In 2009 a consortium from Australia and New Zealand performed an MS case/control GWAS involving 1618 MS cases in the initial discovery phase, and an independent cohort of 2256 MS cases and 2310 healthy controls in the replication phase [Australia and New Zealand Multiple Sclerosis Genetics Consortium (ANZgene), 2009]. This study confirmed the *HLA* at a genome-wide level of significance and identified one novel locus, at 12q13-14 (*CYP27B1*). It also reported evidence of association at 20q13, as well as at the previously identified loci *CD58*, *IL2RA*, and *IL7R* [Australia and New Zealand Multiple Sclerosis Genetics Consortium (ANZgene), 2009].

### **CYP27B1**

The most strongly MS-associated variant at 12q13-14, rs703842 A > G, lies within the 3' untranslated region of *METTL1*, about a 2 kb upstream of *CYP27B1*, which encodes the enzyme 25-hydroxy-vitamin D-1 alpha hydroxylase, an enzyme involved in vitamin D metabolism (Bailey et al., 2007). The variant acts as an eQTL for both *METTL1* and *CYP27B1* (GTEx Portal on 23/01/18). Vitamin D deficiency is a major risk factor for MS, and vitamin D plays an important role in immune function, including the regulation of expression of the MS-associated *HLA-DR15* (Ramagopalan et al., 2009). Other genes in this region include *CDK4*, also previously shown to play a role in immune function and autoimmune disease, and *AGAP2*, which participates in the prevention of neuronal apoptosis by enhancing PI3 kinase activity. *CYP27B1* has not been significantly associated with other autoimmune diseases.

### **CD40**

The most strongly MS-associated variant at 20q13, rs6074022 C > T, lies about 10 kb 5' of *CD40*, which encodes Tumor Necrosis Factor Receptor Superfamily Member 5 (CD40), a costimulatory protein found on antigen

presenting cells (APC). Its ligation by CD154 (CD40L) on CD4 T cells is required for the activation of APC and the subsequent initiation of cellular and humoral immunity; its deficiency can cause hyper-IgM syndrome type 3. The variant rs1883232 A > G is located at -1bp from the start of translation within the Kozak consensus sequence of *CD40*, and the MS resistance allele, rs1883232G, is associated with increased expression as well as susceptibility to RA (Eyre et al., 2012), Graves' disease and Crohn's disease (Jostins et al., 2012), while the MS susceptibility allele, rs1883232A, leads to lower *CD40* expression (Blanco-Kelly et al., 2010).

In the same year, De Jager et al. (2009a) published a meta-analysis that combined 895 subjects with MS from the IMSGC's original association study (IMSGC et al., 2007), 969 subjects from the GeneMSA consortium (Baranzini et al., 2009) and an additional unpublished set of 860 subjects, totaling 2624 cases and 7220 controls. This study confirmed, at a genome-wide level of significance, the *HLA* and *CD58*. It also identified chromosomal regions at 12p13 (gene of interest *TNFRSF1A*), 16q24 (*IRF8*), and 11q12 (*CD6*) as significantly associated. An additional region at 16p13 (*CLEC16A*) had been commented on in several previous underpowered studies and was of particular interest, because it had recently been identified as associated with T1D (Todd et al., 2007; see above). De Jager et al. (2009a) listed the locus as replicated with a  $P = 1.77 \times 10^{-7}$ , as well as *IL2RA* and *IL7R* with similar significance values.

### **TNFRSF1A**

The most strongly MS-associated variant at 12p13, rs1800693 T > C, lies at the splice junction at the 3' end of the sixth exon of *TNFRSF1A*, which encodes TNF receptor superfamily member 1A (TNFRSF1A). The risk allele, rs1800693C, generates a soluble form of TNFR1 that can block TNF signaling (Gregory et al., 2012), mimicking the effect of TNF-blocking drugs, which exacerbate MS (The Lenercept Multiple Sclerosis Study Group and The University of British Columbia MS/MRI Analysis Group, 1999). This is a common variant with modest effect (OR 1.2; De Jager et al., 2009a). In contrast the T allele, at rs4149584 C > G/C > T, is a nonsynonymous coding polymorphism of low frequency but with stronger effect (OR 1.6).

The MS-associated rs1800693C allele also confers susceptibility to primary biliary cirrhosis (Mells et al., 2011; Liu et al., 2012), and another variant in *TNFRSF1A* is associated with ankylosing spondylitis (IGAS et al., 2013); the region showed mild linkage to SLE (Moser et al., 1998).

### **IRF8**

The most significantly MS-associated variant at 16q24, rs17445836 G > A, lies approximately 60 kb 3' of *IRF8*, which encodes the transcription factor Interferon Regulatory Factor 8 (IRF8). IRF8 controls the expression of a wide range of immunologically related genes, including *IL10*, *IL12A*, *IL1B*, and *TLR3* and *TLR4* (TRRUST2; Han et al., 2017). Administration of exogenous IFN $\gamma$  exacerbates MS; *IRF8* is upregulated by IFN $\gamma$  and cooperatively enhances the IFN $\gamma$ -induced apoptosis of oligodendroglial progenitor cells (Horiuchi et al., 2011). *IRF8* is a key target of vitamin D, through binding the nuclear vitamin D receptor (Ramagopalan et al., 2010).

Variants in this region are associated with Sjögren's syndrome (Lessard et al., 2013), RA (Eyre et al., 2012), inflammatory bowel disease (Jostins et al., 2012), and primary biliary cirrhosis (Liu et al., 2012).

### **CD6**

The most significantly MS-associated variant at 11q12, rs17824933 C > A/C > G, lies in the first intron of *CD6*. *CD6* is a type 1 transmembrane glycoprotein found on T lymphocytes in association with the signaling components of the TCR. It acts as a costimulator of T-cell proliferation via its ligand, Activated Leukocyte Cell Adhesion Molecule (ALCAM; Zimmerman et al., 2006). The MS susceptibility (minor) allele, rs17824933G, is associated with a decreased expression of full-length *CD6* in T cells and an increase in a splice variant lacking exon 5, resulting in diminished proliferation during long-term activation of CD4 $^{+}$  T cells (Kofler et al., 2011). Nevertheless, the role of *CD6* in MS is not clear, as it can attenuate T-cell activation, possibly via the regulation of *CD5* tyrosine phosphorylation (Oliveira et al., 2012), and appears to play a role in leukocyte trafficking across the blood–brain barrier and into the CNS via its interactions with ALCAM on the endothelium transmigratory cups (Cayrol et al., 2008).

