parks, C.G., Germolec, D.R., Leung, P.S., Selmi, C., et al., 2012a. Criteria for environmentally associated autoimmune diseases. *J. Autoimmun.* 39 (4), 253–258.

In addition to meeting those criteria, the study group suggested that complete information regarding the history and examination, laboratory reports, core demographic data, family history, prior infections or physiology-altering exposures, all prior diagnoses, and the type, route, dose, and duration of the exposure are detailed in the report.

The *second stage* involves testing the possible association. This should include epidemiologic studies that use surveillance criteria to evaluate the relationship between a given exposure and a given syndrome. In vitro, in vivo, and animal studies should also be conducted to assess the biologic effects of the agent and plausibility of the development of the syndrome. Other approaches—such as clinical, laboratory, or genetic risk factor studies—could determine in case-control settings if cases of environmental disease differ from those with similar diseases without the exposure or differ from subjects similarly exposed but who do not develop disease.

If data from the second stage produce convincing evidence that the association is real, then in the *third stage*, preliminary criteria for that environmentally associated disease are developed. Classification criteria will distinguish, with reasonable sensitivity and specificity, groups of patients with one disorder from those with closely related diseases. Expert committee consensus, mathematical algorithms, or other approaches could be used to develop such criteria. Symptom, sign, and laboratory criteria should be expressed in clinically sensible and practical formats with precise definitions of constituent elements. Diagnostic, prognostic, and outcome criteria, and disease activity and damage indexes should be considered when adequate data exist.

In the *fourth stage*, if new information is obtained and warranted a redefinition of the disease, the same processes used in the third stage are repeated. Although this proposed staging structure has limitations, in that the decisions as to when to progress to the next stage remain somewhat subjective, it nonetheless provides an overall framework to plan for future studies, and it allows the classification of the known environmental agents into groups with different levels of evidence for their association with specific syndromes. Most environmental agents suspected of being associated with autoimmune diseases today remain in stage 1 or 2. Similar approaches to assess the strength of associations with established diseases and in-clinic situations have also been proposed by an expert consensus approach (Miller et al., 2012a).

## NONINFECTIOUS AGENTS ASSOCIATED WITH AUTOIMMUNE DISEASES

### Drugs

Of all the noninfectious environmental exposures associated with autoimmunity, drugs are the best recognized and most often reported (Table 20.2). This is partly due to their widespread use and to more careful monitoring by clinicians, the strict regulatory oversight and adverse event reporting systems in many countries, and the ease of collecting dechallenge and rechallenge evidence to make associations in individual patients. Although several hundred drugs have been associated with autoimmune diseases, in case reports or case series, few of the publications have met the consensus criteria described above to allow the exclusion of confounding factors, and few drugs have been studied in epidemiologic investigations. Chemical agents have been the most frequently reported drugs that precede the development of autoimmunity, although the increasing use of biologic agents has resulted in more focus on them recently. The most commonly recognized drug-related syndromes are lupus-like disorders (Hess and Mongey, 1991). They are characterized by autoantibodies to histones and single-stranded DNA rather than autoantibodies to double-stranded DNA, as are found more often in nondrug-related lupus. Drug-related lupus also differs from nondrug-related lupus in that it has more frequent arthritis and less frequent neurologic and renal involvement, as well as possibly different genetic risk factors. Virtually all the 80 or more autoimmune diseases have been reported anecdotally to be associated with one or more drugs. In some cases drug-linked disorders differ from nondrug-related forms in clinical, serologic, or genetic features, but in other cases, they do not.

It is noteworthy that although some drugs appear to be associated with many autoimmune conditions (Table 20.2), there are no common structures, mechanisms of action, metabolites, or other features among them that consistently allow prediction of their toxicity or a current understanding of the pathogenesis of these syndromes. The challenge today is to decipher the genetic and other risk factors that interact with exposure to drugs and result in disease, so that those interactions can be predicted and disease prevented.

**TABLE 20.2** Selected Drugs Associated in Case Reports or Case Series With Autoimmune Disorders<sup>a</sup>

Drug	Associated autoimmune disorders
$\alpha$ -Methyldopa	Lupus-like syndrome, hemolytic anemia, thrombocytopenia
Allopurinol	Lupus-like syndrome, vasculitis
Aminoglutethimide	Sjögren's syndrome
Bleomycin	Scleroderma
Captopril	Lupus-like syndrome, vasculitis, membranous glomerulopathy, autoimmune thrombocytopenia
Chlorpromazine	Lupus-like syndrome, hemolytic anemia
D-Penicillamine	Lupus-like syndrome, myositis, hypothyroidism, Goodpasture's syndrome
Diphenylhydantoin	Linear IgA bullous disease
Erythromycins	Lupus-like syndrome, myositis, hepatitis
Estrogens	Lupus-like syndrome, myositis
Gold salts	Lupus-like syndrome, membranous glomerulopathy
Halothane	Hepatitis
Hydralazines	Lupus-like syndrome, vasculitis, hepatitis
Interferon-alpha	Lupus-like syndrome, antiphospholipid syndrome, arthritis, hemolytic anemia, thrombocytopenia, hepatitis, hypothyroidism
Interferon-gamma	Lupus-like syndrome, myositis, arthritis, hypothyroidism
Interleukin-2	Scleroderma, antiphospholipid syndrome, arthritis, hypothyroidism
Iodine	Hypothyroidism
Isoniazid	Lupus-like syndrome, arthritis, hepatitis, vasculitis, hypothyroidism
L-Tryptophan	EMS, scleroderma, myositis, neuropathies
Levamisole	Vasculitis
Lipid-lowering agents	Lupus-like syndrome, hepatitis, thrombocytopenia
Methyldopa	Lupus-like syndrome
Minocycline	Lupus-like syndrome
Penicillins	Anemia, lupus-like syndrome, hepatitis
Phenytoin	Scleroderma, lupus-like syndrome, hepatitis, thrombocytopenia
Procainamide	Lupus-like syndrome
Propylthiouracil	Lupus-like syndrome, ANCA-associated vasculitis, myositis
Quinidine	Lupus-like syndrome, arthritis, thrombocytopenia
Rifampin	Thrombocytopenia, vasculitis
Statins	Immune-mediated necrotizing myopathy
Sulfonamides	Lupus-like syndrome, vasculitis
Tetracyclines	Lupus-like syndrome, arthritis, vasculitis
TNF inhibitors	Lupus-like syndrome

<sup>a</sup>Reviewed in Love and Miller (1993), Bigazzi (1997), Mackay (1999), D'Cruz (2000), Hess (2002), Liu and Kaplowitz (2002), Chang and Gershwin (2011), Carmona-Rivera et al. (2017).

ANCA, Antineutrophil cytoplasmic antibodies; EMS, eosinophilia–myalgia syndrome; TNF, tumor necrosis factor.

## Occupational Exposures

Limited but growing epidemiologic and experimental data have linked several occupational exposures to autoimmune diseases (Table 20.3). The most studied of these include silica, solvents, pesticides, and ultraviolet radiation (Miller et al., 2012b; Westberg et al., 2009; Cooper et al., 2002a, 2010; Parks et al., 2011; Haupt-Jorgensen et al., 2017). One of the first rheumatic diseases associated with an occupational exposure was Caplan's syndrome, which is seropositive rheumatoid arthritis associated with a specific form of pneumoconiosis that develops in miners of anthracite coal and in persons exposed to silica and asbestos (Williams, 1991). The strongest occupational associations with autoimmune disease (i.e., a relative risk of 3.0 and higher) have been documented in investigations of silica dust and rheumatoid arthritis, lupus, scleroderma, and ANCA-associated glomerulonephritis (Parks et al., 1999; Khuder et al., 2002; Ilar et al., 2018). Weaker associations are seen, however, for solvent exposures (in scleroderma, undifferentiated multisystem rheumatic disease, and multiple sclerosis) and for farming or pesticide exposures (in rheumatoid arthritis, type 1 diabetes, and lupus). Vinyl chloride has been linked to the development of a scleroderma-like disease characterized by skin thickening, Raynaud's phenomenon, acroosteolysis, and pulmonary involvement. This observation, and the publication of several case reports, stimulated research into associations between scleroderma and other chlorinated solvents (e.g., trichloroethylene and trichloroethane) with varying results (Cooper et al., 2002a, 2009).

There are many difficulties in assessing the role of occupational exposures in disease. First, there are few biomarkers for such exposures and essentially none that allow an estimate of lifetime cumulative exposure. Second, there are few validated occupational exposure questionnaires, and those that do exist can be awkward, time

**TABLE 20.3** Occupational Exposures Associated With Autoimmune Diseases Via Epidemiologic Studies

Exposure	Disease	Summary of results
Silica	Scleroderma	Increased risk was found in occupational cohort studies; mixed results in several population-based case-control studies
	Rheumatoid arthritis	Threefold increased risk (or higher) in occupational cohort studies
	Lupus	10-Fold increased risk in multiple occupational cohort studies
	ANCA vasculitis	Fourfold increased risk in multiple case-control studies
Solvents	Scleroderma	Mixed results, but some evidence of two- to threefold increased risk with specific solvents (e.g., paint thinners and removers, trichloroethylene) and with "any" solvent
	Undifferentiated multisystem rheumatic diseases	Twofold increased risk with paint thinners and removers, mineral spirits; threefold increased risk with specific solvent-related occupations
	Rheumatoid arthritis	Weak or no association with specific solvents, but twofold increased risk among spray painters and lacquer workers
	Multiple sclerosis	Two- to threefold increased risk with solvent exposures in most studies
Farming	Lupus	Lupus has been associated with agricultural pesticide mixing and pesticide mixing has been associated with positive antinuclear antibody status
	Type 1 diabetes	Bakers and farm workers exposed to grain had a decreased risk of type 1 diabetes
	Rheumatoid arthritis	Specific pesticides as well as solvents and fertilizers have been shown to be risk factors, although livestock exposure has been protective
Ultraviolet radiation	Multiple sclerosis	Reduced risk (OR 0.74) of multiple sclerosis and mortality with increased occupational exposure to sunlight
	Dermatomyositis	Positive correlation of the proportion of dermatomyositis with global surface sunlight intensity in international and US studies

ANCA, Antineutrophil cytoplasmic antibodies; OR, odds ratio.

Data from Love, L.A., Weinberg, C.R., McConaughay, D.R., Oddis, C.V., Medsger, T.A., Jr., Reveille, J.D., et al., 2009. Ultraviolet radiation intensity predicts the relative distribution of dermatomyositis and anti-Mi-2 autoantibodies in women. *Arthritis Rheum* 60 (8), 2499–2504; Cooper, G.S., Miller, F.W., Germolec, D.R., 2002. consuming, and costly to apply. Third, most studies in this area have been underpowered because of the rarity of the diseases, the likely effects of different genotypes, coexposures, and the occupations of interest, resulting in imprecise or inconsistent risk estimates. And finally, there is possible confounding from multiple concurrent exposures that makes it difficult to ascertain whether different effects can be attributed to different chemicals. Thus it may not be surprising that in some cases discrepancies exist in different investigations, making it difficult to assess the true overall risks of most occupational exposures.

## Others

A variety of other exposures with greatly different properties has been proposed to be associated with autoimmune diseases (Table 20.4). The evidence supporting these proposed associations ranges from case reports to epidemiologic studies, and many are speculative at this time. They are listed below by category into which they may be classified.

**TABLE 20.4** Other Exposures Proposed as Possible Risk or Protective Factors for Autoimmune Diseases

Exposure	Disease	Comments (Reference)
Foods (gluten)	Celiac disease	Celiac disease develops after ingestion of foods containing gluten and related proteins in some genetically susceptible persons (Alaedini and Green, 2005).
Alcohol	Rheumatoid arthritis	Alcohol has been shown to be protective for developing antibody positive rheumatoid arthritis (Scott et al., 2013).
Vitamin D	Rheumatoid arthritis, psoriasis, multiple sclerosis, systemic lupus erythematosus, and vitiligo	Seasonal variations in vitamin D are considered a possible reason for seasonal variations in disease flare and onset for many autoimmune diseases (Watad et al., 2017; Zhang et al., 2017).
Cigarette smoking	Rheumatoid arthritis	Studies suggest relative risks of 1.5–3 with a greater effect in seropositive disease and those with the HLA shared epitope (Krishnan, 2003; Stolt et al., 2003; Kallberg et al., 2011). Specific phenotypic features are also associated with smoking (Perricone et al., 2016).
	Myositis	Strongest association seen in connective tissue disease overlap myositis and Hungarian patients, in whom there is possible interaction with HLA DR3 (Lilleker et al., 2018; Schiffenbauer et al., 2018).
	Autoimmune thyroid disease	Meta-analyses suggest two to threefold increased risks of Graves' and Hashimoto's diseases (Vestergaard, 2002).
	Inflammatory bowel disease	Smoking increases risks for Crohn's disease but decreases risks for ulcerative colitis (Perricone et al., 2016).
	Psoriasis and psoriatic arthritis	There is a dose-response relationship between smoking and psoriasis and an increased risk of psoriasis in smokers that decreases with smoking cessation (Perricone et al., 2016).
	Behcet's disease	Smoking has been shown to improve oral and genital ulcers in Behcet's patients with the possibility of a gene-environment interaction (Perricone et al., 2016).
	Lupus	Studies show an increased risk of lupus in smoker OR 1.31; 95% CI, 1.02–1.70 with a stronger association found in cutaneous lupus (Perricone et al., 2016).
	Multiple sclerosis	Multiple sclerosis has an OR of 1.6 among current smokers and 1.2 among former smokers and has demonstrated a dose-response relationship (Perricone et al., 2016). There is also a possible gene-environment interaction.

(Continued)

**TABLE 20.4** (Continued)

Exposure	Disease	Comments (Reference)
Heavy metals	Multiple syndromes	"Pink disease" (acrodynia) and glomerulopathy from mercury toxicity; related syndromes with elements of autoimmunity from cadmium and gold salt toxicity; granulomatous pneumonitis from beryllium exposure; support for genetic risk factors in animal models (Bigazzi, 1994; Dally, 1997; Fontenot and Kotzin, 2003).
Microchimerism	Scleroderma, lupus, primary biliary cirrhosis, autoimmune thyroid disease	Fetal cells detected in maternal blood or target tissue specimens years after pregnancy—not all findings have been reproduced, possibly due to different methodologies with different sensitivities to detect rare microchimeric cells (Sarkar and Miller, 2004).
Collagen implants	Myositis	In one study, OR = 5.05; 95% CI, 2.31–9.59 for all forms of myositis (Cukier et al., 1993).
Silicone implants	Multiple syndromes	Most studies do not find associations with defined autoimmune diseases (Janowsky et al., 2000; Tugwell et al., 2001; Singh et al., 2017); rare or atypical multisystem rheumatic diseases and fibromyalgia remain inadequately studied (Singh et al., 2017; Brown et al., 1998; Brown, 2002).
Air pollution	Juvenile idiopathic arthritis (JIA) Juvenile dermatomyositis (JDM)	Small particulate matter has been associated with the development of JIA in several studies (Rider and Miller, 2017). Maternal exposure to inhaled carbon monoxide in the third trimester was associated with JDM (OR 12.21, CI 1.28–115.96) (Orione et al., 2014).
Microbiome	Lupus, Sjogren's syndrome, Behcet's disease, scleroderma, multiple sclerosis, and rheumatoid arthritis	Epidemiological data show associations of specific perturbations of the microbiome with diseased populations, particularly oral disease, but more work is needed to show a risk or protective effect (Talotta et al., 2017; Shahi et al., 2017; Maeda and Takeda, 2017).
Stress	Graves' disease Type 1 diabetes	Stressful life events in the 12 months preceding the diagnosis were significantly higher than controls (OR 5.6.3, CI 5.2.7–14.7) (Winsa et al., 1991); other diseases were poorly studied. Stressful life events, stress levels, and poorer coping skills were significantly associated with type 1 diabetes compared to controls (Faresjo, 2015).

## Foods

Foods are some of the better examples of environmental agents associated with autoimmune diseases. The best example is celiac disease, which is characterized by an immune response to ingested wheat gluten and related proteins of rye and barley, that leads to autoantibodies to transglutaminase resulting in inflammation, villous atrophy, and crypt hyperplasia in the intestine (Alaedini and Green, 2005). There is good evidence for gene–environment interaction in celiac disease, with human leukocyte antigens DQ2 and DQ8 being the major known genetic risk factors. Celiac disease is one of the few medical conditions for which dietary intervention is the main treatment modality, and a gluten-free diet markedly decreases symptoms in many individuals. Although there is less support for an autoimmune etiology of other food-associated inflammatory disorders, including the L-tryptophan-associated eosinophilia–myalgia syndrome (EMS) (Sullivan et al., 1996a,b) and the contaminated rapeseed oil–associated toxic oil syndrome (Gelpi et al., 2002), it is possible that some cases of these illnesses represent food-associated autoimmunity, given their frequent autoantibodies and immunogenetic associations (Okada et al., 2009). And it is possible that certain diets may also play a role in the development of some autoimmune diseases (Manzel et al., 2013).

## Vitamin D

Vitamin D has been found to have many impacts on the immune system. Often it is difficult to tell if vitamin D deficiency is a cause or consequence of autoimmunity. Seasonal variations in vitamin D and its interaction with the immune system have made it an exciting target for explaining the seasonal variations in disease onset

for autoimmune disease. Vitamin D deficiency has been implicated in rheumatoid arthritis, psoriasis, multiple sclerosis, systemic lupus erythematosus, and vitiligo (Watad et al., 2017; Zhang et al., 2017).

### Tobacco Smoke

Tobacco smoke has been associated epidemiologically with a higher risk of seropositive rheumatoid arthritis (Bang et al., 2010), all combined autoimmune thyroid disease, and Crohn's disease, in which a gene–environment interaction is clear, but inconsistent results were found in studies of smoking and systemic lupus erythematosus, multiple sclerosis, and Hashimoto's thyroiditis (Miller et al., 2012b; Perricone et al., 2016). Smoking has also been associated with specific phenotypes of the idiopathic inflammatory myopathies (Chinoy et al., 2012; Lilleker et al., 2018). There is also evidence that second-hand smoke is a risk factor for childhood lupus (Conde et al., 2018) and for disease severity in rheumatoid arthritis (Hamam and Gheita, 2017).

Conversely, smoking may be associated with a reduced risk of ulcerative colitis, an inflammatory bowel disease, implying that the complex mix of chemicals in tobacco smoke may have different effects in different backgrounds.

### Heavy Metals

Exposures to heavy metals, including mercury, cadmium, gold salts, and beryllium, have been associated with a variety of pathologic syndromes, some of which have features of autoimmunity. A study of communities in Amazonian Brazil with well-characterized exposures to mercury was the first to document immunologic changes, indicative of autoimmune dysfunction, in persons exposed to mercury (Silva et al., 2004). The overall clinical evidence of mercury impacting autoimmunity has not been clear (Crowe et al., 2017; Pigatto and Guzzi, 2010; Yeter et al., 2016; Somers et al., 2015), with low levels of mercury seen in patients with celiac disease, but elevated levels were associated with antinuclear antibody positivity and Kawasaki disease. In addition, many animal models have documented inflammatory and sometimes highly specific autoimmune responses to heavy metals, even at subtoxic doses, which appear to differ in different genetic backgrounds (Bagenstose et al., 1999a,b). The mechanisms for these many effects remain unclear, but possibilities include changing the response repertoire by direct and indirect means via changes in cytokine profiles, influencing expression of new antigens, new peptides, and/or antigen presentation by modifying the antigen-presenting complex (Rowley and Monestier, 2005), as has been reported for abacavir loading of novel self-peptides into human leukocyte antigen (HLA)-B\*57:01 (Norcross et al., 2012), or altering the Th17 response (Hemdan et al., 2013).

### Microchimerism

Microchimerism is the persistence of a low level of nonhost stem cells or their progeny in an individual. A possible role of microchimerism in the pathogenesis of some autoimmune diseases (systemic sclerosis, systemic lupus erythematosus, rheumatoid arthritis, primary biliary cirrhosis, autoimmune thyroid diseases, and juvenile myositis) but not all has been suggested (Sarkar and Miller, 2004; Nelson, 2012; Boddy et al., 2015). The initial impetus to explore this exposure was that many of the diseases associated with microchimerism have features that are shared with graft-versus-host disease, suggesting a possible mechanism. Although an appealing hypothesis, controversy in the area continues due to the lack of reproducible studies to date and the lack of proof of the role of microchimeric cells in the pathogenesis of these disorders. The possibility that cells of multiple origins and different genetic backgrounds may combine to result in functional organ systems, both in mothers and their offspring, requires a reevaluation of many current paradigms. It is possible that such chimeric mixtures play a role in autoimmunity, tissue repair, and other areas (Fugazzola et al., 2011). Further research using standardized, sensitive, and validated methods is needed to address the many questions that the early findings in this field have raised.

### Vaccines

Because vaccines are foreign proteins often injected with adjuvants into muscle to induce immune responses, it may not be surprising that immune-mediated adverse events have been reported after a wide variety of immunizations. Although a number of autoimmune diseases have been found to develop after vaccinations, only a few have been deemed to be associated with disease by the Advisory Committee on Immunization Practices (Robinson et al., 2017) and are now compensated by the National Vaccine Injury Compensation Program (<http://www.hrsa.gov/vaccinecompensation/index.html>). These include cases of chronic arthritis after rubella virus vaccine and thrombocytopenic purpura after measles vaccine. There remains significant controversy over other illnesses possibly caused by immunizations, but most epidemiologic studies in this area have not shown significant associations

(Wraith et al., 2003; De Martino et al., 2013). A report from the Institute of Medicine concluded that there was no increased risk of type 1 diabetes or Guillain–Barré syndrome from vaccination (Medicine Io et al., 2002).

### Implants

Bovine collagen implants are biomaterials used to correct dermal contour deformities. The use of bovine collagen implants in patients with a history of autoimmune diseases is contraindicated by the manufacturer due to concerns that they might induce adverse immune responses because anticollagen autoantibodies are present in some patients with multisystem rheumatic diseases. Few epidemiologic studies have been performed in this area, although one study evaluated the development of myositis in nine patients who received collagen implants (Cukier et al., 1993). Eight of the nine patients had a delayed-type hypersensitivity response at the test or treatment site, and five of six patients tested had elevated serum antibodies to collagen. Compared with the general population, the incidence of dermatomyositis or polymyositis among collagen-treated patients was significantly higher. There have also been case reports of autoimmune-like illness after such implants (Garcia-Domingo et al., 2000; Bonnet et al., 1996).

Silicone implants remain some of the most controversial environmental agents proposed to be associated with connective tissue disorders. Studies in this area have been hampered by the extensive litigation involved in adverse events following silicone breast implants and the lack of adequate regulatory review prior to their initial use. Most studies have not found associations with defined autoimmune diseases (Janowsky et al., 2000; Tugwell et al., 2001; Singh et al., 2017). However, there is ongoing research into whether there are atypical autoimmune disease manifestations associated with silicone implants (Colaris et al., 2017). Of interest, women who develop myositis after silicone implants appear to be an immunogenetically distinct subgroup with different allelic associations that are seen in women who develop myositis without implants (O'Hanlon et al., 2004).

### Stress

There is anecdotal evidence that stressful life events have preceded the development of many autoimmune diseases. A large population-based, case–control study of patients with Graves' disease showed that they had more negative life events in the 12 months preceding the diagnosis, and negative life-event scores were significantly higher than those of controls (Winsa et al., 1991; Vita et al., 2017; Wiersinga, 2016). There is also evidence for a link between stress and type 1 diabetes, celiac disease, lupus, juvenile idiopathic arthritis, alopecia areata, and vitiligo (Faresjo, 2015). Although the mechanisms for how stress may play a role in autoimmune disease remain unclear, it has been hypothesized that, under certain conditions, stress hormones may boost immune responses by inducing tumor necrosis factor (TNF)-alpha, interleukin (IL)-1, and IL-8, and by inhibiting transforming growth factor-beta production (Elenkov and Chrousos, 1999). Therefore conditions that are associated with significant changes in stress system activity may modulate the neuroendocrine–immune axis and perturb systemic cytokine balances, resulting in proinflammatory changes and disease induction.

### Air Pollution

Air pollution has often been considered a potential agent to dysregulate the immune system and incite autoimmune disease. This area of study is currently evolving, but some initial evidence indicates that air pollution might be a risk factor for systemic autoimmune disease, particularly juvenile idiopathic arthritis (Sun et al., 2016; Bernatsky et al., 2016). A Brazilian study showed an association between increased air pollutants and increased disease activity in patients with pediatric lupus (Fernandes et al., 2015).

### Exercise

The role of exercise in autoimmunity had garnered much attention. Animal models have demonstrated significant decreases in disease activity with the adoption of an exercise regimen (Aqel et al., 2017). In human studies lack of exercise has been associated with worse symptoms in rheumatoid arthritis, lupus, myositis (Pinto et al., 2017), and scleroderma (Azar et al., 2018). Some studies have shown the ability of exercise to help in disease management, such as in Sjogren's syndrome (Saraux et al., 2016) and myositis, although in lupus no benefit was seen (Abrahao et al., 2016; Thomas, 2013). Further studies are certainly needed to better understand the impact of exercise on autoimmune disease and to determine the optimal exercise regimens for patients.

### Microbiome

The microbiome represents a part of the environment that travels with individuals. It is being studied aggressively for its impact on autoimmune disease. Evidence has emerged suggesting a role for the microbiome in the

pathogenesis of lupus, Sjogren's syndrome, Behcet's disease, scleroderma (Talotta et al., 2017), multiple sclerosis (Shahi et al., 2017), and rheumatoid arthritis (Maeda and Takeda, 2017). This area poses an exciting target for inquiry as new tools are developed to better determine the microbiome and to fully assess the various geographic microbiota of humans (nasal, intestinal, skin, and others). Please see Chapter 21 for a more in-depth discussion on the microbiome.

## POSSIBLE MECHANISMS BY WHICH ENVIRONMENTAL AGENTS MAY INDUCE AUTOIMMUNE DISEASES

Although the mechanisms for the development of autoimmune diseases associated with exposures to noninfectious agents remain poorly understood, a variety of theories have postulated how xenobiotics might induce disease (Table 20.5). The wide range of these theories underscores the lack of understanding of mechanisms, even for the most carefully defined environmentally associated diseases, and suggests that different pathogenic mechanisms are likely at work in different syndromes.

Whatever specific mechanisms are involved in the development of an autoimmune disease, it has been suggested that an overall framework should include the concept of heterogeneity within the currently defined diseases. A working hypothesis that addresses this issue has been termed the "elemental disorder hypothesis," which posits that each autoimmune disease as currently recognized contains many elemental disorders (Gourley and Miller, 2007; Shamim and Miller, 2000; Schmidt, 2011). An elemental disorder is defined as a unique sign–symptom–laboratory complex (syndrome) that results from a distinct pathogenesis as a result of the interaction of the necessary and sufficient genetic and environmental risk factors. If this concept is true, elemental disorders are likely confounding most studies of disease today by inducing "comparisons of apples and oranges." If identified, elemental disorders should greatly increase the homogeneity of populations under study and thus decrease the numbers of individuals needed for genetic, environmental, and therapeutic studies. In the future identification of elemental disorders could allow for the prevention of some illnesses by avoidance of environmental risk factors, increasing exposure to protective factors, or via gene therapy to correct genetic risk factors.

## OVERVIEW AND FUTURE DIRECTIONS

The multifactorial nature of autoimmune diseases has inhibited our understanding of the mechanisms that initiate and sustain them. Autoimmune syndromes are believed to arise, however, from a complex and ill-understood interplay of predisposing genetic and environmental risk factors. Although progress is being made in defining the multiple genetic risk factors, we are in our infancy in identifying the environmental risk factors for autoimmune illnesses. By understanding the interactions of the elements that are necessary for disease to develop, we can prevent or treat autoimmune diseases in novel ways. Before that can be accomplished, however, important questions remain to be answered, such as: Which specific gene–environment interactions lead to which specific clinical syndromes? What are the pathogenic mechanisms involved? Is every autoimmune disease, as currently understood, actually composed of many subsets or "elemental disorders," each of which may be defined by a unique pathogenesis resulting from interactions of necessary and sufficient risk factors? Can selected autoimmune diseases be better treated, cured, or even prevented through answers to some of the above questions?

**TABLE 20.5** Possible Mechanisms by Which Environmental Agents May Induce Autoimmunity and Promote and Sustain Autoimmune Diseases (Possible Examples in Parentheses)<sup>a</sup>

1. Alteration of target tissue autoantigen structure (bystander drugs, heavy metals)
2. Upregulation or altered locations of normally sequestered autoantigens (UV radiation)
3. Cytotoxic, inhibitory, or stimulatory effects on components of the immune system (interferons, interleukins)
4. Molecular mimicry—structures shared between environmental agent and self (infectious agents)
5. Induction of epigenetic changes and subsequent gene activation or suppression (smoking)
6. Other effects and combinations of the above

<sup>a</sup>Initiators of autoimmunity may differ in action from promoters, sustainers, or agents that cause flares of autoimmune disease.

We live in an increasingly complex sea of xenobiotics, which complicates exposure assessments. More than 80,000 chemicals are registered for use in commerce in the United States, and an estimated 2000 new ones are introduced annually to be included in our foods, personal care products, drugs, household cleaners, and a host of industrial processes. The long-term effects of most of these chemicals on human health are unknown, yet we may be exposed to them during the manufacture, distribution, use, and disposal of products or as pollutants in our air, water, or soil. As a result, none of us knows the full range of environmental agents we are exposed to on a daily basis.

The concept of the exposome, which consists of all the exposures that an individual has experienced during their lifetime, has been proposed as a useful construct to focus attention on the critical need for more comprehensive environmental exposure assessments. Currently we are not able to simultaneously measure all the many important components of the exposome—including xenobiotics approved in commerce, the additional thousands of compounds not approved but to which we are exposed, plus stressful life events, cigarette smoke, or alcoholic drink compositions, drugs and dietary supplements, nanoparticles, biotoxins, cosmetics, hair dyes, ultraviolet and other radiation and climatic factors, and electric and magnetic fields—at any single time point in an individual, let alone over a lifetime. Much more work is needed to develop novel assessment tools that could evaluate these multiple exposures, either directly or indirectly, via their effects on gene expression or epigenetic modification, microRNA levels, or protein composition of various matrices in the body, both in real time and in summation over time.

Many challenges have prevented us from better understanding the environmental risk factors that might trigger autoimmune diseases in genetically susceptible individuals. These challenges include inadequate validated exposure assessment tools and bioassays; poor training in the evaluation of environmental exposures; the lack of population-based incidence, prevalence, demographic information, and databases or repositories for most diseases; inadequate funding; and the lack of accepted and standardized approaches for defining the minimal criteria for an environmentally triggered disease. Many coordinated initiatives may be useful in overcoming these obstacles and making more progress in the future (Box 20.2). Central to all these efforts are greater attention to and funding for understanding the essential environmental exposures that initiate, promote, or sustain autoimmune disorders. Such investments are likely to be very cost effective because they would have important clinical and financial implications for improving public health.

#### BOX 20.2

#### POSSIBLE APPROACHES TO ENHANCE IDENTIFICATION OF ENVIRONMENTAL RISK FACTORS FOR AUTOIMMUNE DISEASES

1. Foster national and international collaborations and coordination to integrate existing and newly developed clinical databases, registries, specimen repositories and other resources, and minimize duplication of effort
2. Develop and validate clinically useful standardized environmental exposure assessment tools
3. Develop and validate standardized biomarkers for environmental exposures
4. Increase support for well-designed, population-based and case-control hypothesis-testing studies for suspected environmental agents
5. Increase support for hypothesis-generating studies to identify new agents and syndromes
6. Collect systematic descriptive epidemiologic data for all autoimmune diseases and their major phenotypes as a baseline for future comparisons
7. Increase use of information technology and other novel approaches to enhance communications, coordinate efforts, and facilitate clinical studies
8. Improve coordination between animal model and epidemiologic studies
9. Develop novel mathematic, statistical, and bioinformatic approaches to enhance epidemiology studies
10. Define gene–gene, gene–environment, and environment–environment interactions
11. Establish an international coordinating committee to oversee and facilitate the above, encourage multidisciplinary research and prepare for and respond to epidemics of environmentally induced, immune-mediated diseases

## Acknowledgments

We thank Drs. Christine Parks, James Katz, and Peter Grayson for their useful comments and Lisa Maroski for technical assistance with the manuscript. This research was supported in part by the Intramural Research Program of the NIH, National Institute of Environmental Health Sciences.

## INTRODUCTION

The recognition of self from nonself is an immune phenomenon that has evolved over time and is crucially important for host preservation. The detrimental impact of alterations in this fine balance includes the emergence of opportunistic infections when there are deficits in nonself-discrimination or, when a loss of self-recognition occurs, overt immune attack on host tissues resulting in immunopathology and autoimmunity. Failure in the checks and balances regulating self-/nonself-recognition has been mapped to numerous genetic loci, especially those associated with immune activation and regulation. However, genetic predisposition to autoimmunity does not always result in the development of autoimmune disease. In many cases, overt clinical symptoms manifest after viral or bacterial infections. The precise immune mechanisms underlying the induction of autoimmune disease after infection are not known, but it is clear that multiple pathways are involved. In addition, there are numerous pathogenic and/or opportunistic microbes that may trigger an autoimmune reaction. The multiplicity of immune pathways and myriad possible microbes that may trigger

autoimmunity make it difficult to identify with confidence, distinct immune response pathways, and the pathogens associated with any particular autoimmune disease. Notwithstanding, a number of pathogens have been implicated in triggering autoimmunity. Here, these will be reviewed, with a special emphasis on the underlying mechanisms by which microbe–host interactions may result in the breakdown of peripheral tolerance or a loss of the ability to regulate self-/nonself-discrimination that results in autoimmunity. Importantly, while viruses have received arguably the greatest level of attention in the literature and are a primary focus here, bacteria and other eukaryotic pathogenic organisms have also been implicated in the etiology of autoimmune diseases and likely use similar mechanisms.

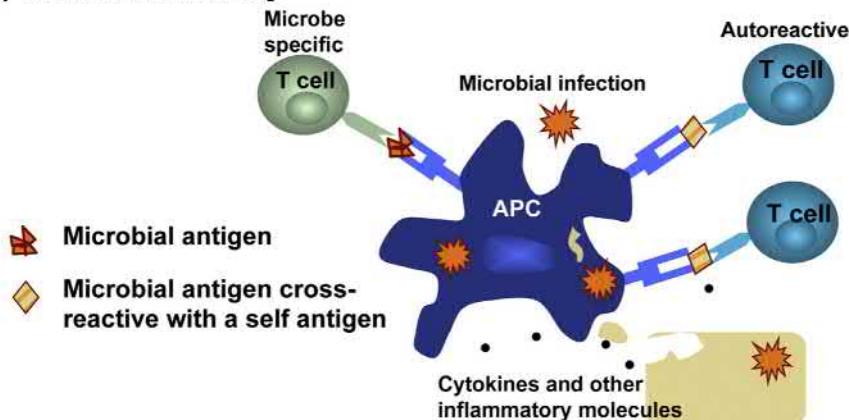

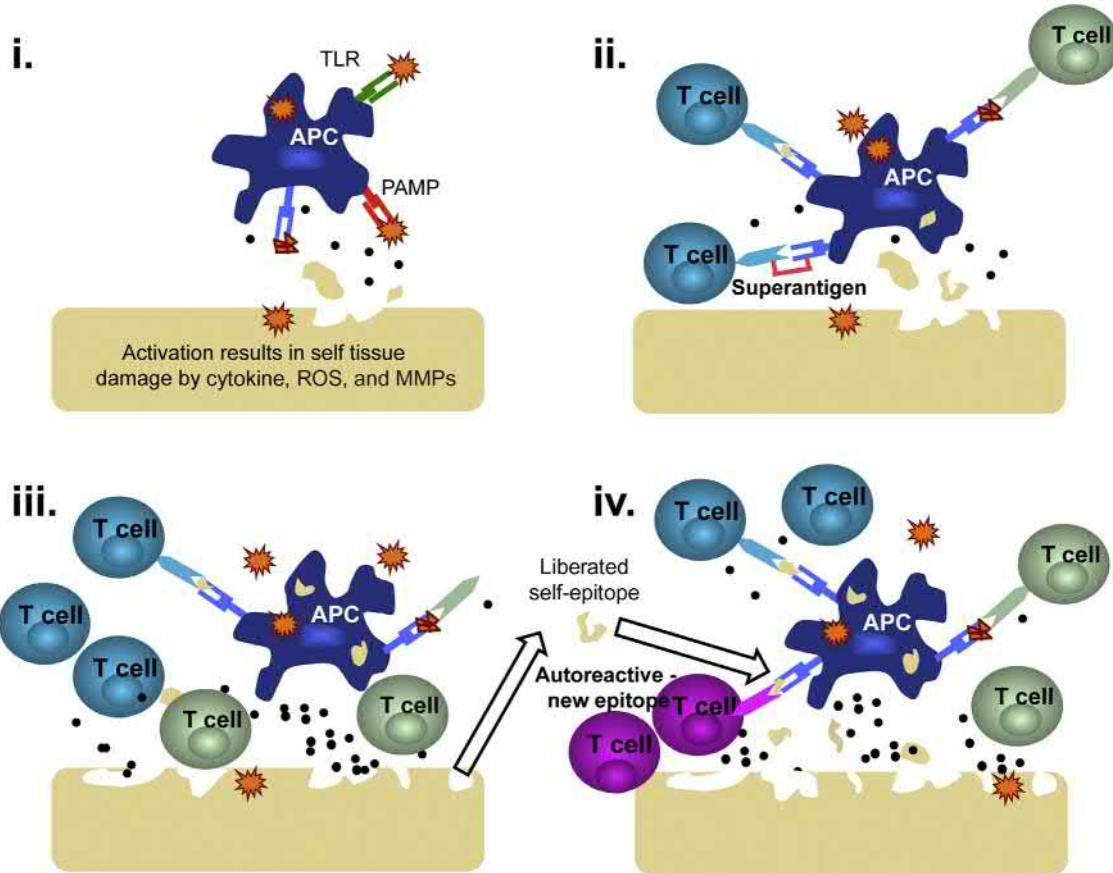

## INFECTIOUS TRIGGERING OF AUTOREACTIVE T CELLS

Pattern recognition receptors (PRR) are a broad family of proteins, expressed by numerous cells of the innate immune system, recognizing conserved molecular moieties commonly associated with pathogens. PRR include Toll-like receptors (TLR), nucleotide-binding and oligomerization domain (NOD)-like receptors, (RIG-I)-like helicases, and a subset of C-type lectin receptors (reviewed in [Ishii et al., 2008](#)). They recognize pattern-associated molecular patterns which are located within proteins, RNA and DNA. A successful early detection of pathogen infection is mediated by the innate immune cell recognition of microbes via PRR. The activation of these receptors results in the activation of a number of signal transduction cascades associated with inflammation, such as transcription and secretion of several cytokines, including type 1 interferons, costimulatory molecules, and chemokines. Together, these molecules serve to reduce the infection of parenchymal bystander cells, increase the recruitment of immune cells, and support the activation and expansion of adaptive T- and B-cell responses. These early responses to infection elicit a potent armory of weapons which, if not appropriately deployed and controlled, may result in bystander tissue damage and even death. This is convincingly shown both in murine models of viral infection, such as West Nile Virus (WNV) encephalitis, where fatality is immune-mediated ([Getts et al., 2014](#); [Terry et al., 2012](#)), and in humans in whom Ebola and SARS mortality has been associated with dysregulated immune responses to these viruses ([Basler, 2017](#); [Channappanavar and Perlman, 2017](#); [McElroy et al., 2015](#); [Younan et al., 2018](#)). In these examples, overexuberant immune responses result in damage to healthy tissue, culminating in immune pathology and mortality. Less striking examples that do not cause immediate mortality, but are nonetheless debilitating, include the development of myelin-specific autoimmunity in mice cerebrally infected with Theiler's Murine Encephalomyelitis Virus (TMEV) ([Munz et al., 2009](#)). In this example, autoimmunity results in the activation of myelin-specific T cells that migrate into the CNS and destroy myelinated axons. It has been demonstrated that the immune-mediated clearance of TMEV results in bystander damage and subsequent de novo induction of myelin-specific autoreactivity ([McMahon et al., 2005](#); [Miller et al., 1997](#)).