Variants in this region are also associated with inflammatory bowel disease (Jostins et al., 2012).

In 2011 a very large collaborative GWAS for MS was published by IMSGC et al. (2011). This study involved 22 collections of patient samples and controls from national blood services and other sources; 9772 MS samples and 17,376 control samples from throughout Europe, America, and Oceania were genotyped. A total of 57 genetic loci associated with MS in addition to the *HLA* were identified at a genome-wide level of significance, of which 28 had not been previously reported. Previously identified genes included *MMEL1*, *EVI5*, *CD58*, *IRF8*, *RGS1*,

*C1orf106, CBLB, TMEM39A, IL12A, IL7R, PTGER4, OLIG3, IL7, IL2RA, ZMIZ1, CD6, TNFRSF1A, CYP27B1, MPHOSPH9, CLEC16A, IRF8, STAT3, TYK2, and CD40.*

The 28 novel independent regions identified at a genome-wide level of significance were 1p21 (gene of interest *VCAM1*), 2p21, 2p13 (*PLEK*), 2q13 (*MERTK*), 2q37 (*SP140*), 3p24 (*EOMES*), 3q13 (*CD86*), 5q33 (*IL12B*), 6q15 (*BACH2*), 6q22 (*THEMIS*), 6q23 (*MYB*), 6q23.3 (*IL22RA2*), 6q25 (*TAGAP*), 7q36 (*ZNF746*), 8q24 (*MYC*), 8q24.2 (*PVT1*), 10q23 (*HHEX*), 12p13 (*CLECL1*), 14q24 (*ZFP36L1*), 14q24.3 (*BATF*), 14q31 (*GALC*), 18q21 (*MALT1*), 19p13 (*TNFSF14*), 19p13.11 (*MPV17L2*), 19q13 (*DKKL1*), 20q13 (*CYP24A1*), 22q11 (*MAPK1*), and 22q13 (*SCO2*).

Once again, outside of the *HLA*, all associations showed only modest ORs, between 1.1 and 1.3. The many of associated variants were located either near or within immune-system related genes, and a large proportion of the regions implicated had previously been associated with other autoimmune diseases.

## CD86

The most significantly MS-associated variant at 3q13, rs9282641 G > A, lies within the 5' UTR of *CD86*, which encodes CD86 (B7-2), a membrane receptor expressed by APC, that is the ligand for the T-cell costimulator CD28 and the immune checkpoint molecule CTLA4. *CD86* is expressed on macrophages within the brain lesions of MS patients (Windhagen et al., 1995), and inhibition with a CTLA4-Fc fusion protein prevented the onset of experimental autoimmune encephalomyelitis (EAE; an animal model of CNS autoimmunity) in the great majority of mice treated (Cross et al., 1995).

No other autoimmune diseases have been associated with polymorphisms in this gene to date.

## EOMES

The most significantly associated variant at 3p24, rs11129295 C > T, is approximately 24 kb 5' of *EOMES*, which is a member of the TBR1 (T-box Brain Protein 1) subfamily of T-box genes that encodes a transcription factor positively regulating the expression of IFN- $\gamma$  (TRRUST2; Han et al., 2017). The lymphocytes from MS patients produce elevated levels of IFN- $\gamma$  ex vivo (Hirsch, Panitch and Johnson, 1985) and treatment of MS patients with IFN $\gamma$  exacerbates disease (Panitch et al., 1987). *EOMES*-expressing CD4 T cells are increased in numbers in the peripheral blood and cerebrospinal fluid of patients with SPMS and T-cell specific gene deletion of *Eomes* in mice attenuates the severity of EAE (Raveney et al., 2015).

Another variant, 4 kb 5' of *EOMES*, rs3806624 G > A, is associated with RA (Okada et al., 2014).

## IL12B

The most significantly MS-associated variant at 5q33, rs2546890 A > G, lies 2.4 kb 5' of *IL12B*, in the second exon of an uncharacterized open reading frame (*LOC285626*). *IL12B* encodes the 40 kDa subunit of IL-12 and IL-23, cytokines have been strongly implicated in the pathogenesis of both MS and EAE (Langrish et al., 2005). The gene encoding the 35-kDa subunit of IL-12 (*IL12A* on 3q25) has also been implicated in MS by GWAS (IMSGC, 2010). IL-12 is expressed by activated DC, macrophages, and monocytes, and sustains IFN $\gamma$  production, which is essential for the differentiation of cytotoxic CD8 T cells and generation and maintenance of memory/effector Th1 cells. In contrast, IL-23 supports the differentiation of CD4 Th17 cells that produce IL-17, IL-17F, IL-6, and TNF (Thakker et al., 2007). Nevertheless, treatment of MS with ustekinumab, a neutralizing anti-IL-12 p40 mAb, did not reduce the gadolinium-enhancing T1-weighted lesions by magnetic resonance imaging (MRI; Segal et al., 2008).

Other variants in the region are associated with Crohn's disease (Franke et al., 2010), ulcerative colitis (Anderson et al., 2011), and ankylosing spondylitis (IGAS et al., 2013).

## CD5

The most strongly MS-associated variant at 11q12, rs650258 T > C, lies within the uncharacterized open reading frame *LOC105369325*, approximately 100 kb upstream of *CD5*, which encodes the type-I transmembrane glycoprotein CD5. The expression of CD5 is normally restricted to T cells and a subset of B (termed B-1) cells, on which it acts to mitigate antigen receptor signaling. Consistent with its role in downmodulating T-cell responses, in mice, targeted the deletion of *Cd5*, or its blockade with CD5-Fc fusion protein, decreased the severity of EAE by inducing activation-induced cell death in T cells (Axtell et al., 2004, 2006). The expression of CD5 on the B lymphocytes of patients with MS correlated positively with severity of disease activity as measured by the number of gadolinium-enhancing MRI lesions and inversely with disease duration (Seidi, Semra and Sharief, 2002). Increased expression is associated with increased risk that a patient presenting with their first demyelinating event (clinically isolated syndrome) will progress to MS (Villar et al., 2011).