## PROPOSED MECHANISMS UNDERLYING AUTOIMMUNITY

### Molecular Mimicry

[Fujinami and Oldstone \(1985, 1989\)](#) first raised the idea of molecular mimicry, which proposed that a microbe-specific T-cell receptor (TCR) may cross-react with self-tissue-expressed antigens ([Fig. 21.1A](#)). As the TCR recognition domain cross-reacts with both viral and self-antigens, the T cell is unable to adequately discriminate between pathogenic challenge and self. As such, molecular mimicry is believed to be a significant virus-induced trigger of autoimmunity. While the ability for a TCR to recognize both self and nonself would at first glance appear to be an unfortunate random event associated with recombination-activating gene (RAG) recombination, the frequency of autoimmune disease suggests that other mechanisms are also involved. Certainly, similarities in shape and peptide charge distribution within the TCR binding domain have been described, both playing important roles in engagement of TCRs that exhibit significant promiscuity ([Gautam et al., 1994](#); [Gregersen et al., 2006](#); [Hammer et al., 1993](#); [Hemmer et al., 1999](#); [Lang et al., 2002](#); [Wucherpfennig et al., 1994](#); [Wucherpfennig and Strominger, 1995](#)). Furthermore, in vitro studies have shown that viral peptides can have significant homology with various self-peptides such that self and foreign antigens can cross-reactively stimulate autoreactive T cells ([Wucherpfennig and Strominger, 1995](#)).

**(A) Molecular mimicry****(B) Bystander activation and epitope spreading**

**FIGURE 21.1 Mechanisms of infection-induced autoimmunity .** (A) *Molecular mimicry* occurs through cross-reactive recognition between a microbial antigen/self MHC complex and a self-antigen/self MHC complex. (B) (i) Microbial PAMPs stimulate an immune response leading to tissue destruction via inflammatory mediators originating from cells of the innate immune system. (ii) During *bystander activation*, the engulfment of self-tissue debris leads to self-antigen presentation to autoreactive T cells (concomitant with presentation of virus antigen to virus-specific T cells) (see Chapter 64). Alternatively, an infection can lead to microbial *superantigen*-induced activation of a subset of T cells, some of which are specific for self-antigen. (iii) T-cell-mediated tissue destruction along with innate immune cell-derived inflammatory molecule-mediated destruction leads to release of endogenous self-epitopes from tissue. (iv) During *epitope spreading*, the response spreads to T cells specific for additional endogenous self-antigens.

MMP, matrix metalloproteinase; PAMP, pathogen-associated molecular pattern; ROS, reactive oxygen species; TLR, Toll-like receptor.

Numerous animal models support triggering of autoimmunity via molecular mimicry (Table 21.1). This triggering mechanism has been demonstrated in multiple pathogen-induced autoimmune models including *Acanthamoeba castellanii*-induced experimental autoimmune encephalomyelitis (EAE) in Swiss Jim Lambert (SJL) mice (Massilamany et al., 2010, 2011), herpes simplex virus (HSV) stromal keratitis, in which HSV infection leads to T-cell-mediated blindness in both humans and mice (Deshpande et al., 2001; Zhao et al., 1998), various diabetes models, autoimmune demyelinating disease associated with Semliki Forest Virus infection (Mokhtarian et al., 1999), autoimmune myocarditis associated with Coxsackievirus infection (Gauntt et al., 1995), and others (Lawson, 2000).

Other, albeit more synthetic models, that support molecular mimicry as a mechanism of autoimmunity development include transgenic models engineered to express tissue-specific self-associated epitopes. Infection results in the local production of inflammatory mediators, while microbially expressed "self"-antigens are processed and presented by host antigen-presenting cells in association with major histocompatibility complex molecules leading to T-cell activation. This results in the breakdown of peripheral tolerance mechanisms with activation and expansion of T cells specific for the "self"-transgene (Evans et al., 1996; Ohashi et al., 1991; Oldstone et al., 1991; von Herrath et al., 1994). The potential for molecular mimicry to cause autoimmunity has been confirmed in the TMEV-induced demyelinating disease (TMEV-IDD) model where the requirement for cerebral inoculation of TMEV to cause demyelinating disease was overcome by peripheral infection with TMEV engineered to express the immunodominant myelin proteolipid protein (PLP)139–151 epitope (Olson et al., 2001). Furthermore, infection with TMEV engineered to express peptides mimicking PLP<sub>139–151</sub> derived from infectious agents such as *Haemophilus influenzae* or murine hepatitis virus, respectively (Carrizosa et al., 1998), has also been shown to cause severe demyelinating disease similar to that induced by infection with TMEV containing PLP<sub>139–151</sub> itself (Croxford et al., 2006; Olson et al., 2001).

In humans, primary symptomatic Epstein–Barr virus (EBV) infection has been associated with an elevated risk of developing multiple sclerosis (MS) (Nielsen et al., 2007; Thacker et al., 2006). Patients with MS have circulating T cells specific for the EBV-encoded nuclear antigen 1 (EBNA1), the most consistently recognized EBV-derived CD4<sup>+</sup> T-cell antigen in healthy virus carriers, which may also recognize myelin antigens (Lunemann et al., 2008c). Interestingly, unlike EBNA1 monospecific TCR, myelin cross-reactive EBNA1 TCRs secrete less IFN-γ and interleukin-2 when activated, which may explain the persistence of these T-cell clones, as they are less susceptible to exhaustion and/or activation-induced cell death (Harari et al., 2007). Longitudinal studies have provided support for this hypothesis, with a long-term persistence of individual myelin-specific T-cell clones tracked over several years in the blood of EBV + ve patients with MS (Goebels et al., 2000; Meini et al., 1993; Muraro et al., 2003). Furthermore, the persistence of memory T cells that have self and viral reactivity has been observed in a number of other infectious diseases (Table 21.2).

## Bystander Activation of Autoreactive Cells and Epitope Spreading

The complex immune response associated with viral and bacterial containment and clearance unfortunately also results in the destruction of parenchymal tissues and subsequent liberation of other potential autoantigens. antigen-presenting cells (APCs) may uptake these antigens and either present them locally or in the secondary lymphoid tissues to autoreactive T and B cells. This process is loosely referred to as bystander activation, especially when it occurs locally within the infected tissue microenvironment (Enouz et al., 2012; Walker and Abbas, 2002; Zipris et al., 2005) (Fig. 21.1B). Another mechanism of bystander activation of T cells is associated with the ability of certain Vβ TCRs to be triggered nonspecifically by microbial-derived superantigens. If a superantigen-activated T-cell population expresses an autoreactive TCR, this may trigger or exacerbate autoimmunity (Wucherpfennig, 2001). In murine autoimmune models of MS (EAE), arthritis, and inflammatory bowel disease, superantigens have been shown to increase the severity of disease by initiating, or at least exacerbating, autoimmunity (Brocke et al., 1993; Cole and Griffiths, 1993; Dalwadi et al., 2001) (Table 21.1).

A further extension of bystander activation is the phenomenon known as epitope spreading. Epitope spreading occurs when novel TCR epitopes are liberated from tissues during the inflammatory process. Inflammatory tissue destruction associated with the response to an initiating epitope/antigen thus enables the presentation and activation of T cells specific for a new set of self-epitopes. These epitopes may be on the same protein molecule as the initiating epitope (intramolecular spreading) or to an epitope on a completely different protein (intermolecular spreading) (Fig. 21.1B). In either situation, the outcome is the activation and expansion of a novel set of autoreactive T cells. In the context of a pathogenic infection, an increase in the number of reactive T cells clones may be argued to be a positive event, as the immune repertoire focused on clearing infection is expanded. However, this expansion becomes problematic if the liberated epitopes are self-expressed proteins and result in a novel autoimmune reaction or potentiate an already active autoimmune response. The pathogenesis of many autoimmune diseases that are characterized by a relapse-remitting symptomatology, such as MS and type 1 diabetes (T1D), is potentially mediated by epitope spreading. While not confirmed in these human conditions, epitope spreading has been shown in EAE, a noninfectious model of MS (McRae et al., 1995; Yu et al., 1996), as well as in TMEV-IDD (Borrow et al., 1998; Katz-Levy et al., 1999, 2000; Miller et al., 1997) and in the

EBV, Epstein–Barr virus; MS, multiple sclerosis; RA, Rheumatoid arthritis; SLE, systemic lupus erythematosus; T1D, Type 1 diabetes.

nonobese diabetic (NOD) mouse model of T1D (Kaufman et al., 1993; Prasad et al., 2012). In these models, the T-cell repertoire has been carefully examined, with epitope spreading clearly occurring in an orderly, directed, and hierarchical manner. More precisely, the initial immune response, usually triggered by an immunodominant epitope, sets in motion a series of cyclical episodes of immunopathology, each generated by specific responses to less and less dominant epitopes over time.

## Emerging Mechanisms of Infection-Induced Autoimmune Disease

Along with molecular mimicry and bystander activation, a recent study has proposed that microbial enhancement and/or maintenance of autoreactive T cells and APC signaling may additionally amplify or trigger autoimmunity. For examples, in an animal model of systemic lupus erythematosus, disease was induced by Cholera toxin B from *Vibrio cholerae* (Deng and Tsokos, 2008; James and Robertson, 2012).

Viruses such as EBV are able to immortalize B cells and assist their differentiation into long-lived memory B cells (Thorley-Lawson and Gross, 2004). Interestingly, infected memory B cells that usually do not express latent EBV proteins are resistant to cell death (Nanbo et al., 2002). The reservoir of EBV-infected B cells, observed in submeningeal aggregates of MS brains (Serafini et al., 2007), thus could potentially be preserved to present autoantigens, therefore promoting autoimmunity. Indeed, recent evidence in MS patients that depleting B cells with ocrelizumab (anti-CD20 monoclonal antibody) slows disease progression may support the role of B cells in disease.

Establishing a clear link between a particular microbial infection and a specific autoimmune disease is hampered by the ability of pathogens to evade host immune responses and/or produce a subclinical infection without clear clinical symptoms. This suggests that the investigation of other viral infections and changes in pathogen–host interactions should be considered. WNV, a pathogen that has spread significantly in the last decade (King et al., 2007) and, more recently, Zika virus (ZIKV), demonstrate numerous potential mechanisms through which immune responses to infections may result in or accelerate autoimmune diseases. However, with the exception of the higher incidence of Guillain–Barré syndrome associated with recent ZIKV infection (Brasil et al., 2016; do Rosario et al., 2016; Dos Santos et al., 2016; Parra et al., 2016), a direct link between flaviviruses and autoimmunity in humans remains to be established. This is complicated by the fact that the majority of infections by both WNV and ZIKV are asymptomatic. Moreover, the evidence of autoimmunity is likely to become clinically apparent only after a considerable period of subclinical autoimmune responses. WNV, while more efficiently replicating in cycling than quiescent cells (about 10-fold greater), paradoxically increases MHC expression to a much greater degree in quiescent cells (King et al., 2007). This decoy mechanism likely preferentially promotes immune-mediated killing of G0 cells that yield low virus outputs over infected proliferating cells, which better support virus replication. Nonetheless, increased MHC expression on infected cells which increases the avidity of interaction between T cells raises the possibility that WNV infection may activate poly-specific T cells which range from having a high affinity for MHC/virus peptide to those with significant cross-reactivity for self. Consequently, WNV may indirectly result in bystander self-reactive T-cell activation. This cross-reactivity of low affinity antiviral T cells with self has been demonstrated in a mouse model of WNV (King et al., 1989; Mullbacher et al., 1991). This may also be true of ZIKV, since this infection with this virus also increases MHC expression (Glasner et al., 2017).

A more recent study, investigating the role for viral infection in the etiology of celiac disease, has highlighted the potential for viral infection to potentially act as a trigger of disease. Infection of mice with reovirus at the same time as they were exposed to gliadin, the primary antigen associated with celiac disease, resulted in the emergence of gluten sensitivity as shown by the development of circulating antibody titers for gliadin, whereas animals exposed to gluten in the absence of infection did not develop antigliadin antibodies (Bouziat et al., 2017). Together, this highlights not only the potential role for infection in the emergence of celiac disease but also the underlying complexities as researchers attempt to identify host–pathogen relationships associated with autoimmunity.

## Reciprocal Relationships of Pathogen-Derived Mechanisms of Autoimmunity

It is important to recognize that the development of autoimmunity subsequent to infection is likely to result from numerous factors and that all of the mechanisms described above are interrelated, nonmutually exclusive, and dynamic, so the idea of microbial infection eliciting autoimmunity must be viewed not as a defined event that occurs via a particular mechanism, but as a process that can occur through many pathways simultaneously and/or sequentially. For example, epitope spreading can be initiated via molecular mimicry, as illustrated by the activation of PLP<sub>178–191</sub>-specific T cells in SJL mice in which autoimmunity was induced by infection with TMEV expressing PLP<sub>139–151</sub> (Olson et al., 2001), or following bystander damage (Miller et al., 1997). Molecular mimicry can initially activate autoreactive T cells that then expand and become pathogenic via bystander activation, or vice versa. As a result, it can be difficult to discriminate a specific cause from among the postulated mechanisms,

even in seemingly simple animal models (Benoist and Mathis, 2001; Deshpande et al., 2001; Fujinami and Oldstone, 1985; Fujinami et al., 2006).

The fact that the various mechanisms for infection-induced autoimmunity discussed here are nonmutually exclusive makes them both more complicated and more plausible as potential causes for human autoimmune disease. As the potentially multimechanistic nature of autoimmunity is considered, it is important to remember that an established autoimmune response can also have effects on pathogen-directed immune responses occurring in the same organ or elsewhere in the body.

## HOW DO THESE MECHANISMS LEAD TO AUTOIMMUNE DISEASE?

The development of autoimmune diseases is complex, but it is clear that there is a breakdown of the underlying mechanisms that regulate central and peripheral tolerance, resulting in the activation and effector function of autoreactive T cells. While T-cell development in the thymus results in the deletion of many self-reactive T cells, some clones escape deletion and enter into the periphery. Interestingly, the presence of these in the periphery does not necessarily result in autoimmune disease. Many patients may have circulating autoreactive T cells and never develop any signs of autoimmune disease. It is therefore argued that events, such as infection, are necessary to activate these T-cell clones. However, infection with the precise microbe is apparently required, as most common infections do not trigger autoimmunity, even when there are circulating autoreactive T cells. Therefore, microbes must exhibit certain physiochemical characteristics, many of which remain to be fully understood. Adding to the complexity, autoimmune disease may not be elicited even in the presence of both an appropriate infection and autoreactive immune cells. In these cases, autoreactive cells may need to be "primed" or previously activated and consequently exist at a higher precursor frequency (Hamilton-Williams et al., 2005). For instance in Pichinde virus infection in mice expressing the lymphocytic choriomeningitis virus (LCMV), nuclear protein (NP), under the rat insulin promoter (RIP) (RIP-LCMV-NP), a self-mimic-encoding Pichinde virus was not sufficient to initiate overt autoimmunity, but it was able to accelerate autoimmune disease that had already been established by infection with LCMV (Christen et al., 2004).

The development of autoimmune disease may also rely on the affinity of autoreactive TCRs for their cognate self-peptide/MHC complexes (Gronski et al., 2004). The speed in which autoimmune disease develops is decreased in RIP-LCMV mice expressing a self-antigen in the thymus during development (von Herrath et al., 1994). Thymic antigen expression is believed to reduce TCR affinity for the self-antigen. In T cells with a higher affinity for self-antigen, TLR interaction and subsequent signaling can be sufficient for the establishment of autoimmune diseases (Lang et al., 2005; von Herrath et al., 1994). However, since most T cells will have low affinity for self, studies in which TCR affinity for self-antigen is low may have greater relevance to the induction of human autoimmune disease.

Therefore, while the potential for the development of overt disease is dependent on the presence of autoreactive T cells, whether overt disease actually occurs may depend on various other coincident events. These include the number, avidity, and affinity of autoreactive T cells, and the presence of innate inflammatory signals required for the activation and differentiation of those T cells to a pathogenic phenotype. Despite the requirement for all these elements, it is apparent that these events do not necessarily need to happen at the same time or in the same place to elicit autoimmune disease.

### Autoimmunity Can Occur at a Site Distal to the Initiating Infection

In many animal models of infection-induced autoimmune disease, the immune response occurs exclusively in the infected organ. However, it has also been shown that autoimmunity can occur at sites temporally and/or spatially distal from the target organ in which the initiating infection occurred. Autoreactive responses that are limited to a particular organ in animals make a model that is much simpler to study. For example, mice expressing an LCMV protein in the CNS manifested autoimmune responses there, even though LCMV was peripherally inoculated and not detectable in the CNS (Evans et al., 1996). In humans, immune responses to an infection within a particular organ are usually not as easily associated with the development of autoimmunity, making definitive conclusions more difficult to draw. Thus, animal models that enable the study of this aspect of infection-induced autoimmune disease are few but in time may provide important new insights relevant to human disease.

## CONCLUSIONS

The pathogenesis of autoimmune diseases is extremely complex and multimechanistic in nature. Inherent genetic susceptibility clearly plays a major role in the generation of autoimmune disease. In addition, epidemiological and animal studies have shown that infection is an equally important factor in the generation of autoimmune disease. With recent evidence highlighting the importance of the gastrointestinal microflora for healthy immune regulation, future studies are likely to further investigate the potential role of the gut microbiome in the initiation and progression of autoimmune diseases. Numerous questions remain regarding how pathogenic challenge may disrupt immune regulation and trigger autoimmunity. In addition to molecular mimicry, bystander damage, epitope spreading, and infection-induced maintenance of signaling in APCs and autoreactive T cells, it is likely that other novel immune regulatory mechanisms yet to be described also contribute to clinical autoimmune disease.

## INTRODUCTION

Vaccines are essential components of any public health program. Their beneficial effects have been largely recognized, and vaccination is generally considered the most cost-effective approach in preventive medicine. Therefore vaccines are used extensively, and coverage can reach over 90% in a given population. Since autoimmune diseases affect approximately 5%–10% of the population in Europe and North America, most people that develop an autoimmune disease are likely to be exposed to some vaccines at some time before or after the onset of the disease process. While earlier vaccines were mainly targeted for pediatric age-groups, the development of recent vaccines for adolescents [e.g., human papillomavirus vaccine (HPV)] and older individuals (e.g., pneumococcus and influenza) may increase the probability of coincidental associations of vaccination with autoimmune diseases.

Two major questions are of particular relevance to vaccination and autoimmune diseases. First, can vaccination trigger or enhance autoimmune responses? This frequently expressed concern is based either on a putative mimicry between vaccines and host antigens or on the fact that vaccination is associated with a transitory and variable activation of innate immunity. The use of adjuvants exploiting the immunostimulatory effect of Toll-like receptors (TLRs) has also triggered concerns related to their possible role in autoimmune disease development. Indeed, TLR-related pathways are being independently studied by investigators for their role in autoimmune disease modulation. Second, should patients with chronic autoimmune diseases be routinely vaccinated? Since

several infections are known to enhance disease activity in some autoimmune diseases, one can expect that their prevention, when feasible, would be beneficial. However, activation of innate immunity with some vaccines may also bear a theoretical risk of enhancing disease activity. Therefore, it is of importance to define guidelines regarding the use of essential vaccines in patients with autoimmune diseases. Such guidelines have been proposed by the American College of Rheumatology and the European League Against Rheumatism and form the basis of recommendations to be discussed in subsequent sections in this chapter.

## CONCERNS FOR AUTOIMMUNE DISEASES IN THE CONTEXT OF VACCINATION

Under the generic term of “vaccines,” there is a whole range of products that include complex live-attenuated microorganisms as well as purified proteins or polysaccharides. The common purpose of vaccination is to trigger a protective immune response in the host (similar to that seen with naturally acquired infection). Some vaccines are associated with a transient fever, and some vaccines commonly result in inflammation at the site of injection. Whether a vaccine can trigger or contribute to the initiation or worsening of autoimmune disease is a subject that is widely discussed.

Fear of adverse reactions versus the immense known benefit of approved vaccines continues to be a topic of lively debate. In the United States, the *National Childhood Vaccine Injury Act* of 1986 (42 U.S.C. §§ 300aa-1 to 300aa-34) was established under President Ronald Reagan as federal law (<https://www.nytimes.com/1986/11/15/us/reagan-signs-bill-on-drug-exports-and-payment-for-vaccine-injuries.html>) to provide a legal basis for contesting whether or not a particular individual may have suffered harm from a given vaccine. The fund is financed by a tax on vaccines and is administered by the Federal Courts in the United States. The legal standard is the “preponderance of evidence”—a standard that is accepted in civil litigation in the United States. The standard is often at variance with the vague standards established for scientific review where “statistical significance” is usually invoked.

Both in the previous decades for live or nonadjuvanted vaccines and more recently for adjuvanted vaccines, a major safety concern has centered on the possibility of potent stimulators of the immune response increasing the risk of developing an autoimmune disease. The old rabies vaccine that was produced using rabbit brain tissue was associated with the occasional (0.33/1000) development of immune-mediated encephalitis and antimyelin T-cell responses (Swaddiwudhipong et al., 1998). This is no longer observed with modern rabies vaccines produced with cell lines. Measles vaccination is also occasionally associated with a transitory immune thrombocytopenic purpura—like thrombocytopenia. However, this syndrome is observed 6–10 times more frequently after natural measles infection (Beeler et al., 1996; Wraith et al., 2003). The swine influenza vaccine that was used in 1976 was associated with a significant increase in the frequency of Guillain–Barré syndrome (incidence of 1 in 100,000) in the weeks following vaccination (Wraith et al., 2003), but this risk was significantly reduced with refinements in the manufacturing process of subsequent seasonal vaccines (risk of Guillain–Barré reduced to 1 in 1,000,000) (Schonberger et al., 1979; Chen et al., 2001).

In 2011, an epidemiological association of narcolepsy with the use of an AS03-adjuvanted H1N1 pandemic influenza vaccine was reported in Finland (National Narcolepsy Task Force Interim Report, 2011; Statement on Narcolepsy and Vaccination, 2011). The incidence of narcolepsy was 9.0 in the vaccinated as compared to 0.7/100,000 person years in the unvaccinated individuals, the rate ratio being 12.7. This H1N1 pandemic wave was shown in China to also be associated with a 3–4 rise of narcolepsy in the absence of vaccination (Han et al., 2011). A study published in 2015 may have established an immunologic link between the influenza virus and narcolepsy through antigenic molecular mimicry. Specifically, molecular mimicry was identified between a fragment of one of the influenza antigens (nucleoprotein) contained in the AS03-adjuvanted pandemic vaccine and a portion of the human brain, hypocretin receptor 2, that is responsible for promoting wakefulness (Ahmed et al., 2015). Using mass spectrometry, influenza nucleoprotein was demonstrated to be present in significant amounts in the AS03-adjuvanted inactivated split-virion pandemic vaccine compared to the MF59-adjuvanted inactivated subunit pandemic vaccine (that was not associated with narcolepsy and contained 73% less influenza nucleoprotein). The authors additionally demonstrated the presence of antibodies capable of cross-reacting with both influenza nucleoprotein and the hypocretin receptor that could, theoretically, disrupt wakefulness that is normally triggered by binding of hypocretin protein to the hypocretin receptor 2. These findings and the association of narcolepsy with influenza infection make the role of adjuvants, by themselves, in triggering autoimmune disease in genetically susceptible subjects less likely. However, both Guillain–Barré and narcolepsy should serve as reminders that vaccine antigen formulations need to be carefully selected to avoid potential autoimmune disease development in a percentage of the population receiving vaccines, and that disease development may, rarely, be potentiated by adjuvants in the presence of a cross-reactive antigen.

## CROSSFIRE AND COINCIDENCE

The associations described previously underscore the extent of our current capabilities in identifying risks associated with vaccines—that is, through statistical associations. While identifying causation would be ideal (e.g., a clear and unequivocal link between vaccination and rare adverse events, such as autoimmune disease), this is difficult given the individual, environmental, and temporal variables that occur during the window of immunization. While disease incidence in the setting of vaccination can be identified using statistical tools, this analysis can be confounded by the occurrence of “coincidental” associations. There is a background rate of these events that occur despite vaccination and a risk of such event occurring at the same time as the vaccine, by chance alone, which can confound the interpretation of vaccine safety.

One possible but not always a practical solution is to collect autoimmune disease prevalence and incidence data in a given population before vaccination to illustrate these coincidental associations. Such an approach was utilized prior to the large-scale introduction of the HPV vaccine where a cohort study of 214,896 female adolescents and 221,472 young adults was carried out to monitor the prevalence of autoimmune disease before vaccine introduction (Siegrist et al., 2007). This elegant approach collected data on the frequency of immune-mediated conditions leading to outpatient visits, the number of women hospitalized, and the most frequently diagnosed autoimmune disease. These data were then used to model temporal associations that would have occurred theoretically had the vaccine been used with 80% coverage. One can quickly appreciate how such population-based efforts enable one to identify, in advance, confounding issues affecting safety perception to avoid a negative impression of an inherently safe vaccine.

**Table 22.1** has been adapted primarily from autoimmune disease epidemiological data reported in a systematic review (Jacobson et al., 1997); in which, four additional categories were added from a study published in 2003 (Cooper and Stroehla, 2003). These combined data represent, to our knowledge, the most comprehensive and conservative estimates to date. **Table 22.1** intentionally focuses on the incidence of autoimmune diseases more commonly occurring in adults because the adult population is traditionally enrolled in first-in-human clinical trials with vaccines (the rates of autoimmunity in pediatric patients, though limited, suggest that they are quite different and reflect the contributions of time and environmental exposure to disease development). These autoimmune diseases, based on previously reported estimates of incidence (Jacobson et al., 1997; Cooper and Stroehla, 2003), would have been responsible for 204,789 new cases of autoimmune disease in a population >18 years of age in the United States based on the 2010 US Census (US Census Bureau, 2011). With this extrapolated

**TABLE 22.1** Autoimmune Disease Epidemiological Data Reported in a Systematic Review

Autoimmune disease <sup>a</sup>	Incidence <sup>a</sup> (per 100,000 persons per year)	Expected new diagnoses <sup>b</sup> (persons >18 years of age)
Adult rheumatoid arthritis	23.7	55,092
Thyroiditis (hypothyroidism)	21.8	50,675
Graves' disease (hyperthyroidism)	13.9	32,311
Type 1 diabetes (age 20 years)	8.1	18,829
Systemic lupus erythematosus	7.3	16,969
Sjögren disease	3.9	9065
Multiple sclerosis	3.2	7438
Primary systemic vasculitis	2.0	4649
Polymyositis/Dermatomyositis	1.8	4184
Systemic sclerosis	1.4	3254
Addison disease	0.6	1394
Myasthenia gravis	0.4	929
Total		204,789

<sup>a</sup>The table is obtained with permission from Ahmed, S., Plotkin, S.A., Black, S., Coffman, R.L., 2011. Assessing the safety of adjuvanted vaccines. *Sci. Transl. Med.* 3, 93rv2.

<sup>b</sup>Expected new diagnoses in the United States were extrapolated using the 2009 US Census data for population >18 years of age.

**TABLE 22.2** Incidence Data From Autoimmune Diseases

	Study sample size				
	N = 200	N = 1000	N = 2000	N = 3000	N = 10,000
Probability to observe at least one case <sup>a</sup>					
Autoimmune disease <sup>a</sup>					
Adult rheumatoid arthritis (%)	4.6	21.1	37.8	50.9	90.7
Thyroiditis (hypothyroidism) (%)	4.3	19.6	35.3	48.0	88.7
Graves' disease (hyperthyroidism) (%)	2.7	13.0	24.3	34.1	75.1
Type 1 diabetes (age >20 years) (%)	1.6	7.8	15.0	21.6	55.5
Systemic lupus erythematosus (%)	1.4	7.0	13.6	19.7	51.8
Sjögren disease (%)	0.8	3.8	7.5	11.0	32.3
Multiple sclerosis (%)	0.6	3.1	6.2	9.2	27.4
Primary systemic vasculitis (%)	0.4	2.0	3.9	5.8	18.1
Polymyositis/dermatomyositis (%)	0.4	1.8	3.5	5.3	16.5
Systemic sclerosis (%)	0.3	1.4	2.8	4.1	13.1
Addison disease (%)	0.1	0.6	1.2	1.8	5.8
Myasthenia gravis (%)	0.1	0.4	0.8	1.2	3.9
Total (%)	15.0	55.5	80.2	91.2	100.0

<sup>a</sup>The table is obtained with permission from Ahmed, S., Plotkin, S.A., Black, S., Coffman, R.L., 2011. Assessing the safety of adjuvanted vaccines. *Sci. Transl. Med.* 3, 93rv2.

table, one rapidly gains a perspective on the risk of coincidental association that can occur when an autoimmune disease is diagnosed in a subject immunized during a vaccine clinical trial (independent of the vaccine's effect). Table 22.2 uses the incidence data from these autoimmune diseases and calculates the probability of observing at least one case of autoimmune disease in clinical trials ranging from 200 to 10,000 subjects. As demonstrated, there is an increase in the probability of observing one patient with autoimmune disease when examining a trial with 200 subjects (15%) versus 3000 subjects (91%), which illustrates why coincidental associations occasionally occur during large phase III vaccine studies and even more during postlicensure monitoring of vaccination adverse events. Whether a given case of new onset autoimmune disease is "expected" statistically or due to an underlying predisposition to susceptibility is a recurrent issue. Sample sets, such as the Department of Defense serum repository, may help us to design studies to analyze who may be at substantial risk from a given immunization (Arbuckle et al., 2003).

### EXAMPLE OF AN ANIMAL MODEL DEVELOPED TO UNDERSTAND ACUTE DISSEMINATED ENCEPHALOMYELITIS OBSERVED WITH OLDER RABIES VACCINE—THE EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS MODEL

Animal models have played a major role in understanding how vaccines might induce damage. As mentioned in the Introduction, the old rabies vaccine that was produced using rabbit brain tissue was associated with the occasional (0.33/1000) development of immune-mediated encephalitis and antimyelin T-cell responses (Swaddiwudhipong et al., 1998). The model known as experimental allergic or experimental autoimmune encephalomyelitis (both now abbreviated EAE) was actually developed in the 1930s by Thomas Rivers and colleagues at the Rockefeller to help understand acute disseminated encephalomyelitis that was seen following rabies vaccine used at that time (Rivers et al., 1933). The EAE model comes in many forms these days and no longer requires adjuvant for induction. EAE has directly contributed to six new therapies for multiple sclerosis. It has provided a fertile test system for exploring how vaccines might induce neuroinflammatory damage in susceptible hosts (Steinman, 2003; Steinman and Zamvil, 2006).

## PRACTICAL APPROACH TO VACCINATION IN PATIENTS WITH AUTOIMMUNE DISEASE

What is frequently forgotten, but is commonly observed by clinicians managing patients with autoimmune diseases, is that natural infection, unlike vaccination, is a more *likely and proven risk factor* for triggering (flare) and augmenting severity of autoimmune diseases. For example, an influenza vaccine study with 69 patients with systemic lupus erythematosus (SLE) and 54 patients with rheumatoid arthritis demonstrated that every viral and bacterial infection (seen predominantly in the nonvaccinated cohort) resulted in worsening of the main disease (Stojanovich, 2006). Similarly, a case report described a severe flare of SLE in a patient infected with parvovirus B19 (Hemauer et al., 1999). A meta-analysis arrived at a similar conclusion that several vaccine-preventable infections occurred more often in patients with autoimmune disease, that vaccines were efficacious in these patients, and that there did not appear to be an increase in vaccination-related harm compared to nonvaccinated patients (van Assen et al., 2011). Influenza and other acute respiratory infections are also commonly associated with an increased frequency of relapses in patients with relapsing multiple sclerosis (Oikonen et al., 2011). This risk is markedly reduced in patients that received the seasonal influenza vaccine (De Keyser et al., 1998).

### THE REALITY FACING CLINICIANS CURRENTLY

The last 10 years have ushered in several new vaccines which rheumatologists caring for their patients should be familiar with. Some of these vaccines may be live-attenuated versus being inactivated (thus not capable of replication) and thus need to be considered carefully depending on the clinical interventions being considered for the patient. These vaccines include those for cholera (live oral), meningitis (quadrivalent conjugate and serogroup B recombinant), pneumococcus (conjugate), papillomavirus (alum and TLR4 adjuvanted), rotavirus, and, lastly, the DTaP vaccine (diphtheria, tetanus, and acellular pertussis). A shingles vaccine (containing varicella zoster virus (VZV) glycoprotein with AS01B T-cell boosting adjuvant) has been submitted in 2016 for evaluation by the FDA and has now been approved by the FDA (<https://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm581491.htm>). Yet despite evidence of the impact and benefits of vaccinations, clinicians are not adequately vaccinating their patients according to established guidelines. The most significant barrier to vaccination identified by the Centers for Disease Control is the *lack of knowledge* about vaccines among adult patients and providers (Kroger et al., 2011). This section will provide guidance to the practicing rheumatologist regarding the role for vaccines in the patients that they treat based on Vaccine Recommendation and Guidelines published by the Advisory Committee on Immunization Practices (ACIP) and detailed guidelines that have been proposed by the American College of Rheumatology and the European League Against Rheumatism (to be discussed next).

### CERTAINTY ABOUT VACCINES, UNCERTAINTY ABOUT COMPATIBILITY OF ADMINISTRATION IN CERTAIN SETTINGS

For those physicians that are aware of the vaccines currently available and recommended for their patients, questions are sometimes raised regarding what to do when patients are being treated with immunomodulators or the efficacy of vaccines in patients that are immunosuppressed. These concerns are based on the observation that immunosuppression resulting from primary or secondarily altered immunocompetence creates the greatest risk for infections in patients. Most patients being managed by rheumatologists are immunosuppressed by drugs prescribed to control their autoimmune disease and, thus, the immunodeficiency is a function of dose and type of therapy. A publication from the American College of Rheumatology Drug Safety Committee succinctly addresses this challenge and is the source of the recommendations highlighted in the following sections (Dao and Cush, 2012).

Distinguishing those vaccines that are live from those that are inactivated is critical when considering immunization of patients with autoimmune diseases on immunomodulatory treatments. Examples of live vaccines include the following: smallpox, adenovirus type 4 and 7, Bacille Calmette–Guérin, typhoid (oral), rotavirus, cholera, yellow fever, herpes zoster, influenza (live attenuated), varicella zoster, and measles–mumps–rubella. In the case of live vaccines, therapy with low doses of methotrexate and azathioprine are not considered sufficiently immunosuppressive, and corticosteroid therapy is not usually a contraindication in the following cases: duration of

treatment is less than 2 weeks, use of a dose less than 20 mg/day, duration of  $\geq 2$  weeks but with alternate-day treatment of short-acting formulations, doses that are physiologic, or the route of administration is topical or injected within joints, tendons, or bursae. However, the ACIP identifies patients receiving tumor necrosis factor (TNF) inhibitors or doses of prednisone greater than 20 mg/day (for longer than 2 weeks) to be sufficiently immunosuppressed that the use of live-attenuated vaccines is not recommended due to the concern for uncontrolled replication of the viral/bacterial microorganism in the host. If higher doses of steroids are used ( $>20$  mg/day for more than 2 weeks), it is recommended to wait a month after immunosuppression before a live vaccine is given as severe complications have been reported following vaccinations with live vaccines. Such concerns do not apply to inactivated vaccines (whether killed whole-organism, subunit, recombinant, polysaccharide, or toxoid vaccines). However, one should keep in mind that methotrexate + TNF inhibitors, anti-CD20 antibody, abatacept, and possibly azathioprine can reduce the immune response to these vaccines. Especially in the case of B-cell depleting biologic therapy, vaccines should be administered before the start of therapy. Examples of inactivated vaccines include the following: typhoid (polysaccharide), tetanus-diphtheria/acellular pertussis, hepatitis A, hepatitis B, human papilloma, influenza (A/B/H1N1), pneumococcal, polio, rabies, and meningococcal. The reader should be aware that some vaccines licensed for immunization and distribution in the United States (e.g., influenza and typhoid) have been developed by different manufacturers as distinct live or inactivated products. A complete list may be found at the following website: <http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/UCM093833>.

## SEARCH AND YOU WILL FIND

Guidance has been published for the use of vaccination in patients with autoimmune diseases. This has been in part due to the increasing awareness of the importance of vaccines in healthy populations and, ironically, also due to the perceived risk with newer vaccines containing adjuvants. Furthermore, more studies are being conducted and published on the value of vaccinations in patients with autoimmune diseases. A recent review paper has succinctly summarized the epidemiology of vaccine-preventable infectious diseases and the efficacy and safety of vaccination to prevent these diseases in patients with autoimmune diseases (Westra et al., 2015). Influenza, pneumococcal disease, herpes zoster, and HPV infection are all more common (or cause complications more frequently) in these patients. Most vaccines are effective in preventing disease in patients with autoimmune disease despite their chronic use of immunomodulatory treatments with the exception of rituximab and abatacept that probably can suppress immune responses after vaccination (Westra et al., 2015). A summary of the 2010 EULAR recommendations for vaccination of adults with autoimmune disease is included in that review paper, and a more detailed publication outlining timing and specific notes for available vaccines was published in 2016 (Tanriöver et al., 2016). The reader is also referred to the Centers for Disease Control and Prevention web-based article (“What vaccines are recommended for you,” 2017) at the following website: <https://www.cdc.gov/vaccines/adults/rec-vac/index.html> for additional details.

## CONCLUSION

The primary focus of this chapter is to update clinicians treating patients with autoimmune disease with a concise overview of the challenges facing vaccine development and the best application of this health intervention for their patient population. Those familiar with autoimmune diseases and those involved with vaccine development may already be aware of the common thread to both fields—that is, the triggering of the immune response. However, for those not familiar with these specialties, this common thread has also led, sometimes, to unjustified speculations regarding the relationship between this disease state and this disease intervention.