Other variants in this region have been associated with RA (Eyre et al., 2012) and inflammatory bowel disease (Jostins et al., 2012).

### **Signal Transducer and Activator of Transcription 3**

The most significant MS-associated variant at 17q21, rs9891119 A > C, lies within an intron of, and is an eQTL for, *STAT3* (GTEx Portal on 11/01/18), which encodes STAT3. STAT3 is activated by phosphorylation in response to receptor ligation by cytokines such as IL-5, IL-6, and the IFNs and then translocates to the nucleus where it induces the transcription of a wide range of targets, including BCL-2-family members, chemokines, growth factors, cytokines, and other transcription factors. Lee et al. (2017) examined the cytokine dependencies of the generation of pathogenic T cells that could successfully transfer EAE in mice. They found that the induction of pathogenic Th1/Th2 CD4 T cells required IL-23 signaling mediated by a STAT3/STAT4 heterodimer. Mice with a targeted deletion of *Stat3* in CD4 T cells were completely resistant to EAE (Liu et al., 2008). CD4 memory T cells from MS patients had significantly higher levels of p-STAT3 and p-STAT4, and p-STAT3/p-STAT4 heterodimers were observed upon IL-23 signaling (Lee et al., 2017). Phospho-STAT3 was increased in CD4 and CD8 T cells and monocytes of patients in relapse, its expression strongly correlated with severity of disease (Frisullo et al., 2006), and it predicted the conversion of clinically isolated syndrome to MS (Frisullo et al., 2008). 1,25-Dihydroxyvitamin-D3 inhibits the IL-12-induced tyrosine phosphorylation of STAT3 and STAT4, resulting in decreased T-cell proliferation and, in mice, the inhibition of EAE (Muthian et al., 2006).

Other variants at 17q21 are associated with Crohn's disease (Franke et al., 2010), psoriasis (Tsoi et al., 2012), and inflammatory bowel disease (Jostins et al., 2012).

In 2013 the IMSGC used the ImmunoChip (i.e., limited to genomic regions of "immunological interest"—primarily loci implicated in autoimmunity) to genotype 14,498 subjects with MS and 24,091 healthy controls for the discovery phase and applied previous GWAS data from independent cohorts of 14,802 subjects with MS and 26,703 healthy controls for replication (IMSGC et al., 2013). They identified 48 new MS-associated susceptibility variants at a genome-wide level of significance ( $P < 5 \times 10^{-8}$ ), mapping to a total of 103 discrete loci outside the MHC. These new regions included 1p36 (gene of interest *PLEKHG5*), 1p22 (*BCL10* and *DDAH1*), 1p12 (*PHGDH*), 1q23 (*FCRL1* and *SLAMF7*), 2p23 (*CENPO*), 2p16 (*FLJ16341*), 2q32 (*STAT4*), 3p24, 3p22 (*CCR4*), 3p13 (*FOXP1*), 4q24 (*TET2*), 5q31 (*TCF7*), 5q31 (*NDFIP1*), 5q35 (*RGS14*), 6p23, 6p21 (*PXT1*), 7p22 (*CARD11*), 7p15 (*JAZF1*), 7p14 (*ELMO1*), 7p12 (*IKZF1*), 8q24, 10p11, 10q22 (*C10orf55*), 11p11 (*AGBL2*), 11q13 (*PRDX5*), 11q23 (*CXCR5* and *TREH*), 12p13 (*LTRB*), 13q32 (*MIR548AN*), 14q32 (*TRAF3*), 15q25 (*CTSH*), 15q26 (*IQGAP1*), 16p13 (*RMI2* and *CLEC16A*), 16p11 (*MAPK3*), 16q22 (*CDH3*), 16q23 (*WWOX* and *MAF*), 17q12 (*IKZF3*), 17q21 (*NPEPPS*), 19p13 (*SLC44A2* and *EPS15L1*), and 20q13 (*SLC9A8* and *SLC2A4RG*).

### **Signal Transducer and Activator of Transcription 4**

The most significantly MS-associated variant in the 2q32 region, rs9967792 T > C, lies within the third intron of *STAT4*, which encodes STAT4. This STAT-family member is activated through phosphorylation in response to receptor ligation by IL-12 and activation of the receptor-associated kinases JAK2 and TYK2; it is then translocated to the cell nucleus where it acts as a transcription factor for several genes involved in Th1 responses, including *IFNG*, *IL2RA*, *TBX21*, *PRF1* (TRRUST2; Han et al., 2017). The phosphorylation and activation of STAT4 in response to IL-12 is inhibited by TGF-β, which prevents the phosphorylation of JAK2 and TYK2 (Bright and Sriram, 1998).

Other variants in the same region have been associated with SLE (Armstrong et al., 2014), Sjögren's syndrome (Lessard et al., 2013), RA (Eyre et al., 2012), systemic sclerosis (Mayes et al., 2014), juvenile idiopathic arthritis (Hinks et al., 2013), primary biliary cirrhosis (Liu et al., 2012), celiac disease (Trynka et al., 2011), and inflammatory bowel disease (Jostins et al., 2012).

### **C-C Motif Chemokine Receptor 4**

The most significantly associated variant at 3p22, rs4679081 T > C, is located within an intron of an uncharacterized open reading frame, LOC105377022, approximately 6 kb 3' of *CCR4*. *CCR4* encodes the G-protein-coupled receptor C-C Motif Chemokine Receptor 4 (CCR4), which is a receptor for MIP-1, RANTES, CCL17, CCL22, and MCP-1. In a comparison of T cells from CSF and peripheral blood at the onset of MS relapse, *CCR4* expression was lower on the T cells from CSF (Misu et al., 2001). In C57BL/6 mice, targeted gene deletion of *Ccr4*, or treatment with a CCR4 antagonist starting before the induction of disease, resulted in reduced severity of EAE (Moriguchi et al., 2013, 2016).