While it is critical to have a high level of scrutiny for the benefit/risk ratio of any prophylactic or therapeutic intervention in human subjects, one needs to keep in mind that vaccines have been responsible for preventing more deaths than virtually any other medicinal product. The value and impact of vaccinations for human health are undeniable—this is the most cost-effective intervention in preventive medicine. Those clinicians not utilizing vaccines routinely in their practices are requested to familiarize themselves in detail regarding vaccines (those with and without adjuvants, live vs inactivated), the patient populations likely to benefit from such interventions (e.g., young girls and HPV vaccination), and their correct use in patients undergoing immunosuppressive treatments. It is hoped that this review has provided a concise overview that will serve as the basis for more detailed study and prepare the clinicians for the questions posed by their patients about the safety of vaccines.

## INTRODUCTION

All common autoimmune diseases are complex genetic traits. That is, they result from a combination of many risk factors—genetic, environmental, and stochastic—each contributing a relatively small degree of risk. They are subject to genocopies (a genotype at one locus contributing to the risk of disease in a manner indistinguishable from that produced by another genotype and/or locus) and phenocopies (an environmental factor mimicking the effects of a susceptibility gene). A consequence of this is that the disease phenotype is only a weak predictor of the presence of a susceptibility allele. As this association underlies all current genetic approaches, the identification of susceptibility genes in complex disease traits is both practically and technologically challenging.

The main benefits of genetic studies of autoimmunity are to (1) provide informed genetic counseling; (2) develop improved models for risk prediction; and (3) develop detailed molecular models of etiology and pathogenesis. As a generalization, the first benefit arose from work prior to the 1990s; the second has, in part, been achieved already; and the third has become a major focus of the field over the last 5 years.

## DISEASES OF INTEREST

In any genetic study, clinical definition is critical since clinical heterogeneity associated with allelic differences weakens the statistical power. Here, we will concentrate primarily on progress in the genetics of type 1 (autoimmune) diabetes (T1D), multiple sclerosis (MS), and systemic lupus erythematosus (SLE).

### Type 1 Diabetes

T1D is an endocrine disease that results from the autoimmune destruction of the insulin-producing  $\beta$  cells in the pancreas, leading to a loss of insulin secretion and hyperglycemia, resulting in osmotic diuresis and the symptoms of polyuria, polydipsia, polyphagia, tiredness, and loss of weight. Potentially fatal complications include ketoacidosis and hyperglycemic coma. Progression from the preclinical stage of  $\beta$ -cell autoimmunity (insulitis) to established diabetes can take up to a decade (Johnston et al., 1989; Bonifacio et al., 1990). Diagnostically, the major confusion is with latent autoimmune diabetes of adults, which is of later onset, and type 2 diabetes, which does not have an autoimmune origin (and therefore lacks antiislet autoantibodies), but is common and of increasing prevalence.

Evidence for a genetic contribution to the risk of T1D includes increased prevalence of disease in first degree relatives (FDR; 2.5%–6.0% risk vs 0.1%–0.3% in the general population of Western countries) with a  $\lambda_s$  (recurrence-risk ratio of disease in siblings of patients) of about 15 (Tillil and Körberling, 1987; Pociot & McDermott, 2002). T1D has a high concordance in monozygotic (MZ) twins and intermediate concordance in dizygotic (DZ) twins, 27% and 3.8%, respectively (Hytinen et al., 2003) and is associated with a lifetime risk for the twin of an affected proband of 44% and 19%, respectively (Kumar et al., 1993). The prevalence of T1D varies markedly between countries and is increasing at a rate of about 3% per year (Onkamo et al., 1999), a change that is associated with alterations in autoantibody profiles and an accelerated onset of disease from the time of identification of autoantibodies. These trends are consistent with changing environmental effects on the pathogenesis of the disease (Ziegler et al., 2011; Long et al., 2012).

### Multiple Sclerosis

MS is a chronic and debilitating disease of the central nervous system (CNS) characterized by myelin loss and axonal degeneration, resulting in neurological symptoms and impairment. It primarily affects individuals of northern European descent with a prevalence of approximately 0.1%–0.2%; more females than males are affected, at a ratio of approximately 3:1. Clinically, MS can be divided into two major subtypes: relapsing–remitting MS (RRMS) and primary–progressive MS (PPMS). RRMS is characterized by relapses followed by periods of remission of variable duration during which there is complete or partial recovery. MS patients with RRMS may eventually progress to secondary–progressive MS (SPMS) characterized by steady decline without remit. PPMS, which affects approximately 5%–15% of all individuals with MS, differs from RRMS in that there are no periods of remission. Prior to genetic studies, there was a broad acceptance that RRMS and PPMS were likely to represent pathogenetically different diseases.

Familial aggregation of MS was noted as early as the 1890s and suggested that there was a genetic influence on disease development (Eichhorst, 1896). More recently, the proportion of MS patients who have a known blood relative with MS has been shown to be approximately 20% (Compston, 1991), reflecting a 3% risk in siblings of affected individuals and a  $\lambda_s$  of about 25 (Robertson et al., 1996). Twin studies have demonstrated a concordance of 25%–30% between MZ twin pairs and concordance similar to that of siblings in DZ twins (Ebers et al., 1986; Sadovnick and Baird, 1988; Sadovnick et al., 1993; Robertson et al., 1996; Carton et al., 1997; Montomoli et al., 2002).

### Systemic Lupus Erythematosus

SLE is a highly variable autoimmune disease diagnosed on the basis of a combination of clinical and laboratory criteria (American College of Rheumatology Ad Hoc Committee on Systemic Lupus Erythematosus Guidelines, 1999). It may be associated with hematologic, musculoskeletal, renal, or neuropsychiatric symptoms. It is generally characterized by the presence in plasma of antinuclear autoantibodies, primarily directed against molecules involved in transcription and translation, such as DNA, the U1 small nuclear ribonucleoprotein/Smith

(Sm) complex, and the Ro/SSA and La/SSB ribonucleoprotein autoantigens. The prevalence of SLE is around 40–50 cases per 100,000 people, primarily affecting women (F:M ratio is 9:1); the prevalence is much higher, and the course of disease much more pernicious, in Africans and Afro-Caribbean people living in Western countries and particularly in the Aborigines of northern Australia, where the prevalence reaches >90 per 100,000 (Stoll et al., 1996; Bossingham, 2003). SLE shows familial clustering, with approximately 1.5%–3.0% of FDR affected, but the variable and often mixed racial backgrounds of patients complicate the calculation of a  $\lambda_s$ , which lies somewhere between 5.0 and 30 (Block et al., 1975; Lawrence, Martins and Drake, 1987; Alarcón-Segovia et al., 2005). In twin studies, 24%–69% of MZ pairs and 2%–3% of DZ pairs were concordant (Block et al., 1975; Deapen et al., 1992).

## HUMAN LEUKOCYTE ANTIGEN AND OTHER CANDIDATE GENES

The major histocompatibility complex (MHC) was originally identified by murine allogeneic tumor transplantation (Gorer, 1937). Identification of the analogous gene complex in humans [termed the human leukocyte antigen (*HLA*) complex] was made when three groups described antibodies in sera from multitransfused patients or multiparous women that aggregated the leukocytes of many, but not all, donors (Dausset, 1958; van Rood et al., 1958; Payne and Rolfs, 1958). The collaborative dissection of the *HLA* complex is described elsewhere (Thorsby, 2009). After an association was reported between Hodgkin's disease and the 4c complex (subsequently known as *HLA-B*; Amiel, 1967), many diseases were tested for association with *HLA* alleles. The strongest *HLA* association with autoimmune disease found to date is with ankylosing spondylitis; 88%–96% of ankylosing spondylitis patients carry *HLA-B\*27* compared with 4%–8% of healthy controls (Brewerton et al., 1973; Schlosstein et al., 1973). *HLA-B\*27* carries a relative risk of ankylosing spondylitis of up to 100 (Arellano et al., 1984)—the highest genetic association for any autoimmune disease. The relative risk varies between populations and is much lower in African-Americans (Khan et al., 1977).

### Association of Type 1 Diabetes with Human Leukocyte Antigen and Other Candidate Genes

The *HLA* at chromosome 6p21 also shows association with T1D (locus termed *IDDM1*; Nerup et al., 1974; Bertrams, 1984; Todd, 1992; Cucca et al., 2001; Noble et al., 1996; Kelly et al., 2003; Devendra & Eisenbarth, 2003; Valdes, Erlich and Noble, 2005) and accounts for approximately 40% of the familial aggregation of the disease; the predisposing *HLA* Class II haplotypes, *HLA-DRB1\*04*, *DQB1\*03:02* (identified by serology as DR4) and *DRB1\*03:01*, *DQB1\*02:01* (DR3) are present in 95% of affected individuals. DR3/DR4 heterozygotes carry an absolute risk of T1D of approximately 5% (compared to a cumulative incidence of approximately 0.3% in Western communities), which rises to about 20% if a haploidentical sibling is affected (Noble et al., 1996; Valdes et al., 2001). DQ amino acid sequences directly correlate to the risk of T1D, and this association is largely dependent on the identity of residue 57 of the DQ $\beta$  chain, Asp being protective and Ala conferring susceptibility (Todd, Bell and McDevitt, 1987), and residue 52 of the DQ $\alpha$  chain (Arg confers susceptibility; Khalil et al., 1990). Khalil et al. (1990) reported that of 50 T1D patients, all expressed the DQ $\alpha$ -52Arg/DQ $\beta$ -57Ala susceptible heterodimer. Remarkably, the NOD mouse model of T1D expresses an A $\beta$  chain homologous to DQ $\beta$  with a substitution at position 57 (Todd, Bell and McDevitt, 1987).

### INS

Other T1D candidate genes were examined because of their biological relevance to disease. Insulin is primarily transcribed in the beta cells of pancreatic islets and is a major autoantigen in T1D (Kent et al., 2005). There are three common polymorphisms in strong linkage disequilibrium within the insulin (*INS*) gene on 11p15: (1) a variable number tandem repeat (VNTR) locus; (2) the rs3842753 A > C variant; and (3) the rs689 A > T variant within the Hph1 restriction endonuclease site 23 bp upstream of the insulin gene transcription start site. The VNTR is the best candidate because it contains binding sites for many transcription factors, including Myc-Associated Zinc Finger Protein (MAZ) (Kennedy, German and Rutter, 1995), while there is no obvious functional role for either of the other two variants (Barratt et al., 2004). The promoter of the insulin *INS* gene contains the VNTR locus, and the alleles with the shortest repeat sequences (Class I alleles; 26–63 repeats) are associated with T1D in *HLA-DR4*-expressing subjects [odds ratio (OR) 1.9; *IDDM2*; Bell et al., 1984; Julier et al., 1991; Bain et al., 1992; Bennett et al., 1995]. Class III alleles (the longest; 141–209 repeats) of the VNTR are associated with

marginally lower levels of insulin mRNA expression in pancreata (Bennett et al., 1995), but a two to threefold higher expression in fetal thymus (Vafiadis et al., 1997). These data are consistent with the hypothesis that protective alleles of the *INS* VNTR are responsible for increased thymic insulin expression driving more effective induction of central tolerance of insulin-reactive T cells. Although *INS* polymorphisms were associated with T1D in many Caucasian populations, the association was not seen in Chinese subjects because the frequency of the susceptible *INS* allele is ~95% in Chinese controls and close to 100% in Chinese T1D patients (Marron and She, unpublished data cited in Marron et al., 1997).

Consistent with its antigen-specific role in autoimmunity, variants in the *INS* gene are not associated with other autoimmune diseases, although they are associated with type 2 diabetes (Ng et al., 2014).

## **PTPN22**

Protein tyrosine phosphatases were thought to be good candidates for autoimmunity susceptibility genes, because they are involved in limiting T-cell activation by dephosphorylating T-cell receptor (TCR)-associated kinases and their substrates. *PTPN22*, on chromosome 1p13, encodes the lymphocyte-specific protein tyrosine phosphatase Lymphoid Phosphatase (LYP), which is a negative regulator of TCR signaling via the dephosphorylation of several proximal TCR signaling molecules, including the SRC family kinases LCK and FYN, ZAP70, and TCR $\zeta$ . A nonsynonymous variant, rs2476601 G > A, at position 1858 of *PTPN22* was reported to be associated with T1D in many populations (OR for the homozygous AA genotype was 1.7; Bottini et al., 2004; Onengut-Gumuscu et al., 2004; Smyth et al., 2004; Zheng and She, 2005; Steck et al., 2009, reviewed in Steck and Rewers, 2011). It encodes a missense substitution that changes an Arg to a Trp at position 620 causing the inability of LYP to bind its signaling molecule, CSK (Vang et al., 2005), resulting in increased phosphatase activity. T cells from T1D patients and healthy subjects carrying the rs2476601A allele show reduced production of interleukin (IL)-2 and other cytokines following TCR stimulation (Vang et al., 2005; Rieck et al., 2007). The rs2476601 G > A variant is also associated with Graves' disease (Steck et al., 2006), rheumatoid arthritis (RA) (Begovich et al., 2004), Crohn's disease (Franke et al., 2010), vitiligo (Jin et al., 2012), and SLE (Kyogoku et al., 2004).

TCR and immunoglobulin loci were also examined as candidates, without consistent evidence of involvement.

## **Association of Multiple Sclerosis with Human Leukocyte Antigen and Other Candidate Genes**

Association of MS with the HLA Class I alleles *HLA-A\*03* and *HLA-B\*07* (identified by serology as A3 and B7) were reported in 1972 (Jersild, Svegaard and Fog, 1972; Jersild and Fog, 1972; Naito et al., 1972). Further studies found that both of these associations were secondary to those of the Class II alleles *HLA-DRB1\*15:01* (DR2) and *HLA-DQB1\*06:02* (DQ6), which can be inherited together in strong linkage disequilibrium as the HLA-DR15 haplotype (*DRB5\*01:01*, *DRB1\*15:01*, *DQA1\*01:02*-*DQB1\*06:02*; Fogdell et al., 1995). This haplotype confers a relative risk of MS of between 2 and 4 (Francis et al., 1987a, 1987b). Approximately 30% of individuals with MS carry this extended haplotype compared to 15% in the normal population; its effect is dominant and shows evidence of gene dosage (Barcellos et al., 2006). The contribution of HLA to total (genetic) susceptibility to MS is estimated to be between 15% and 50% (Haines et al., 1996, 1998).

There is a very strong association between Epstein–Barr virus (EBV) infection and MS: EBV is unique in being the only virus known to have infected virtually all MS patients, in contrast to healthy subjects, of whom 85%–95% are infected (Sumaya et al., 1985; Myhr et al., 1998); EBV seronegativity has an OR of 0.06 (95% CI 0.03–0.13;  $P < 10^{-9}$ ; Ascherio and Munger, 2007). *HLA-DRB1\*15:01* appears to act synergistically as a risk factor with EBV exposure. The risk conferred by *HLA-DRB1\*15:01* was 2.9-fold higher in patients with a history of infectious mononucleosis and the risk of MS in *HLA-DRB1\*15:01* positive women increased ninefold in those with elevated anti-EBNA-1 (EBV) antibody titers (Nielsen et al., 2009; De Jager et al., 2008). A confounding problem is the potential effects of *DRB1\*15:012* on EBV susceptibility. EBV achieves penetration of the plasma membrane via the binding of its viral glycoprotein gp42 to HLA-DR (Li et al., 1997); the HLA-DR15 haplotype is associated with 15.7- and 8.3-fold higher expression of DQB1 and DRB1, respectively (Alcina et al., 2012), potentially conferring higher infection rates.

MS is also associated with childhood residence at higher geographic latitude (Acheson, Bachrach and Wright, 1960) and a significant component of this association appears to be mediated by low ultraviolet light exposure resulting in reduced 1,25(OH)<sub>2</sub> Vitamin D availability (Nieves et al., 1994; Munger et al., 2006). A functional vitamin D response element (VDRE) has been identified in the promoter region of *HLA-DRB1* (Ramagopalan et al., 2009), suggesting these alleles may be unusual in having vitamin D-regulated MHC Class II expression.

Class I alleles also affect susceptibility to MS: The *HLA-A\*03:01* allele increases the risk (OR 2.1), while *HLA-A\*02:01* and *B\*44* decrease it (OR 0.52 and 0.62, respectively; Fogdell-Hahn et al., 2000; Healy et al., 2010; Bergamaschi et al., 2010; Cree et al., 2010). The presence of *A\*02:01* reduces the relative risk of MS conferred by the HLA-DR15 haplotype from 3.6 to 1.5 (Fogdell-Hahn et al., 2000).

No associations between *HLA* genotypes and specific MS subtypes have been identified (Barcellos et al., 2006), although a significant correlation between the age-of-onset of MS and a variant tagging the HLA-DR15 haplotype has been reported [Masterman et al., 2000; International Multiple Sclerosis Genetics Consortium (IMSGC), 2011]; no associations with gender or disease severity were observed.

Other MS candidate genes that have been tested by association or transmission tests were selected largely on the basis of known or predicted roles in pathogenesis. In particular, genes encoding the T-cell receptor (TCR), IL-1 receptor (IL1R), interferons (IFNs)  $\alpha$ ,  $\beta$ , and  $\gamma$ , and CTLA4, as well as various cytokine/chemokine genes have been investigated with no consistent results.

## Association of Systemic Lupus Erythematosus with Human Leukocyte Antigen and Other Candidate Genes

*HLA-DRB1\*03:01* (identified by serology as DR3) is strongly associated with SLE (Freedman et al., 1993). In African-American patients, *HLA-DRB1\*03* was found in 62% of SLE patients, but only 20% of controls (relative risk of 6.41); in Caucasian patients the strength of the association is a little lower: 30% versus 13% (So et al., 1990). *DRB1\*03:01* is part of the 8.1 ancestral haplotype (*HLA-A\*01*, *C\*07*, *B\*08*, *DRB1\*03:01*, *DQA1\*05:01*, *DQB1\*02:01*), so named because it includes the Class I alleles *HLA-B\*8* (B8) and *HLA-A\*01* (A1). This haplotype therefore confers susceptibility to both SLE and T1D in Europeans, as does the  $H2^{g7}$  MHC haplotype in NOD mice (Price et al., 1999; Jordan et al., 2000). It is also associated with celiac disease (Ahmed et al., 1993), myasthenia gravis (Hammarström et al., 1975), chronic active (autoimmune) hepatitis (Strettell et al., 1997), and scleroderma (Kallenberg et al., 1981).

The Class II allele *HLA-DRB1\*15:01* [serotype DR15, a split of DR2, and usually associated with *DQB1\*06:02*, *DQA1\*0102* (serotype DQ6, a split of DQ1)] is also associated with SLE; it was found in 41% of African-American SLE patients and 18% of African-American healthy controls (relative risk of 3.03). Again, in Caucasian patients, the association is a little weaker: 21% versus 11% (So et al., 1990). The combined relative risk for SLE associated with expression of both haplotypes is 9.0 (Kachru et al., 1984).

### Tumor Necrosis Factor (TNF)

Interest in *TNF* genes in humans followed the finding of a polymorphism within the *Tnf* gene of SLE-prone (NZB × NZW)F1 hybrid mice (Jacob and McDevitt, 1988), in which the decreased expression of *Tnf* was associated with disease and TNF administration delayed nephritis. The same group applied serotyping and bioassays to determine the relevance of quantitative polymorphisms in *TNF* to SLE and lupus nephritis in patients, reporting that in SLE patients, the DR2-DQ1 serotype (inferred haplotype *DRB1\*05:01*, *DQB1\*06:02*, *DQA1\*01:02*) was associated with low levels of induced TNF expression and an increased incidence of nephritis. In contrast, SLE patients with the DR3 (*HLA-DRB1\*03:01*) and DR4 (*HLA-DRB1\*04:01*) serotypes had high TNF production and were not predisposed to nephritis (Jacob et al., 1990). One potential explanation for this association is the rs1800629 A > G variant at position -308 in the promoter of the *TNF* gene: The rs1800629G allele is associated with low TNF expression, whereas the A allele has high expression (Tan and Arnett, 1998; Hajeer and Hutchinson, 2001). This association with expression as well as the variant's association with disease has been controversial, in part due to attempts to generalize the original observation to SLE (as distinct from lupus nephritis) and in part due to racial heterogeneity (Rudwaleit et al., 1996). Where an association was found, often it could not be shown to be acting independently of *HLA-DRB1* alleles (Rudwaleit et al., 1996; Wilson et al., 1994).