Another variant in the same region, rs13314993 A > C, is associated with celiac disease (Dubois et al., 2010).

## Genome-Wide Association Studies of Systemic Lupus Erythematosus

In February 2008, three GWAS of SLE were published. The first was performed under the auspices of the International Consortium for Systemic Lupus Erythematosus Genetics et al. (2008). It was a phased study with an initial genome-wide analysis of 720 female SLE patients of European ancestry and 2337 controls, with the most significantly associated variants typed in an additional 1846 patients. This study confirmed, at a genome-wide level of significance, both the *HLA* and *IRF5*. It also found significant association at four other regions: 16p11 (gene of interest *ITGAM*), 11p15.5 (*PHRF1/IRF7*), 3p14.3 (*PXK*), and 1q25.1.

### **Integrin Alpha M**

The most strongly SLE-associated variant in the 16p11 region, rs9888739 C > T, lies within the 14th intron of *ITGAM*, which encodes the Integrin Alpha M (ITGAM) chain. Together with the beta 2 chain (ITGB2), ITGAM forms the leukocyte-specific integrin CD11b (MAC1, or Inactivated Complement Receptor 3). CD11b is important in the phagocytosis of complement- and antibody-associated aggregates, as well as the adherence and emigration from the bloodstream of neutrophils and monocytes via interactions with a diverse range of ligands, including ICAM-1 and ICAM-2, C3bi, and fibrinogen. In a replication study, the association of SLE with *ITGAM* was confirmed, but a variant with stronger association was identified, rs1143679 G > A, which encodes an Arg to His amino acid substitution at position 77 in the beta-propeller domain of CD11b, with subsequent consequences for MAC1 ligand binding (Nath et al., 2008). In a genome-wide association study of patients bearing anti-dsDNA in SLE, *ITGAM* together with the *HLA*, *STAT4*, and *IRF5*, was found to be significantly associated (Chung et al., 2011).

Another variant in the region, rs57348955 G > A, is associated with autoimmune thyroid disease (Cooper et al., 2012).

### **Plant Homeodomain (PHD) and Ring Finger Domains 1/ Interferon Regulatory Factor 7**

The most strongly SLE-associated variant at 11p15, rs4963128 T > C, lies within the fourth intron of and is an eQTL for, *PHRF1* (GTEx Portal on 11/01/18), which encodes Plant Homeodomain (PHD) and Ring Finger Domains 1 (PHRF1), a ubiquitin ligase that targets TGFB Induced Factor (TGIF) for degradation, promoting TGF-β's cytostatic effect (Ettahar et al., 2013). The 3' end of *PHRF1* almost immediately abuts the 3' end of the IFN response gene *IRF7*, which is in the reverse orientation. In a subsequent study (Bentham et al., 2015), the most significantly SLE-associated variant at 11p15 was rs12802200 C > A, which lies 45.6 kb 5' of, and is an eQTL for *IRF7* (GTEx Portal on 01/19/18). This gene encodes interferon regulatory factor 7 (IRF7), a transcription factor in lymphoid tissues that activates the transcription of a wide range of type I and type III IFNs, as well as CCL5 and CXCL10 (TRRUST2; Han et al., 2017). IRF7 is downregulated by the SLE susceptibility gene *TNFAIP*. A third SLE-associated variant in the region, rs1131665 T > C, is a nonsynonymous variant that encodes a Gln to Arg substitution at position 412 in IRF7. Gln is encoded by the (major) risk allele, which results in a twofold increase in IFN-stimulated transcriptional activity (Fu et al., 2011).

Genetic variation at this locus is associated with IFNα activity in SLE and titers of anti-Sm autoantibody (Salloum et al., 2010). This region has not been associated with other autoimmune diseases.

The second SLE GWAS study published early that year, Kozyrev et al. (2008) genotyped 279 patients and 515 healthy controls from Sweden using the Affymetrix 100k SNP array. Their analysis focused on nonsynonymous substitutions and they quickly settled on those they identified within the *BANK1* gene on 4q24.

### **B-Cell Scaffold Protein with Ankyrin Repeats 1**

Kozyrev et al. (2008) identified three functional variants in *BANK1*: rs10516487 G > A/G > T, encoding an Arg to His substitution at position 61; rs3733197 G > A encoding an Ala to Thr substitution at position 383; and rs17266594 T > C, which is located in a splice junction that affected the relative expression of full length and exon 2-deficient isoforms. They genotyped these variants in four additional cohorts from Argentina (255 cases, 337 controls), Germany (312 cases, 360 controls), Italy (279 cases, 279 controls), and Spain (702 cases, 446 controls), and the fourfold tables from each study were aggregated using a Mantel–Haenszel test. The most strongly associated marker was rs17266594 T > C ( $P = 4.74 \times 10^{-11}$ ), although none of the variants acted independently of the others, due to strong linkage disequilibrium between them. *BANK1* encodes B-cell Scaffold Protein with Ankyrin Repeats 1 (BANK1), which contributes to B-cell receptor-mediated signaling by affecting calcium mobilization and Lyn-mediated tyrosine phosphorylation of inositol 1,4,5-trisphosphate receptors. Variants within the gene have not been associated with other autoimmune diseases.

In the third SLE GWAS study published in early 2008, Hom et al. (2008) performed a GWAS on DNA samples from 1311 patients with SLE and 1783 controls, all North Americans of European descent. Strong confirmation at a genome-wide level of significance was found for *HLA*, *IRF5*, *ITGAM*, and *STAT4*, although there was a partial overlap of subjects included in the original report of *STAT4* association (Remmers et al., 2007). In addition, another region of genome-wide significance was identified, at 8p23 (*BLK*).

### **B-Lymphoid Tyrosine Kinase**

The most strongly SLE-associated variant at 8p23, rs13277113 G > A, is located in the promoter region of *BLK*, about 3 kb upstream of the transcription initiation site. This gene encodes B-Lymphoid Tyrosine Kinase (BLK), a Src tyrosine-kinase that has a role in B-cell receptor signaling and B-cell development, although *Blk*-deficient mice have no obvious phenotype (Texido et al., 2000). The rs13277113A SLE risk allele is associated with reduced *BLK* mRNA in transformed B-cell lines (Hom et al., 2008), but in primary human B lymphocytes, its *cis*-regulatory effects are restricted to naïve and transitional B cells; allelic variation has been shown to affect protein levels (Simpfendorfer et al., 2012). Another variant in this region, rs2736337 T > C, is associated with RA (Okada et al., 2014).

Graham et al. (2008) performed a GWAS on 431 SLE patients of European descent from the University of Minnesota SLE cohort and 2155 controls from publicly available datasets from the National Institute of Mental Health and the Wellcome Trust. Genotyping was performed using the Affymetrix Genome-Wide Human SNP Array 5.0. Three genomic regions met the threshold for genome-wide significance: *HLA*, *IRF5*, and 6q23 (*TNFAIP3*). Replication was performed in 740 independent trios, confirming association at 6q23. The weighted z scores from the two studies were summed and converted to *P* values to obtain a meta-analysis.

### **TNF Alpha-Induced Protein 3**

The most significant variant at 6q23 in the meta-analysis, rs5029939 C > G, is located in an intron of *TNFAIP3*, which encodes TNF Alpha-Induced Protein 3 (TNFAIP3), a zinc finger protein with ubiquitin-editing activity that functions as a negative regulator of NF-κB signaling by ubiquitin modification of the adaptor proteins RIP and TRAF6, in the TNF and TLR/IL1R signaling pathways respectively. In doing so it inhibits TNF-mediated apoptosis. The expression of TNFAIP3 is decreased in patients with SLE and is negatively correlated with the severity of disease (Qian et al., 2017). The B cells of mice bearing a targeted null mutation in *Tnfaip3* are resistant to Fas-mediated cell death and are increased in germinal centers. As a result, the mice develop autoantibodies and glomerular immunoglobulin deposits (Tavares et al., 2010). Mice bearing the same mutation targeted to their DC develop splenomegaly, anti-dsDNA antibodies and nephritis. Their DC captured apoptotic cells more efficiently, resisted the inhibitory effects of apoptotic cells, and induced self-reactive effector lymphocytes, resulting in the accumulation of plasma cells and conversion of CD4 T cells to IFN-γ-producing effector cells (Kool et al., 2011).

Other variants in this region are also associated with RA (Raychaudhuri et al., 2008), celiac disease (Dubois et al., 2010), MS (IMSGC et al., 2013), psoriasis (Tsoi et al., 2012), and inflammatory bowel disease (Jostins et al., 2012).

The Hom et al. (2008) study was followed up with a large-scale replication study of an independent sample of 1963 cases and 4329 healthy controls from the United States and Sweden, using a custom Illumina Infinium II SNP array targeted at genomic regions that had shown nominal (or better) evidence of association in the original GWAS. The three datasets were combined by converting *P* values to *z* scores, which were weighted by each sample size, combined and converted back to a *P* value for each locus (Gateva et al., 2009). They confirmed at a genome-wide level of significance *HLA*, *STAT4*, *IRF5*, *ITGAM*, *BLK*, and *PHRF1* and identified six new loci: 1p13 (gene of interest *PTPN22*), 5q33 (*TNIP1*), 6q21 (*PRDM1*), 7p15 (*JAZF1*), 6p21 (*UHRF1BP1*), and 1q32 (*IL10*).

### **TNF Alpha-Induced Protein 3 Interacting Protein 1**

The most strongly SLE-associated variant at 5q33, rs7708392G > C, lies within an intron of *TNIP1*, which encodes TNFAIP3 Interacting Protein 1 (TNIP1). TNIP1 inhibits NF-κB activation by facilitating TNFAIP3-mediated deubiquitylation of NF-kappa-B Essential Modulator (NEMO), an inhibitor of IKK-γ. TNIP1 is decreased in expression in PBMC of patients with SLE, and it negatively correlates with the severity of disease (Qian et al., 2017).

Another variant at 5q33, rs2233278 G > C, is associated with psoriasis (Tsoi et al., 2012).

### **PRDM1**

The most strongly SLE-associated variant at 6q21, rs6568431 A > C, lies 31 kb 3' of *PRDM1*, which encodes B-Lymphocyte-Induced Maturation Protein 1 (BLIMP1), a transcriptional repressor of *CITA*, *GCSAM*, *LMO2*,

*MK167*, *MYC*, and *PCNA* (TRRUST2; Han et al., 2017). It inhibits proliferation by regulating p53 and plays a critical role in the differentiation of many lymphocyte subsets, including plasma cells, Th2 CD4 T cells, and effector (IL-10-secreting) Treg cells, as well as inhibition of differentiation of Th1, Th17, and Tfh cells (Fu et al., 2017). *PRDM1* mRNA expression in SLE patients is more than two times greater than that in healthy controls, as it is in MRL/lpr SLE-prone mice (Luo et al., 2013). *Prdm1* expression in mice is increased by the expression of the SLE-associated gene *Irf5* and decreased by *Irf5* targeted deletion (Panchanathan et al., 2012). Suppression of *Prdm1* expression by siRNA in MRL-Fas(lpr) lupus-prone mice reduced anti-dsDNA antibody levels, improved histological signs of glomerulonephritis, and decreased proteinuria (Luo et al., 2015).

Other variants in this region are associated with Crohn's disease (Franke et al., 2010) and ulcerative colitis (Anderson et al., 2011).

## IL10

The most strongly SLE-associated variant at 1q32, rs3024505 G > A, lies about 1 kb 3' of *IL10*, which encodes IL-10, an immunoregulatory cytokine produced by leukocytes, especially monocytes. IL-10 suppresses cell-mediated immunity while supporting B-cell survival, proliferation, and antibody production. The spontaneous in vitro production of IL-10 by monocytes and B cells of patients with SLE is over 30-fold higher than in healthy controls (Llorente et al., 1993) and can correlate with the disease severity as measured by SLE disease activity index, ds-DNA titers, and C3 levels (Houssiau et al., 1995). In vitro the addition of IL-10 PBMC from SLE patients resulted in the production of IgM, IgG, and IgA, which was inhibited by the addition of anti-IL-10 mAb (Llorente et al., 1995).