### TNFSF4

Cunningham Graham et al. (2008) explored association between SLE and variants across *TNFRSF4* (OX40L) and its ligand *TNFSF4* (OX40). They genotyped by various methods parent-affected trios (a proband and both parents—in this case, one affected) from the United Kingdom (416 trios) and the United States (Minnesota; 263 trios) as well as 424 unrelated cases and 642 unaffected control samples from the British 1958 birth cohort. No evidence of linkage or association was identified at *TNFRSF4*. TDT analysis of the trios in both cohorts identified an overtransmitted haplotype tagged by multiple rare alleles, with rs12039904 C > T being the most significant in

a combined analysis ( $P = 1 \times 10^{-5}$ ). A similar significance was obtained by haplotype analysis. An association study was then performed on the independent UK case-control collection with the strongest association identified at rs844644 A>C ( $P = 6.8 \times 10^{-5}$ ), which lies just 2.8 kb distal to rs12039904 C>T and tags the undertransmitted haplotype. The linkage and association studies were combined using Fisher's combined probability test with which the significance at rs844644 A>C reached  $P = 6.8 \times 10^{-5}$ . Subsequent large Genome-Wide Association Studies (GWAS) confirmed this association at a genome-wide level of significance ( $P < 5 \times 10^{-8}$ ; see below).

The variant rs844644 A>C lies at 1q24, upstream of the 5' untranslated region (UTR) of *TNFSF4*, which encodes TNF Superfamily Member 4 (TNFSF4), the OX-40 Ligand. TNFSF4 is expressed broadly, including on the DC2 subset where it facilitates Th2 differentiation. Its receptor, OX-40 is expressed mainly on active CD4 T cells. The SLE-associated (minor) rs844644C allele was associated with increased TNFSF4 expression in EBV-transformed B-cell lines and peripheral blood leukocytes from SLE patients (Cunningham Graham et al., 2008).

#### **C4A, C4B**

One of the strongest associations with SLE within the HLA is with the C4 genes in the *HLA* Class III region (Christiansen et al., 1991). Both the major European DR3-associated haplotypes in SLE patients include the disruption of *C4A* or *C4B*. The 8.1 ancestral haplotype common in Western and Northern Europeans contains a null allele of the gene encoding *C4A* (*C4A\*Q0*; Fielder et al., 1983; So et al., 1990). In Caucasians the relative risk for SLE of carrying two *C4A\*Q0* alleles is 16.9 (Howard et al., 1986). Association studies of other *C4A* null alleles in African-American and Asian populations, where they are present on haplotypes other than the 8.1 ancestral haplotype, indicate that that *C4A* null alleles are SLE risk genes independently of *HLA-DRB1\*03:01*, showing a gene dose effect and conferring a relative risk of 2.7 in African-Americans (Howard et al., 1986; Yamada et al., 1990).

A null allele of the gene encoding *C4B* (*C4B\*Q0*) is present in the other major European DR3-associated ancestral haplotype (A30::DQ2, consisting of *HLA-A\*30:02*, *C\*05:01*, *B\*18*, *DRB1\*03:01*, *DQA1\*05:01*, *DQB1\*02:01*), which occurs with frequencies around 15% in Sardinia and Basque, and between 2% and 10% in Southern Europe. The *C4B\*Q0* allele is also relatively common in SLE patients (Fielder et al., 1983) and shows an association with SLE in Australian Aborigines (Christiansen et al., 1991), African-Americans (relative risk 2.0; Howard et al., 1986), and Spanish populations (relative risk 6.0; Naves et al., 1998), but not other Caucasians (Howard et al., 1986).

#### **C2**

The gene encoding the C2 complement component also lies within the Class III region of the HLA, between the *C4* genes and those encoding HSP70, TNF, LT $\alpha$ , and LT $\beta$ . Null alleles of *C2* are likewise associated with SLE, and 33% of Europeans with homozygous *C2* deficiency develop it (Walport, 1993). Homozygosity for null alleles is present in 0.4%–2% of cases compared to 0.01% of the general population; heterozygous *C2* deficiencies are present in 2.4%–5.8% of cases compared to 0.7%–1% of the general population (Sullivan et al., 1994; Lipsker et al., 2000). Patients with *C2* deficiency tend to experience photosensitivity and other forms of skin involvement; amongst *C2*-deficient patients without SLE, benign cutaneous (discoid) lupus is also common (Agnello, De Bracco and Kunkel, 1972; Provost, Arnett, Reichlin, 1983; Lipsker et al., 2000).

#### **C1Q**

Heredity deficiencies of other early complement components (C1q, C1r, C1s) are powerful but rare causes of a SLE-like syndrome. For example, 90% of people with C1q deficiency develop SLE. Onset can occur in childhood (even as early as 1 year of age), and the disease can be associated with very severe CNS and renal complications; of 30 patients, 22 died in childhood (Bowness et al., 1994).

#### **FCGR2A, FCGR3A, FCGR3B**

In the 1970s, reduced Fc-rosette formation of red blood cells from SLE patients was identified and attributed to saturation by circulating complexes (Nakai et al., 1977). While it was known that the Fc $\gamma$  receptors Fc $\gamma$ RI (CD64), Fc $\gamma$ RII (CD32), and Fc $\gamma$ RIII (CD16) contribute to the clearance of IgG and IgG-containing immune complexes, they were not examined as candidates until the 1990s. The C allele of the rs1801274 T>C variant in *FCGR2A* results in a His to Arg substitution at position 131 of Fc $\gamma$ RIIa and reduces the affinity by which Fc $\gamma$ RIIa binds IgG2 (Duits et al., 1995). This substitution also affects the clearance of IgG-coated erythrocytes and has been found to have an inconsistent association with SLE but not to nephritis (Duits et al., 1995; Dijstelbloem et al., 2000; Salmon et al., 1996).

Similarly, the T allele of the rs396991 G > T variant in *FCGR3A* results in a Val to Phe substitution at position 176 of Fc $\gamma$ RIIIa reducing, in 176Phe/Phe homozygotes, the binding of IgG1 and IgG3 by NK cells and monocytes, inhibiting NK cell activation, and activation-induced cell death (Wu et al., 1997). Homozygosity for this allele is present in a significantly higher proportion of SLE patients than controls (Wu et al., 1997; Koene et al., 1998) and is associated with lupus nephritis, arthritis, and serositis, or hematologic cytopenias, depending on the population (Salmon et al., 1999; Dijstelbloem et al., 2000).

Two alleles of *FCGR3B* vary in the encoded amino acid sequence of Fc $\gamma$ RIIb, affecting low-affinity IgG binding by neutrophils. The allele associated with decreased phagocytic activity (NA2) is associated with SLE (OR 1.9; Hatta et al., 1999). *FCGR3B* also shows copy number variation, and a low *FCGR3B* copy number, in particular complete Fc $\gamma$ RIIb deficiency, is strongly associated with SLE as well as with Wegener's granulomatosis (Fanciulli et al., 2007; McKinney and Merriman, 2012).

## **IRF5**

Increased production of type I IFNs and expression of IFN-inducible genes are commonly observed in SLE and appears to play a key role in the molecular pathogenesis of the disease (Baechler et al., 2003). Sigurdsson et al. (2005) performed linkage and association studies of 44 variants in 13 candidate genes involved in the type I IFN pathway on 679 Swedish, Finnish, and Icelandic patients with SLE, 798 unaffected family members, and 438 unrelated control individuals. Two genes were highly significantly associated with SLE: TYK2 (19p13) and *IRF5* (7q32). Remarkably, despite the relatively low power of the study, the *P* value for *IRF5* reached a genome-wide level of significance. This finding was quickly and robustly replicated (Graham et al., 2006). The most highly associated variant in the 7q32 region (rs2004640 T > G) lies in the splice junction of an alternate first exon of *IRF5*. The rs2004640T allele creates a 5' donor splice site allowing expression of several unique *IRF5* isoforms and is in linkage disequilibrium with a *cis*-acting variant associated with elevated expression of *IRF5*. *IRF5* is a transcription factor that regulates type I IFN gene expression. It is critical for the production of the proinflammatory cytokines TNF, IL-12, and IL-6 following Toll-like receptor (TLR) signaling (Takaoka et al., 2005), and it mediates type I IFN induction in response to some viruses (Barnes, Moore and Pitha, 2001). In a genome-wide association study of anti-dsDNA autoantibodies in SLE, *IRF5*, together with the *HLA*, *STAT4*, and *ITGAM*, was found to be significantly associated (Chung et al., 2011).

Other variants in this region are associated with ulcerative colitis (Anderson et al., 2011), Sjögren's syndrome (Lessard et al., 2013), systemic sclerosis (Mayes et al., 2014), RA (Okada et al., 2014), and primary biliary cirrhosis (Liu et al., 2012).

## Mechanisms of Complement and Fc Associations with Autoimmunity

The leading hypothesis explaining the association between SLE and deficiencies in FcR and complement is that these defects impair the catabolism of immune complexes by the mononuclear phagocytic system (Walport, 1993). Tracking of radio-labeled immune complexes revealed the following defects in SLE patients: (1) reduced immune complex uptake by the spleen; (2) accelerated clearance of complexes by the liver; and (3) release of those immune complexes from the liver back into circulation (Davies et al., 1992). In similar studies of a patient with C2 deficiency, a splenic uptake of immune complexes was found to be entirely complement dependent and could be restored by the transfusion of fresh frozen plasma (Davies et al., 1993). As C4A binds more effectively to amino groups than does C4B, it has been proposed that it is more efficient at clearing immune complexes (Schifferli et al., 1986). This may explain the stronger association of SLE with C4A deficiencies.

## Mechanisms of Human Leukocyte Antigen Association with Autoimmunity

The finding of a single ancestral haplotype (8.1) associated with multiple autoimmune diseases suggests a common mechanism mediating susceptibility. The analysis of HLA recombinant patients indicates that, for many autoimmune diseases, genetic association with the HLA can be primarily attributed to associations with the genes encoding specific peptide-presenting molecules, Class I or Class II (Thorsby, 1997). The hypothesis arising from this observation is that disease-associated HLA Class I and Class II alleles permit binding of disease-inducing peptides. The question of why one particular peptide of an autoantigen should be any more disease-inducing than another became the driving force behind a supplementary hypothesis: Molecular mimicry, in which it is proposed that bireactive TCRs permit the priming of T cells by a microbial peptide and effector activation by

autoantigens. The most plausible example of putative molecular mimicry is found in ankylosing spondylitis, which on microbiologic and serologic criteria is associated with *Klebsiella* infection (Ebringer, 1992). The amino acids 72–77 of the HLA Class I molecule B27 are identical to amino acids 188–193 of the nitrogenase of *Klebsiella pneumoniae* (Yu, Choo and Schaack, 1989).

Lang et al. (2002) reported bireactive TCRs of MS patients that bound both DRB5\*0101 presenting a peptide from the DNA polymerase of EBV as well as DRB1\*1501 presenting a myelin basic protein peptide. Crystal structure determination revealed a marked degree of structural equivalence at the surface presented for TCR recognition. In contrast, T cells from patients with SLE show no such cross-reactivity at the level of TCR/peptide/HLA. In addition to MS and SLE, DRB1\*1501 is positively associated with the autoimmune diseases Sjögren's syndrome (Guggenbuhl et al., 1998), Goodpasture syndrome (Fisher et al., 1997), and juvenile idiopathic arthritis (Garavito et al., 2004). Such a wide range of tissue specificities renders it most unlikely that a shared autoantigen is responsible, and there is little evidence of any etiological role for EBV in Goodpasture syndrome or juvenile idiopathic arthritis. The cross-reactivity identified in lupus autoantibodies can be explained by B-cell polyclonal activation, support of antibody production, and inhibition of apoptosis mediated by EBV, and these activities of themselves probably provide sufficient explanation for the association between EBV and SLE.

## GENETIC LINKAGE STUDIES OF AUTOIMMUNITY

The availability of dense maps of polymorphic genetic markers [microsatellites and single nucleotide polymorphisms (SNP)] revolutionized the localization of non-HLA-linked disease genes (Gyapay et al., 1994; Dietrich et al., 1992, 1996; Tsang et al., 2005). Linkage analyses rely on the disproportionate transmission of alleles to affected and unaffected progeny.

### Linkage Studies of Type 1 Diabetes

The first genome-wide scans for linkage to T1D were performed on large collections of T1D families with pairs of affected siblings (sib pairs) by microsatellite (variable number of tandem repeats) analysis in 1994 (Davies et al., 1994; Hashimoto et al., 1994; <http://www.immunobase.org>). These studies easily confirmed linkage to the HLA, both by their own statistical thresholds, as well as by those of Lander and Kruglyak (1995), which are set to a 5% probability per study of a single genomic region exceeding the significance threshold by chance (i.e., a logarithm of the odds (LOD) score >3.6). Davies et al. (1994) calculated that the HLA contributes about 42% of the familial clustering of T1D. Neither group showed evidence of linkage at *INS*.

### **CTLA4**

Owerbach and Gabbay (1995) performed a genome-wide linkage analysis in 162 type I diabetic families with an affected sibling pair and subset their data by the *INS* VNTR and HLA haplotypes. They identified an additional susceptibility locus on chromosome 2q31 near *HOXD8* (*IDDM7*; maximum LOD 4.8) in affected sib pairs lacking high-risk HLA-DR3/4 haplotypes and expressing homozygous high-risk class I VNTR alleles. This region is homologous to that on proximal mouse chromosome 1 where the *Idd5* T1D gene was subsequently identified in diabetes-prone NOD mice (Cornall et al., 1991) and contains the disease candidate genes *CTLA4* and *CD28*, which encode T-cell receptors involved in control of T-cell activation (Walunas et al., 1994).

The candidature of *CTLA4* was also supported by a subsequent linkage analysis in 48 Italian families, transmission disequilibrium testing in 187 Italian families (138 of which had only a single affected child) and 44 Spanish families, and a population-based case/control association study of 966 patients and 1058 controls from Belgium (Nisticò et al., 1996). Similar studies in British, Sardinian, and American families did not support *CTLA4* candidacy (Nisticò et al., 1996). A meta-analysis of 33 independent studies examined the variant rs231775 A > G/A > T, which causes a Thr-to-Ala substitution in the first exon; it showed an OR of 1.45 for the rs231775G allele; with a greater effect in cases with onset <20 years of age (OR 1.61; Kavvoura and Ioannidis, 2005). On the basis of *CTLA4* being 10 cM distal of the *IDDM7* linkage peak (*D2S152*), and the lack of disequilibrium between *D2S152* and *CTLA4* in the association study, the locus at 2q33 was designated *IDDM12* (Nisticò et al., 1996).

Ueda et al. (2003) examined expression levels of two major isoforms of *CTLA4* that are affected by the most T1D-associated variant rs3087243 G > A: the full-length sequence, and a soluble isoform (s-*CTLA4*) that lacks exon 3 (Oaks et al., 2000). The disease-associated rs3087243G allele was associated with a lower expression of

s-CTLA4 in a gene dose-dependent manner. Similarly, sequence-dependent variations in *Ctla4* isoforms were identified in T1D-susceptible NOD mice, and the differential expression of one appeared to mediate the allelic variation in T1D risk that maps to this chromosomal region (Oaks et al., 2000; Vijayakrishnan et al., 2004; Araki et al., 2009). CTLA4 is expressed constitutively on regulatory T (Treg) cells and is thought to, at least in part, mediate their immunosuppressive activities (Manzotti et al., 2002), as an interaction of CTLA4 with CD80 or CD86 inhibits human T-cell activation (Vandenborre et al., 1999). Soluble CTLA4 also has this activity (Oaks et al., 2000), and a knock-down transgene for s-CTLA4 exacerbated T1D in an NOD congenic strain that expresses the wild-type *Ctla4* allele (Gerold et al., 2011).

In addition to T1D, CTLA4 is associated with Graves' disease (Yanagawa et al., 1995; Kouki et al., 2000; Kotsa, Watson and Weetman, 1997), Hashimoto's autoimmune thyroiditis and autoimmune hypothyroidism (Kotsa, Watson and Weetman, 1997; Donner et al., 1997), Addison's disease (Blomhoff et al., 2004; Donner et al., 1997), MS (Harbo et al., 1999; Ligers et al., 1999) and alopecia areata (Petukhova et al., 2010), celiac disease (Dubois et al., 2010), and rheumatoid arthritis (Gonzalez-Escribano et al., 1999; Gregersen et al., 2009).

The 10p11-q11 region (designated *IDDM10* in unpublished data by Todd (1995); maximum LOD 2.03; Hashimoto et al., 1994) contains the putative candidate genes *GAD2* and *IL2RA* (*CD25*).

## **GAD2**

*GAD2* encodes the islet cell-specific (65 kDa) form of Glutamic Acid Decarboxylase (GAD65), a prevalent autoantigen in T1D. Association analysis of a highly polymorphic dinucleotide repeat linked to the gene did not support a significant role for *GAD2* (Wapelhorst et al., 1995).

## **IL2RA**

In contrast, *IL2RA* (10p15), which encodes the IL-2 receptor  $\alpha$  chain (IL2RA), was supported by a tag SNP approach and a large sample size (7457 cases and controls and 725 multiplex families; Vella et al., 2005). IL2RA plays a critical role in the development and maintenance of Treg and may play a role in Treg expression of CD62L, which is required for their entry into lymph nodes (Malek and Bayer, 2004). In association studies, T1D was associated with two independent groups of variants, spanning overlapping regions of 14 and 40 kb, encompassing the first intron of *IL2RA* and the 5' intragenic region (Lowe et al., 2007; Maier et al., 2009b). The T1D susceptibility genotypes were also associated with lower circulating levels of soluble IL2RA (s-IL2RA; Lowe et al., 2007). Dendrou et al. (2009) confirmed gene–phenotype correlation at the RNA level: Individuals with one or two protective G alleles at rs12722495 A > G showed a 27% increase in IL2RA levels on their CD4 $^{+}$ memory T cells when compared to homozygous susceptible individuals (AA) or to those with protective rs11594656A or rs2104286G alleles.

Allelic variation in *IL2RA* is also associated with MS (IMSGC et al., 2007; see below), RA (Stahl et al., 2010), juvenile idiopathic arthritis (Hinks et al., 2013), alopecia areata (Petukhova et al., 2010), primary sclerosing cholangitis (Liu et al., 2013), inflammatory bowel disease (Jostins et al., 2012), and Crohn's disease (Franke et al., 2010).

## **OTHER LOCI**

Other putative diabetes susceptibility loci initially identified using linkage studies were localized to chromosomes: 18q12-q21 (designated *IDDM6*; maximum LOD 3.7; Todd, 1995; Merriman et al., 1997), 6q27 (designated *IDDM8*; maximum LOD 3.4; Luo et al., 1995; Todd, 1995; Luo et al., 1996), 3q22-q25 [designated *IDDM9* (unpublished data, Todd, 1995), maximum LOD 2.4 in DR3/DR4 heterozygotes; Mein et al., 1998; Paterson, Rahman and Petronis, 1999], 14q24-q31 (designated *IDDM11*; maximum LOD 4.0, 4.6 in families without evidence of HLA linkage to T1D; Field et al., 1996), 2q34-q35 (designated *IDDM13*; maximum LOD 3.3; Morahan et al., 1996), and 6q2 (designated *IDDM15*; identified by an extension of identity-by-descent methods as adjacent to HLA,  $P < 5 \times 10^{-5}$ ; Delépine et al., 1997). The latter locus brings to a total four putative loci on chromosome 6q: *IDDM1/HLA*, *IDDM15*, *IDDM5*, and *IDDM8*, in that order from centromere to telomere over about 100 cM.