The SLE-associated rs3024505 C > T variant is also associated with T1D (Gateva et al., 2009), inflammatory bowel disease (Jostins et al., 2012), ulcerative colitis (Anderson et al., 2011), and Crohn's disease (Franke et al., 2010). While the rs3024505T allele is associated with SLE, ulcerative colitis and Crohn's disease, T1D is associated with the C allele.

Cunningham Graham et al. (2011) performed a replication study of loci that had, in Gateva et al. (2009), previously shown moderate evidence of association with SLE ( $P < 5 \times 10^{-3}$ ) without reaching genome-wide significance ( $P < 5 \times 10^{-8}$ ). They genotyped 23 independent variants in 905 British patients with SLE and 5551 controls that included British 1958 Birth Cohort samples and data from the WTCCC2 project. Eight of the variants tested had not been previously genotyped in the WTCCC2 samples, so they were imputed from the existing data. Of these 23 markers, 12 showed evidence of association ( $P < .05$ ). A meta-analysis was then performed incorporating data from Gateva et al. (2009) using Fisher's combined probability test. Five novel loci were identified that showed significant association at a genome-wide level: 1q25 (gene of interest *NCF2*), 2q24 (*IFIH1*), 7p12 (*IKZF1*), 16q24 (*IRF8*), and 19p13 (*TYK2*).

## NCF2

The most strongly SLE-associated variant at 1q25, rs10911363 G > T, lies within an intron of, and is an eQTL for, *NCF2* (GTEx Portal on 07/01/18), which encodes Neutrophil Cytosolic Factor 2 (NCG2), the 67 kDa cytosolic subunit of neutrophil Nicotinamide Adenine Dinucleotide Phosphate (NADPH) oxidase complex responsible for the superoxide burst of phagosomes in monocytes, macrophages, and neutrophils. Fine mapping attributed this association to linkage disequilibrium with a nonsynonymous coding variant in exon 12, rs17849502 G > A/G > C/G > T, which results in a substitution of a His to a Gln at position 389 in the PB1 domain of the NCF2 protein. This substitution reduces the binding efficiency of NCF2 to the ZF domain of the guanine nucleotide exchange factor VAV1. As this interaction plays a critical role in a positive feedback cycle for the Rac GTPase (another component of the NADPH oxidase complex), the substitution results in a twofold decrease in reactive oxygen species production induced following the activation of the Vav-dependent Fc $\gamma$  receptor-elicited NADPH oxidase (Jacob et al., 2012). The NZM 2328 mouse strain spontaneously develops anti-dsDNA IgG autoantibodies by 5 months of age and glomerulonephritis associated with IgG and C3 deposits and proteinuria by 12 months. The presence of one or two deletional mutant alleles of *Ncf2* in NZM 2328 mice significantly accelerated the onset of glomerulonephritis and proteinuria by several months (Jacob et al., 2017).

The rs17849502 G > A/G > C/G > T variant is also associated with risk of childhood-onset SLE (Jacob et al., 2012).

## IRF8

The SLE-associated variant at 16q24, rs2280381 C > T, lies approximately 62 kb 3' of *IRF8* (GTEx Portal on 09/01/18) and encodes the transcription factor IRF8, which controls the expression of a wide range of

immunologically related genes, including the SLE susceptibility gene *NCF2* (TRRUST2; Han et al., 2017). IRF8-deficient NZB. *Ifi8*<sup>-/-</sup> mice produced no Coomb's antibody or antichromatin IgG, reduced glomerular immunoglobulin and complement deposition, and had milder glomerulonephritis than wild-type mice (Baccala et al., 2013).

Variants in the same region are associated with MS (IMSGC et al., 2013), Sjögren's syndrome (Lessard et al., 2013), RA (Eyre et al., 2012), inflammatory bowel disease (Jostins et al., 2012), and primary biliary cirrhosis (Liu et al., 2012).

### UBE2L3

Wang et al. (2012) performed a targeted association study of the 22q1 region, which had been identified repeatedly in SLE linkage and association studies without reaching a genome-wide level of significance. They genotyped 57 variants in the region and a panel of ancestral markers in 8922 independent SLE cases and 8077 independent controls across five ethnic populations. The most strongly SLE-associated variant, rs7444 T > C (combined  $P = 2.21 \times 10^{-14}$ ), lies within the 3' untranslated region (UTR) and is an eQTL for (GTEx Portal on 21/01/18), *UBE2L3*, which encodes Ubiquitin Conjugating Enzyme E2 L3 (*UBE2L3*). *UBE2L3* contributes to the ubiquitination and degradation of p53, c-FOS, and the NF- $\kappa$ B precursor p105. Homozygosity for the risk-associated, (minor) allele, rs7444C (OR 1.23), is associated with twofold increased expression of transcripts and protein in EBV-transformed B-cell lines. Another SLE-associated marker in the region, rs140490 G > A/G > T, lies within an intron of, and is also an eQTL for (GTEx Portal on 21/01/18), *UBE2L3*. The risk-associated rs140490T allele was associated with increased NF- $\kappa$ B translocation in primary human cells from healthy individuals and correlated with basal NF- $\kappa$ B activation in unstimulated B cells and monocytes (Lewis et al., 2015).

Variants in the 22q1 region are associated with psoriasis (Tsoi et al., 2012), RA (Okada et al., 2014), juvenile idiopathic arthritis (Hinks et al., 2013), and celiac disease (Trynka et al., 2011).

The largest GWAS of SLE in subjects of European ancestry published to date studied 7219 cases and 15,991 healthy controls (Bentham et al., 2015). It applied a staged strategy, involving (1) a large GWAS (4036 cases and 6959 controls); (2) a meta-analysis combining the discovery study with the data from the Hom et al. (2008) study (1165 cases, 2107 controls); (3) a replication study (2018 cases, 6925 controls) and postreplication meta-analysis. The initial GWAS identified 25 regions associated with SLE at a genome-wide level. Twenty-one had been previously published: *PTPN22*, *FCGR2A*, *TNFSF4*, *NCF2*, *IFIH1*, *STAT4*, *BANK1*, *TNIP1*, MHC class III, *PRDM1*, *TNFAIP3*, *IRF5*, *BLK*, *WDFY4*, *IRF7*, *CD44*, *ITGAM*, *IRF8*, *TYK2*, *UBE2L3*, and *IRAK1*. Two had been identified previously but not at a genome-wide level of significance: 5q33 (*MIR146A*) and 15q24 (*CSK*), and three were novel: 2p14 (*SPRED2*), 2q34 (*IKZF2*), and 5q31 (*TCF7*).

The replication study and postreplication meta-analysis confirmed nine additional loci that had previously been associated at a whole genome level of significance: *IL10*, *IFIH1*, *PXK*, *UHRF1BP1*, *JAZF1*, *ARID5B*, *ETS1*, *SLC154A*, *IKZF3*, and confirmed *LYST*, which had been previously identified, but not at a whole genome level of significance. Seven newly identified loci were 3q25 (*IL12A*), 11q13 (*DHCR7*), 12q24 (*SH2B3*), 14q24 (*RAD51B*), 16p13 (*SOCS1*), 17p13 (*PLD2*), and Xp21 (*CXorf21*).

### IL12A

The most significant SLE-associated variant at 3q25, rs564799 C > T, lies 15 kb 3' of, and is an eQTL for (GTEx Portal on 01/21/18), *IL12A*, which encodes IL 12A, the p35 (35 kDa) subunit of the proinflammatory heterodimeric cytokine IL-12. The binding partner, p40, is encoded by *IL12B* and is also a component of IL-23. IL-12 is produced by professional APC and acts on T cells and NK cells via STAT4 translocation; it is essential for the secretion of IFN- $\gamma$ , which is required for the differentiation of CD8 T cells into effector cytotoxic cells. *IL12A* transcripts are reduced in the PBMC of untreated patients with SLE and fall further on treatment with corticosteroids; in contrast, *IL12B* transcripts are normal before treatment but drop significantly on treatment. Both transcripts are expressed at higher levels in patients with more severe disease (Huang et al., 2007).

Variants in 3q25 are also associated with celiac disease (Dubois et al., 2010), Sjögren's syndrome (Lessard et al., 2013), systemic sclerosis (Mayes et al., 2014), primary biliary cirrhosis (Liu et al., 2012), and MS (IMSGC et al., 2013).

## CONCLUDING COMMENTS

Over the last two decades, GWASs have been extraordinarily successful in identifying candidate autoimmune disease susceptibility genes. For most autoimmune diseases, 50–100 loci have been identified. Testing these

candidates requires a combination of in vitro and in vivo models. As a generalization, the existing models, supplemented by the molecular manipulation of gene expression, serve this purpose well, so long as the limitations of each model are taken into consideration.

Even at this relatively early stage of functional validation, clear patterns of gene activity associated with each disease are emerging. For example, in the case of MS, which has a relatively low heritability by virtue of the major effects of its environmental risk factors (EBV, sun exposure, and smoking), several candidate genes have been implicated in responding to these factors. For example, the high levels of expression of DQB1 and DRB1 associated with the HLA-DR15 haplotype facilitates EBV attachment and cellular entry. This, rather than antigenic restriction, may be enough to explain the observed HLA association with the disease. This hypothesis is consistent with the clinical observation that MS is not characterized by a single, or even a primary, autoantigen. Both T- and B-cell responses are oligoclonal and vary in specificity between patients. Genetic associations with sun exposure are also observed in MS. The regulatory regions of risk genes *HLA-DRB1* and *IRF8* contain VDREs, CYP27B1 is involved in Vitamin D metabolism, and the phosphorylation of STAT3 and STAT4 in response to IL-12 receptor binding is inhibited by Vitamin D.

In contrast to MS, in T1D the primary autoantigen has been identified: proinsulin within the beta cells of the islets of Langerhans in the pancreas. Insulin is probably targeted because the promoter of its gene contains a VNTR that results in reduced thymic expression and increased pancreatic expression of insulin in people carrying the T1D-associated VNTR allele. This probably results in a mismatch in central and peripheral signaling intensities and consequently impaired central tolerance. The association with HLA-DR3 and HLA-DR4, and particularly CD3/4 heterozygotes, may therefore reflect the antigen restriction structures with highest affinity to insulin peptides. Other T1D candidate genes relate specifically to allelic vulnerabilities within beta cells. For example, variants in *CLEC16A* affect the regulation of mitophagy (selective degradation of mitochondria by autophagy), causing, in those bearing risk alleles, a reduction in cellular ATP, which is required for insulin secretion. Similar defects are seen in other classes of diabetes. Similarly, variants in *PTPN2* may be associated with differences in beta-cell sensitivity to cytokine-induced programmed cell death and impaired glucose tolerance under a high-fat diet. One of the effects of variation at *BACH2* is to modulate the expression of *PTPN2*, potentially explaining its association with T1D.

Other patterns of candidate gene function suggest, not so much "pathways" but, networked interactions associated with emerging complex phenomena. The fundamental cell biological activities of programmed cell death and receptor-mediated activation are affected by candidate genes in most autoimmune diseases: *BACH2*, a derepressor of the antiapoptotic factors *BCL2* and *BCL-XL*, maintains the longevity of Tregs; variants in *BACH2* are associated with T1D, MS, and many other autoimmune diseases. In SLE the expression of *TNFAIP3* is decreased; it functions as a negative regulator of NF- $\kappa$ B signaling, and its deficiency results in NF- $\kappa$ B driven proliferation instead of death-receptor-mediated programmed cell death. Again, variants associated with *TNFAIP3* are associated with many autoimmune diseases: RA, celiac disease, inflammatory bowel disease, psoriasis, and MS. Another SLE candidate gene, *TNIP1*, encodes a protein that interacts with *TNFAIP3*. *TNIP1* is decreased in expression in PBMC of patients with SLE, and its expression negatively correlates with the severity of disease.