## **LINKAGE ANALYSES OF COMBINED DATASETS AND THE LIMITS OF LINKAGE ANALYSES**

By 1998, very large collections of families were being analyzed. Mein et al. (1998) studied 356 affected sib-pair families from the United Kingdom but found significant linkage only to three regions: (1) *IDDM1/HLA*; (2) *IDDM10/IL2RA* (10p13; maximum LOD 4.7); and (3) 16q22-24 (maximum LOD 3.4). Remarkably, most of the previously reported loci were excluded by exclusion mapping at a  $\lambda_s$  of 3 and a LOD of -2. Similarly, a two-staged analysis of 616 multiplex families from the United Kingdom and the United States identified only

*IDDM1/HLA* (maximum LOD 34.2) as significant by multipoint analysis, and a single previously unreported locus on 1q of suggestive significance (LOD 3.31; Concannon et al., 1998). The data were consistent with a locus distal from the *HLA*, at *IDDM15* (6q21) with a maximum LOD 3.8, but its proximity to the *HLA* required correction for linkage disequilibrium, resulting in an adjusted LOD of 2.27. On chromosome 2q, previous studies had proposed three loci (*IDDM7*, *IDM12*, and *IDDM13*) but Concannon et al. (1998) reported a maximum LOD in this region of 1.07, and little evidence for distinct loci. By multipoint analysis, even modest contributions ( $\lambda_s \geq 1.5$ ; LOD  $< -2$ ) to T1D could be excluded for *IDDM3*, *IDDM4*, *IDDM6*, *IDDM9*, and *IDDM10*. In an identity-by-descent (IBD) analysis of previously reported loci (other than *IDDM1/HLA* and *IDDM2/INS*), only *IDDM7/IDDM12/IDDM13* and *IDDM15* had LOD scores greater than 1; negligible support was found for six of the previously reported loci: *IDDM3*, *IDDM4*, *IDDM6*, *IDDM9*, *IDDM10*, and *IDDM11*.

To further increase the power of linkage analyses, multinational consortia were formed, allowing the analysis of combined datasets. The Type 1 Diabetes Genetics Consortium (T1DGC) was established for this purpose in 2002. Concannon et al. (2005) performed, under the auspices of the T1DGC, a combined linkage analysis of four datasets, three previously published (Concannon et al., 1998; Mein et al., 1998), providing a total sample of 1435 families with 1636 affected sib pairs. By multipoint linkage analysis, only the *HLA* was significant (*IDDM1*; LOD 116;  $\lambda_s$  of 3.35), and four other regions showed suggestive significance (i.e., uncorrected  $P < 7.4 \times 10^{-4}$ ): 2q31-33 (*IDDM7/IDDM12/CTLA4*; LOD 3.34;  $\lambda_s$  of 1.19), 6q21 (*IDDM15*; LOD 22.39;  $\lambda_s$  of 1.56), 10p14-q11 (*IDDM10/IL2RA*; LOD 3.21;  $\lambda_s$  of 1.12), 16q22-24 (LOD 2.64;  $\lambda_s$  of 1.19). LOD scores above 1 were found at *IDDM2/INS* and five other regions: 3p13-14, 9q33-34, 12q14-12, 16p12-q11, and 19p13. The 19p13 region contains the insulin receptor gene (*INSR*).

In 2009 T1DGC published a pedigree disequilibrium test (a family-based test of linkage disequilibrium applicable to larger-than-nuclear families; Martin et al., 2000) analysis of 2496 multiplex families (Concannon et al., 2009). Three of the most strongly associated (but not significant at a genome-wide level) loci had been previously identified (*INS*, *IFIH1*, and *CLEC16A*; the latter locus previously identified by genome-wide association study, discussed below). A fourth strongly associated variant was in the sixth intron of the gene *UBASH3A*, and this finding was validated by linkage analysis in 2214 parent-affected child trio families and association in panel of 7721 cases and 9679 control subjects (OR 1.10;  $P = 4.4 \times 10^{-12}$ ).

### UBASH3A

This gene encodes the protein ubiquitin-associated and SH3 domain containing A, which is expressed primarily in T cells. CRISPR/Cas9 manipulation of expression levels in Jurkat lymphoblastic T cells showed that its expression suppresses TCR-induced NF- $\kappa$ B signaling by inhibiting I $\kappa$ K $\alpha$ /b phosphorylation, I $\kappa$ B degradation, and NF- $\kappa$ B translocation to the nucleus. As a result, IL-2 secretion is inhibited (Ge et al., 2017). The T1D-associated *UBASH3A* rs11203203A (minor) allele is associated with increased expressions of *UBASH3A* and reduced *IL2* mRNA compared to subjects homozygous for the rs11203203G (major) allele (Ge et al., 2017).

The rs11203203 G > A variant is also associated with vitiligo (Jin et al., 2012) and rs1893592 A > C variant, which lies within an intron of *UBASH3A*, is associated with celiac disease (Trynka et al., 2011).

The following year (2009) T1DGC published the details of a linkage reanalysis of their collection of 2496 multiplex families applying a linear nonparametric linkage model that was less conservative in handling missing data (Kong and Cox, 1997). Only the *HLA* was significant at genome-wide significance levels (*IDDM1*; LOD 213), with significance at 6q21/*IDDM15*, resulting from an effect partly due to linkage disequilibrium with *HLA*. Suggestive linkage was found at *CTLA4* (*IDDM7/IDDM12*; LOD 3.28) and *INS* (*IDDM2*; LOD 3.16) and two regions on chromosome 19: 19p13 (*INSR*; LOD 2.84) and 19q13 (LOD 2.54; Concannon et al., 2009). The sample size of this study provided unprecedented power to detect linkage but provided little support for most loci previously implicated in T1D.

### Linkage Studies in Multiple Sclerosis

In contrast to the moderate progress in T1D, attempts to identify MS genes by linkage analysis of families such as affected sib-pair analysis or patient and unaffected parent trios were relatively unsuccessful. For example, Sawcer et al. (1996) studied 282 families using a staged approach but only obtained a maximized LOD score at the *HLA* of 2.8, compared to 8.0 for T1D (Davies et al., 1994). Only one other locus surpassed the statistical threshold for suggestive linkage, 17q22. In none of the other linkage studies did the *HLA* reach a significant maximized LOD score (Ebers et al., 1996; Kuokkanen et al., 1997; Haines et al., 1996; Coraddu et al., 2001;

Broadley et al., 2001; Ban et al., 2002). Ebers et al. (1996) reported linkage to a region just outside the *HLA* ( $\chi^2$  of 10.8 by transmission disequilibrium test), Kuokkanen et al. (1997) reported linkage (maximized LOD 3.6) at 17q22-24 and the Multiple Sclerosis Genetic Group reported suggestive linkage to *HLA-DR* and 7q21-22 (Haines et al., 1996). Several groups applied a modified threshold for suggestive significance (based on reduced marker density) and identified suggestive linkage at 1q31 (Coraddu et al., 2001), 2p13, 4q26-28 and 6q26 (Ban et al., 2002), 10q23 and 11p15 (Coraddu et al., 2001), and Xp11 (Ban et al., 2002).

The issue of why genome-wide linkage studies were relatively successful in T1D but not MS is an important one. Where the effective strength of putative loci could be determined, they were of similar orders between the two diseases. Patient heterogeneity is also an unlikely explanation, because the consolidation of sample sets occurred later for MS than it did for T1D; as a generalization, the MS results reflected samples collected within relatively restricted geographical areas. Similarly, while the power of several of the MS studies was rather low, others used sample sizes comparable to those used in many of the T1D studies. The most likely explanation lies in the relative heritability (the proportion of variation in risk within a community attributable to genetics) of the two diseases: that of T1D is about twice that of MS (Baxter, 1997; Baxter, 2007; Hawkes and Macgregor, 2009), an observation consistent with the identification of several major environmental factors contributing to the risk of MS including geographic latitude, cigarette smoking, and EBV infection.

## Linkage Studies in Systemic Lupus Erythematosus

Following the identification of linkage to distal chromosome 1 in the NZB/NZW and New Zealand mixed (NZM) mouse models of SLE, Tsao et al. (1997) examined seven markers in the syntenic region of human chromosome 1 (1q31-42) in 52 affected sib pairs and confirmed linkage to SLE.

In 1998 two major genome-wide linkage studies of SLE were published (Gaffney et al., 1998; Moser et al., 1998). Analysis of 105 families with at least two affected siblings identified just two loci surpassing the Lander and Kruglyak (1995) thresholds for significant linkage: 6p11-21 (just centromeric to the *HLA*; maximized LOD 3.9) and 16q13 (maximized LOD 3.6; Gaffney et al., 1998). Both these regions were confirmed in a subsequent reanalysis that included an additional 82 sib-pair families (maximized LODs of 4.1 and 3.9, respectively; Gaffney et al., 2000). Two other regions fulfilled the criteria for suggestive linkage: 14q21-23 (maximized LOD 2.8) and 20p12 (maximized LOD 2.6). A peak, albeit nonsignificant, was consistent with a linkage to 1q42, as reported in Tsao et al. (1997).

The other major analysis examined 94 African- and European-American multiplex extended pedigrees identifying four regions of suggestive linkage: 1q23 (maximized LOD 3.5), 13q32 (maximized LOD 2.5), 20q13 (maximized LOD 2.5), 1q31 (maximized LOD 2.0; Moser et al., 1998). Additional suggestive loci were identified only in African-American families—1q41 (maximized LOD 3.5), 11q14-23 (maximized LOD 2.1)—and only in European-American families—14q11 (maximized LOD 2.2), 4p15 (maximized LOD 2.2), 11q25 (maximized LOD 2.2), 2q32 (maximized LOD 2.1), 19q13 (maximized LOD 2.1), 6q26-27 (maximized LOD 2.0), and 12p13-11 (maximized LOD 2.0). No linkage to the *HLA* (6p21) was identified, probably reflecting the reduced power of genetic studies in mixed populations. The 1q23 locus is syntenic with the major murine chromosome 1 locus (Vyse and Kotzin, 1998) and contains the SLE candidate gene *FCGR2A*, and the 1q41 linkage is consistent with that found by both Tsao et al. (1997) and Gaffney et al. (1998).

## TNFR1, TNFR2, LTBR

The 12p13 locus (Moser et al., 1998) contains the genes *TNFR1* (*TNFRSF1A*) and *LTBR* (*TNFRSF3*), which encode TNF receptor 1 and the LT $\beta$  receptor, respectively. Similarly, the location of *TNFR2* (*TNFRSF1B*; encoding the TNF receptor 2) on 1p36 was sufficiently close to minor linkage peaks reported by Gaffney et al. (1998) and Shai et al. (1999) for Tsuchiya et al. (2000) to test and confirm the association of the nonsynonymous coding variant rs1061622 T > G with SLE in Japanese subjects. SLE is associated with serum concentrations of a soluble TNF receptor (s-TNFR; both type I and type II) sufficient to effectively inhibit the bioactivity of TNF (Aderka et al., 1993). Perhaps the clearest evidence of the disease's heterogeneity comes from an open-label trial of TNF blockade in SLE. While the majority of patients expressed increased titers of high-affinity autoantibodies to dsDNA, chromatin, and histones over the period of therapy, seven of nine patients with lupus nephritis experienced the stabilization of serum creatinine and a reduction in proteinuria of >50%, and all five patients with lupus arthritis underwent remission lasting for weeks after treatment was halted (Aringer et al., 2009).

In addition to the association of rs1061622 T>G with SLE, primary biliary cirrhosis (Liu et al., 2012), juvenile idiopathic arthritis (Hinks et al., 2013), MS (IMSGC et al., 2013), and ankylosing spondylitis [International Genetics of Ankylosing Spondylitis Consortium (IGAS) et al., 2013] are associated with different variants in this region.

### **Signal Transducer and Activator of Transcription 4**

A small genome-wide linkage study of RA identified a region on chromosome 2q33 with significant linkage (Amos et al., 2006). A subsequent high-resolution association study confirmed the involvement of this region in RA and implicated the gene *STAT4*, since the five most significantly associated variants all lay within the second intron of *STAT4* (Remmers et al., 2007). Signal Transducer and Activator of Transcription 4 (*STAT4*) is a cytokine-responsive transcription factor that mediates responses to IL-12 and plays a critical role in the differentiation of Th1 cells. The authors also genotyped 1039 SLE patients and 1248 controls at rs7574865 T>G, which lies within the third intron of the *STAT4* gene and was the variant most highly associated with RA. They found that the RA susceptibility rs7574865T (major) allele was also associated with SLE (Remmers et al., 2007). In SLE, this variant was strongly associated with anti-dsDNA AAB, particularly severe nephritis and early onset of disease (Taylor et al., 2008; Chung et al., 2011). The same risk allele also confers susceptibility to primary Sjögren's syndrome (Nordmark et al., 2009) and primary biliary cirrhosis (Liu et al., 2013).

Other variants within *STAT4* are associated with inflammatory bowel disease (Jostins et al., 2012), celiac disease (Trynka et al., 2011), juvenile idiopathic arthritis (Hinks et al., 2013), MS (IMSGC et al., 2013), and systemic sclerosis (Mayes et al., 2014).

### **RACIAL HETEROGENEITY IN SYSTEMIC LUPUS ERYTHEMATOSUS**

Since genome-wide linkage analyses had confirmed the importance of racial heterogeneity in SLE inheritance, Shai et al. (1999) analyzed 80 families with affected sib-pairs (43 Mexican-American families and 37 Caucasian families) and found no significant loci and only a single suggestive locus: 1q44. An analysis of the data by race made it clear that the linkage could be attributed only to the Mexican-American subgroup; there was no support for a gene in this region in the Caucasian families. Lindqvist et al. (2000) analyzed six Icelandic and eleven Swedish pedigrees with multiple affected members. The combined dataset showed significant linkage to 2q37 (LOD score 4.24). This region contains the *INPP5D* gene, which encodes an SH2-containing phosphatase which is recruited through tyrosine phosphorylation of FcgRIIB, CD19, or CD22 after the ligation of the B-cell receptor, and is thought to be important in FcgRIIB-mediated inhibition of B-cell activation. Suggestive linkage was identified at 4p15-13 and 19p13 when the Icelandic subjects were analyzed independently. The 4p15-13 locus is syntenic with the *Lmb2* murine lupus susceptibility gene. In most cases (14/16 markers), aggregating the data from the two countries eliminated any suggestion of linkage. In many subsequent studies, particularly in the genome-wide association studies that followed, experimental power was improved by restricting racial heterogeneity—generally to populations of European descent.

## **GENOME-WIDE ASSOCIATION STUDIES OF AUTOIMMUNITY**

Genome wide *linkage* analyses were limited in resolution by the recombination frequency observable over a few generations and limited in power by the relatively low number of multiplex families available. By the year 2000 a reasonable draft of the human genome sequence was completed, millions of SNP's had been deposited into public databases, and high-throughput technologies were under development for SNP genotyping. It was predicted that *case-control association studies* involving thousands of patients and population-based controls would provide far better resolution and power for the identification of disease-associated genes (Cardon and Bell, 2001). In contrast to linkage studies GWASs can detect alleles with much more modest effects on risk, if those alleles are relatively common and the sample size sufficiently large (Wang et al., 2005). In each region of the genome, preselected variants are chosen that are expected to represent the total genetic variation that is in linkage disequilibrium with the markers. Kruglyak (1999) estimated that in GWAS, linkage disequilibrium was unlikely to extend beyond an average distance of 3 kb in the general population; this implies that a minimum of 500,000 variants would be required for whole genome coverage; in practice, a marker density about twice that is used.

GWASs of autoimmune diseases were facilitated by the development of the ImmunoChip, an Illumina Infinium SNP genotyping microarray that interrogates approximately 200,000 SNPs and approximately 1000

small insertions–deletions putatively associated with at least one of 12 immune-mediated diseases: ankylosing spondylitis, autoimmune thyroid disease, celiac disease, Crohn's disease, juvenile idiopathic arthritis, MS, primary biliary cirrhosis, psoriasis, RA, SLE, T1D, and ulcerative colitis. This array particularly facilitated the direct comparison of risk- and protection-associated alleles between immune-mediated diseases (Parkes et al., 2013). The case/control association statistics from the ImmunoChip consortium have been integrated and curated on the ImmunoBase web-based resource ([www.immunobase.org](http://www.immunobase.org)), which contains complete association summary statistics and facilitates the direct comparison of these data for the ImmunoChip diseases at published genes, markers, and chromosomal regions.

## Genome-Wide Association Studies of Type 1 Diabetes

Smyth et al. (2006) performed a multilocus case–control association study of T1D using >6500 coding, nonsynonymous variants. Although not discussed in the paper, the rationale for studying nonsynonymous variants was the expectation that most alleles affecting common, complex diseases would alter the coding sequence, and therefore the causal variants might be amongst the markers selected (Weiss and Terwilliger, 2000). In an interim analysis of approximately 2000 cases and 1700 control samples, the most significantly associated variant was the previously published and confirmed rs2476601 G>A variant in *PTPN22* (Bottini et al., 2004). The authors referred to the next two most significantly T1D associated variants: one in *CAPSL*, which is adjacent to *IL17R* at 5p13, and the other on chromosome 2q24 in *IFIH1*.

### ***IFIH1***

The most strongly T1D-associated variant at 2q24, rs1990760 T>C, is a nonsynonymous variant in exon 15 of *IFIH1*, which encodes IFN Induced with Helicase C Domain 1 (IFIH1), a pattern recognition receptor for viral dsRNA. The T1D-associated rs1990760T (major) allele encodes an Ala to Thr substitution at position 946. The strength of the association with the rs1990760 T>C variant was increased by genotyping an additional 2471 cases and 4593 controls and by examining an independent collection of 2134 parent–child trios; the combined analysis for the locus reached a  $P = 1.42 \times 10^{-10}$  (Smyth et al., 2006).

The rs1990760T allele is also associated with rheumatoid arthritis (Stahl et al., 2010) and vitiligo (Jin et al., 2010) but is a resistance allele for Crohn's disease (Barrett et al., 2008). Other variants within the *IFIH1* haplotype block are associated with psoriasis (Genetic Analysis of Psoriasis Consortium & the Wellcome Trust Case Control Consortium 2 et al., 2010), inflammatory bowel disease (Jostins et al., 2012), and vitiligo (Jin et al., 2012).

Wellcome Trust Case Control Consortium et al. (2007) published a major genetic milestone: a GWAS of seven complex diseases (bipolar disorder, coronary artery disease, Crohn's disease, RA, T1D, and type 2 diabetes) with about 2000 cases per disease, and a shared group of approximately 3000 controls, typed at 500,568 variants using the Affymetrix GeneChip500k Mapping Array Set. Prior to the genome-wide analysis of the dataset, the authors examined the association at previously identified loci. For T1D, they confirmed association for *HLA*, *CTLA4*, *PTPN22*, *IL2RA*, and *IFIH1*; *INS* could not be tested because a suitable variant was not identified. It is sobering to note that the  $P$  values obtained for these “proof of principal” associations only surpassed genome-wide significance ( $P < 5 \times 10^{-8}$ ) for *HLA* and *PTPN22*. Even more concerning was the finding that, even after raising the significance threshold 500-fold, the only other previously reported genetic region identified was *IL2RA*. The study did, however, identify three new loci significantly associated with T1D: 12q13, 12q24, and 16p13. Two other loci identified by multilocus analysis were reported but were unlikely to be significant after correction for the additional hypotheses tested.

In a follow-up study, the Wellcome Trust Case Control Consortium (WTCCC) (Todd et al., 2007) genotyped an additional 4000 cases and 5000 controls (total 6000 affected, 6200 controls) and 2997 family trios, confirming genome-wide significance for 12q13 (*ERBB3*), 12q24 (gene *SH2B3*), 16p13 (*CLEC16A*), and 18p11 (*PTPN2*). Around the same time, Hakonarson et al. (2007) performed a GWAS on 563 patients and 1146 controls as well as 483 family trios of European ancestry. Significance was determined by  $\chi^2$  and transmission disequilibrium test, respectively, and the analyses combined using Fisher's combined probability test. Results for *HLA*, *PTPN22*, and *INS* surpassed a genome-wide level of significance ( $P < 5 \times 10^{-8}$ ), as well as at three variants associated with *CLEC16A* on 16p13. The latter associations were confirmed in a replication cohort of 939 affected trios. Two other chromosomal regions were identified in the discovery study, 1p31 and 7q21, but could not be validated with the replication cohort.

### **SH2B3**

The variant most strongly associated with T1D at 12q24, rs3184504 T>C, is a nonsynonymous variant that results in an Trp to Arg substitution at position 262 in exon 2 of *SH2B3*, which encodes SH2B Adaptor Protein 3 (SH2B3; previously named the lymphocyte adaptor protein), a negative regulator of lympho- and myelopoiesis as well as of cytokine signaling. *SH2B3* is highly expressed in lymphocytes (Velazquez et al., 2002), and *SH2B3* deletion is associated with acute lymphoblastic leukemia (Roberts et al., 2012). The T1D-associated rs3184504T (major) allele substitutes a Trp into position 262 in the Lymphocyte Adapter Protein (LNK)-family pleckstrin homology domain, resulting in reduced signaling (Li et al., 2000). As a consequence, this allele is associated with the increased proliferation of peripheral blood lymphocytes (Lavrikova et al., 2011), perhaps through its regulation of IL-7 receptor signaling (Cheng et al., 2016). *SH2B3* is also expressed in DC, and the DC of *Sh2b3*<sup>-/-</sup> knockout mice were increased in numbers and hyperresponsive to IL-15 and Granulocyte-Macrophage Colony-Stimulating Factor (GMCSF), expressed increased IL-12R $\beta$  and IFN $\gamma$ , and drove the differentiation of IFN $\gamma$ -producing CD4 T cells (Mori et al., 2014). Remarkably, *Sh2b3*<sup>-/-</sup> knockout DC could drive Th1 differentiation even in the presence of TGF- $\beta$ . In an extraordinary parallel to human T1D, diabetes-susceptible NOD mice, while not bearing a mutant allele of *Sh2b3* (Li et al., 2012), respond paradoxically to TGF- $\beta$ , by decreasing expression of *Sh2b3* instead of increasing it, consistent with the strain's Th1 polarization (Hisanaga-Oishi et al., 2014).

The *SH2B3* rs3184504 C>T variant is also associated with celiac disease (Trynka et al., 2011), juvenile idiopathic arthritis (Hinks et al., 2013), primary sclerosing cholangitis (Liu et al., 2013), and vitiligo (Jin et al., 2012). Other markers within the *SH2B3* haplotype block are associated with primary biliary cirrhosis (Liu et al., 2012), RA (Okada et al., 2014), and ankylosing spondylitis (IGAS et al., 2013).

### **ERBB3**

The most significantly T1D-associated variant in the 12q13 region, rs2292239 T>G, lies within an intron of *ERBB3*, in a major haplotype block that includes *SILV*, *SUOX*, *IKZF4*, *RPS26*, and *RPL41*; it is a quantitative trait locus (eQTL; i.e., its alleles are associated with differences in expression of protein coding genes) for *SUOX* and *RPS26* (Wang et al., 2010). *ERBB3* encodes the Erb-B2 Receptor Tyrosine Kinase 3 (ERBB3), a member of the epidermal growth factor receptor (EGFR) family of receptor tyrosine kinases. Although it lacks a kinase domain, it can signal by forming heterodimers with kinase-active members of the EGFR family. The rs2292239 G>T variant is also associated with alopecia (Betz et al., 2015).

### **CLEC16A**

The most significantly T1D-associated variant at 16p13, rs12708716 A>G, lies within an intron of *CLEC16A*, which encodes C-type Lectin Domain Containing 16A (CLEC16A), a membrane-associated endosomal protein that interacts with the E3 ubiquitin ligase NRDPL. The rs12708716 A>G variant acts as an eQTL affecting the levels of expression of *CLEC16A* in human pancreatic  $\beta$  cells (Soleimanpour et al., 2014), *DEXI* and *SOCS1* in thymus, *DEXI* in monocytes and lymphoblastoid cell lines, and *CLEC16A* and *SOCS1* in CD4 T cells (Leikfoss et al., 2015). Individuals expressing the T1D-associated rs12708716A (major) allele have reduced islet *CLEC16A* expression and reduced insulin secretion (Soleimanpour et al., 2014). The proposed mechanism of action in beta cells is that reduced CLEC16A increases the expression of the NRDPL target PARKIN, which is a regulator of mitophagy (selective degradation of mitochondria by autophagy), causing a reduction in cellular adenosine triphosphate (ATP), which is required for insulin secretion (Soleimanpour et al., 2014). Remarkably, *PDX1*, a gene associated with both type 2 diabetes and monogenic diabetes of the young, regulates *CLEC16A*, and its reduced expression in these diseases recapitulates the mitophagy in  $\beta$  cells seen in T1D (Soleimanpour et al., 2015).

The rs12708716 A>G variant is also associated with susceptibility to MS (IMSGC, 2009; Hoppenbrouwers et al., 2009). Other variants within *CLEC16A* have been associated with primary biliary cirrhosis (Liu et al., 2012) and celiac disease (Dubois et al., 2010).

### **PTPN2**

The most significantly T1D-associated variant at 18p11, rs1893217 A>G, lies within an intron of *PTPN2*, which encodes Protein Tyrosine Phosphatase, Non-Receptor Type 2 (PTPN2). Upon stimulation by IFN $\gamma$  and other inflammatory cytokines, PTPN2 acts to reverse cytokine-induced STAT1 and Signal Transducer and Activator of Transcription 3 (STAT3) phosphorylation, inhibiting cytokine-induced, BAX-mediated apoptosis of pancreatic beta cells (Moore et al., 2009; Santin et al., 2011). Its effect on STAT3 also affects beta-cell endocrine function; *Ptpn2*<sup>-/-</sup> mice fed a high-fat diet have reduced glucose-stimulated insulin secretion and impaired

glucose tolerance (Xi et al., 2015). Within T cells, PTPN2 dephosphorylates and inactivates Src family kinases to regulate T-cell responses. Mice bearing a T-cell specific deficiency develop widespread inflammation and autoimmunity that was transferable with CD8 T cells (Wiede et al., 2011).

Having said this, it is not clear that this locus does affect PTPN2 function or expression; the rs1893217 A > G variant has not been found to be associated with differences in PTPN2 expression in genome-wide screens (GTEx Portal on 06/01/18), although Long et al. (2011) report that the rs1893217G T1D risk allele is associated with reduced PTPN2 expression and decreased phosphorylation of STAT5 in response to IL-2 receptor binding.

The rs1893217 A > G variant is also associated with celiac disease (Dubois et al., 2010) and Crohn's disease (Franke et al., 2010), and other variants in the same region are associated with juvenile idiopathic arthritis (Hinks et al., 2013) and RA (Okada et al., 2014).

In 2009 Hakonarson's group (Grant et al., 2009) reviewed their data published in 2007 (Hakonarson et al., 2007), selecting 982 markers with  $P < .5$  in both discovery cohorts for analysis in 636 independent nuclear families with 974 affected offspring. Six variants were selected that had reached the same threshold in, not only these three datasets but also, the WTCCC dataset (Todd et al., 2007). These markers were then tested by case-control association in a further independent sample of 1303 patients and 1673 controls, with two reaching significance in that validation study and surpassing a genome-wide significance in a meta-analysis that combined all five cohorts of samples: *BACH2* at 6q15 and *UBASH3A* at 21p22.

## BACH2

The most strongly T1D-associated variant at 6q15, rs597325 G > A, lies within an intron of *BACH2*, which encodes BTB Domain and CNC Homolog 2 (*BACH2*), a basic leucine zipper transcription factor that regulates the expression of *IL2*, *BCL2*, and *XBP1*. It acts as a repressor of *XBP1*, which itself encodes a transcription factor regulating a wide range of targets, including *CCL2*, *CXCL8*, *IL-6*, multiple heat shock proteins, and *NOS2* (TRRUST2; Han et al., 2017), acting to repress the differentiation of multiple effector linages of CD4 T cells (Roychoudhuri et al., 2013). *Bach2*<sup>-/-</sup> mice show a severe reduction in the numbers of FoxP3-expressing Treg cells and develop a progressive wasting disease associated with extensive pulmonary infiltration by macrophages and GATA3-expressing CD4 T cells. Expression of IL-13 and IL-4 is greatly increased with a little change in numbers of T-bet and IFN- $\gamma$  or IL-17 positive cells (Roychoudhuri et al., 2013; Kim et al., 2014). In the absence of *BACH2*, Tregs express reduced levels of FoxP3 and Bcl-2 (Kim et al., 2014), and in vitro, *BACH2* is required for the induction of FoxP3 and differentiation of induced Tregs (Kim et al., 2014). *BACH2* also appears to play a role in pancreatic beta cells, as INS-1E rat insulinoma cells transfected with *BACH2* siRNA to reduce its expression also decreased the expression of *BCL2* and *BCLXL* and increased Bcl-2 Interacting Mediator Of Cell Death (BIM) phosphorylation, exacerbating cytokine-induced apoptosis (Marroquí et al., 2014). Remarkably, *BACH2* inhibition also significantly diminished cytokine-induced *PTPN2* expression in beta-cell lines and dispersed beta cells (Marroquí et al., 2014).

Other variants within the same region have been associated with MS (IMSGC et al., 2013), celiac disease (Dubois et al., 2010), primary sclerosing cholangitis (Liu et al., 2013), Crohn's disease (Franke et al., 2010), and autoimmune thyroid disease (Cooper et al., 2012).

A combined meta-analysis incorporating cases from the WTCCC studies (Todd et al., 2007) and a combined British and US GWAS (Cooper et al., 2008) examined a total of 7514 case and 9045 reference samples (Barrett et al., 2009). By performing a meta-analysis of all three scans, they confirmed, at a genome-wide level of significance ( $P < 5 \times 10^{-8}$ ), association with 12 previously identified regions: 1p13 (gene of interest *PTPN22*), 2q24 (*IFIH1*), 2q33 (*CTLA4*), 4q27 (*IL2*), 6p21 (*HLA*), 10p15 (*IL2RA*), 11p15 (*INS*), 12q13 (*ERBB3*), 12q24 (*SH2B3*), 16p13 (*CLEC16A*), 18p11 (*PTPN2*), and 21p22 (*UBASH3A*) and obtained genome-wide significance for 18 other loci: 1q32 (*IL10*), 4p15, 6q22 (*C6orf173*), 7p15, 7q12 (*COBL*), 9p24 (*GLIS3*), 10q23 (*C10orf59*), 12p13 (*CD69*), 14q24, 14q32, 16p11(*IL27*), 16q23, 17q12 (*ORMDL3*), 17q21, 19q13, 20p13, 22q12, and Xq28.

## IL2

The chromosomal region 4q27 is of particular interest, because it is syntenic with the NOD mouse diabetes susceptibility gene *Idd3* (Denny et al., 1997). Within it, the variant most strongly associated with T1D is rs4505848 A > G, which lies within an intron of the gene *KIAA1109*, about 200 kb 3' of the *IL2* and *IL21* cytokine genes.

Variants within this haplotype block are associated with inflammatory bowel disease (Jostins et al., 2012), juvenile idiopathic arthritis (Hinks et al., 2013), alopecia areata (Petukhova et al., 2010), celiac disease (Dubois et al., 2010), and primary sclerosing cholangitis (Liu et al., 2013).

## **IL10**

The most significantly associated variant at 1q32, rs3024505 G > A, lies about 1 kb 3' of *IL10*, which encodes IL-10, an immunoregulatory cytokine produced by leukocytes, especially monocytes. IL-10 has pleiotropic effects on adaptive and innate immunity, suppressing cell-mediated immunity, while supporting B-cell survival, proliferation, and antibody production (Moore et al., 2001). Its ability to inhibit the production of inflammatory cytokines and chemokines, including IL-1 and TNF, and suppress the expression of MHC class II antigens and the costimulators CD80 (B7) and CD86 (B7.2), contribute to its antiinflammatory activities.

The T1D-associated rs3024505 C > T variant is also associated with SLE (Gateva et al., 2009), inflammatory bowel disease (Jostins et al., 2012), ulcerative colitis (Anderson et al., 2011), and Crohn's disease (Franke et al., 2010). While T1D is associated with the rs3024505C (major) allele, SLE, ulcerative colitis, and Crohn's disease are associated with the T allele.

## **CD69**

The most strongly associated variant at 12p13, rs4763879 G > A, lies within *CD69*'s first intron, which contains a *cis*-regulatory element (Vazquez et al., 2012). *CD69* is a member of the calcium-dependent lectin superfamily of type II transmembrane receptors that is induced on T cells when activated and mediates their costimulation. Significantly, *CD69* suppresses Sphingosine-1-Phosphate Receptor-1 (S1P1) function (Bankovich et al., 2010). S1P1 plays a critical role in lymphocyte recirculation; its pharmaceutical downmodulation by the agonist fingolimod sequesters lymphocytes in lymph nodes, inhibiting relapses of MS. MS is also associated with a variant in the 3' UTR of *CD69* (IMSGC et al., 2013).

Bradfield et al. (2011) extended the meta-analysis approach to combine their data with all publicly available genome-wide T1D and control data sets. The discovery cohort consisted of 6523 cases and 6648 controls genotyped by Illumina BeadChip and 3411 cases and 10,308 controls genotyped on Affymetrix arrays. Imputed data produced from each platform were analyzed separately and the *P*-values, betas (natural log of the OR) and standard errors at each locus for the two platforms combined using inverse-variance meta-analysis. This study had more than twice the power of Barrett's 2009 analysis to identify variants with a relative risk (RR) of 1.2 and approximately three times the power to identify those with a RR of 1.1. Of the 45 known T1D-associated autosomal variants, Bradfield et al. (2011) reached the threshold for genome-wide significance ( $P < 5 \times 10^{-8}$ ) for 11: *PTPN22*, *IL10*, *IFIH1*, *CTLA4*, *HLA*, *BACH2*, *GLIS3*, *IL2RA*, 12q13, *SH2B3*, and 16p13.

Excluding the known T1D-associated loci, an additional 52 independent variants with meta-analysis  $P < 1 \times 10^{-5}$  were tested in an independent replication cohort consisting of 1120 T1D-affected trios genotyped by Sequenom iPLEX and analyzed by the transmission disequilibrium test. For these loci the meta-analysis and the replication were combined using Fisher's combined probability test. Three additional loci surpassed a  $P < .05$  significance threshold in the replication set as well as met the significance threshold for genome-wide significance in the combined analysis: 13q22 (gene of interest *LMO7*), 2p23 (*EFR3B*), and 6q27.

## **Genome-Wide Association Studies of Multiple Sclerosis**

GWAS of MS soon followed those of T1D, and many studies were coordinated through the large collaborative network, the International MS Genetics Consortium (IMSGC). The first of these was published in 2007 (IMSGC et al., 2007); the discovery phase of the study involved 931 trios and interrogation of 334,923 variants. A total of 110 variants were then selected for a follow-up in a replication phase consisting of 2322 MS cases, 609 parent-case trios, 789 controls, and additional genotype data from two external control datasets, resulting in a combined analysis of 12,360 subjects. In addition to the *HLA*, two other regions were found to be strongly associated with MS risk: 5p13 (*IL7R*) and 10p15 (*IL2RA*).

## **IL7R**

The most significantly MS-associated variant in the 5p13 region, rs6897932 G > A/G > C, lies within exon 6 of *IL7R*, which encodes the IL 7 Receptor (*IL7R*). This receptor signals through CD132 (*IL2RG*), which is a common gamma chain shared by the receptors of various cytokines. It plays a critical role in V(D)J recombination, and null mutations cause a severe combined immunodeficiency. *IL7R* is alternately spliced and this variant affects gene expression; the MS-associated rs6897932G (major) allele encodes the amino acid Thr rather than Ile at amino acid position 244, disrupting an exonic splicing silencer, resulting in a twofold increase in the skipping of exon 6,

and a relative increase in the proportions of soluble, as distinct from membrane-bound, isoforms of the protein (Gregory et al., 2007).

Polymorphisms within *IL7R* are also associated with ulcerative colitis (Anderson et al., 2011), primary biliary cirrhosis (Mells et al., 2011), and T1D (Onengut-Gumuscu et al., 2015).

### **IL2RA**

The most strongly MS-associated variant at 10p15, rs2104286 A > G, lies in the first intron of *IL2RA*, while that most associated with T1D (rs12251307 C > T) lies about 20 kb upstream. Maier et al. (2009a) performed a careful association analysis of *IL2RA* alleles in a DNA collection of 9407 healthy controls, 2420 MS, and 6425 T1D subjects as well as 1303 MS parent/child trios. They observed significant complexity at this locus: the rs41295061C allele was associated with T1D but not MS; the rs11594656T allele was associated with susceptibility to T1D but protection from MS, and the rs2104286T allele conferred susceptibility to both diseases.

The presence of MS risk alleles at rs2104286 A > G and rs12722489 C > T were associated with increased soluble (s) IL2RA, explaining 15%–18% of variance in sIL2RA levels, and sIL2RA levels were particularly increased in very severe MS (Maier et al., 2009b). In contrast the T1D-associated alleles correlated with decreased sIL2RA expression (Lowe et al., 2007). Although sIL2RA inhibits IL-2 mediated signaling, it promotes T-cell activation and proliferation, presumably by reducing activation-induced cell death.

This region is also associated with Crohn's disease (Franke et al., 2010), primary sclerosing cholangitis (Liu et al., 2013), juvenile idiopathic arthritis (Hinks et al., 2013), RA (Stahl et al., 2010), and inflammatory bowel disease (Jostins et al., 2012).

Although not significant, moderate associations were also reported for an additional 13 variants, including those located at 1p13 (*CD58*), 1p22 (*EVI5*), and 16p13 (*CLEC16A*). It was not until replication studies were performed in independent cohorts of MS cases and controls that these genes could be confirmed as MS risk-associated variants (Weber et al., 2008; Hoppenbrouwers et al., 2008; Rubio et al., 2008).

### **CD58**

The most significantly MS-associated variant at 1p13, rs2300747 A > G, lies within the first intron of *CD58*, which encodes the costimulatory molecule LFA-3. The MS-protective rs2300747G (minor) allele is associated with a dose-dependent increase in *CD58* mRNA in lymphoblastic cell lines and peripheral blood mononuclear cell (PBMC) from MS subjects (De Jager et al., 2009a). The hypothesis that increased LFA-3 expression on circulating mononuclear cells is protective is supported by the finding that *CD58* mRNA expression is increased in MS subjects during clinical remission. One proposed mechanism of action is via the engagement of CD2 by LFA-3 upregulating the expression of transcription factor FoxP3, leading to the enhanced function of CD4<sup>+</sup>CD25<sup>+</sup> Treg cells (De Jager et al., 2009b). This locus has not been significantly associated with other autoimmune diseases.