Many candidate autoimmune disease susceptibility genes are implicated in the regulation or stimulation of leukocyte activation and proliferation. Confusingly, the direction of activity is inconsistent between genes. For example, while T1D-associated alleles at variants near *SH2B3* are associated with its reduced expression and increased T-cell proliferation, the T1D-associated alleles at variants in *PTPN22* are associated with the gain of function and decreased T-cell proliferation. One possible explanation for paradoxes of this sort is the existence of two activation thresholds for CD4 T cells: One for initiating effector function and the other for Treg differentiation. Candidate genes related to leukocyte activation in MS include *IL2RA*, *CD5*, *CD6*, *CD40*, *STAT3*, and *STAT4*, and most of these have been implicated in multiple other autoimmune diseases.

A third class of candidate autoimmune susceptibility genes encompasses the genes associated with specific immune mechanisms. Perhaps the best recognized in this category are those involved in the phagocytosis and lysis of immune complexes in SLE. For example, *ITGAM*, *FCGR2A*, *FCGR3A*, *FCGR3B*, *C1Q*, *C2*, and *C4B* are all involved in immune complex clearance, while *NCF2* contributes to the oxidative burst in phagosomes. These genes are relatively restricted in their disease associations to SLE and SLE-like disease, such as childhood-onset lupus. In contrast, *IL2RA* and *BACH2*, which contribute to the differentiation and maintenance of Treg, are tagged by variants that are associated with T1D, celiac disease, autoimmune thyroid disease, MS, RA, juvenile idiopathic arthritis, alopecia areata, primary sclerosing cholangitis, inflammatory bowel disease, and Crohn's disease. Another example of a specific immune mechanism associated with autoimmune disease commonly targeted by candidate susceptibility genes is that of immune deviation. *IL-12B* is a component of IL-23 and IL-12, both of

which signal via STAT3 and STAT4, and all of which are required for the differentiation of destructive Th1 and Th17 immune responses. As a generalization, increased STAT3/4 phosphorylation mediates more severe autoimmune disease. Variants in these genes are associated with SLE, Sjögren's syndrome, RA, systemic sclerosis, juvenile idiopathic arthritis, primary biliary cirrhosis, celiac disease, Crohn's disease, ulcerative colitis, and psoriasis.

These collections of interacting genes, which are both shared between diseases and create disease-specific patterns, elaborate and enhance our previous understanding of disease mechanisms. As we complete the identification of causative mutations and the identification of tissue-specific eQTL, this mapping from location to function and drugable target will only improve.

## Acknowledgments

This work was supported by MS Research Australia, Lions Clubs of Australia, National Health and Medical Research Council of Australia. AGB is grateful for the kind hospitality of the staff and students at the Peter Doherty Institute for Infection and Immunity for hosting him on sabbatical while he worked on this manuscript.

Androgens	422	References	425

## INTRODUCTION

Sexual dimorphism is the term that refers to differences between males and females of the same species and is most obvious as differences in external appearances. However, there can also be sexual dimorphism of internal organs and biological functions, including the immune system. Sexual dimorphism in the immune system is important in medicine because it can lead to sex differences in the responses to infection and vaccination and sex differences in the development of autoimmune disease (McCombe et al., 2009). This chapter focuses on the effects of sexual dimorphism on immunocompetence, and on some of the possible mechanisms underlying these effects, including the effects of the sex hormones, sex chromosomes, and sexually dimorphic cultural and environmental effects on immunity. The possible consequences for autoimmunity of sexual dimorphism in the immune system are also considered.

## OVERVIEW OF SEXUAL DIMORPHISM

The sex chromosomes evolved many millions of years ago (Livernois et al., 2012). In humans, most males have X and Y chromosomes and most females have two X chromosomes, although other combinations of sex chromosomes are found, with such as one X chromosome (Turner's syndrome) or XXY (Klinefelter's syndrome). Sexual dimorphism was noted by Darwin (1871) who thought it was due to sexual selection, as, for example, larger stronger males might have a reproductive advantage. Other possibilities for the evolution of sexual dimorphism include intersexual competition for food (Hedrick and Temeles, 1989) and other ecological factors (Kruger et al., 2014). More recently, it has been suggested that males and females have evolved to be dimorphic

in the “Pace of Life” because of differing requirements (Immonen et al., 2018). Overall, in humans, males are larger than females, with greater strength, but shorter life expectancy. In medicine, there are sex differences in the prevalence of many diseases, and there can be sex differences in response to medications.

Sexual dimorphism is related to the sex chromosome complement of an individual (Wijchers and Festenstein, 2011). Many genes show sex-specific differences in expression (Mank, 2009; Ellegren and Parsch, 2007; Mank, 2017). There are also reports of sex differences in DNA methylation (Ho et al., 2018). We will now discuss the sex differences in the immune system.

## SEXUAL DIMORPHISM IN THE IMMUNE SYSTEM

Immunocompetence is a word used to describe the overall level of function of the immune system and is a complex genetic trait (Flori et al., 2011). It has been recognized that females have increased immunoreactivity (immunocompetence) compared to males and suggested that this leads to increased autoimmune disease in females (Zandman-Goddard et al., 2007). In the past, it has been suggested that the expression of male sexual traits is inversely related to immunocompetence (the immunocompetence handicap hypothesis) (Folstad and Karter, 1992). However, further studies have not confirmed this (Roberts et al., 2004) and others have suggested that the differences in overall immunocompetence between males and females are related to the pressures of selection on the basis of fitness. It is thought that fitness in females is maximized by lengthening the lifespan through greater investment in immune defenses whereas in males require fitness early in life to maximize sexual mating and so do not need to invest in immune defenses to prolong the lifespan (Nunn et al., 2009). There are also differences between males and females in immunosenescence, which is the decline in immune function in later life, with greater decline in males (Yan et al., 2010; Das et al., 2008).

Overall immunocompetence is the sum of the elements of the immune system. There is sexual dimorphism of many of the individual components of the immune system. In terms of cell counts, there are numerical differences between the males and females. In males the total lymphocyte count is similar to that in females (Bouman et al., 2004; Giltay et al., 2000), but the percentage of T cells within the lymphocyte population is lower (Bouman et al., 2004). The ratio of CD4<sup>+</sup>:CD8<sup>+</sup> cells is greater in females than in males (Wikby et al., 2008; Das et al., 2008). There are estrogen receptors (ERs) on regulatory T cells (Tregs); this could be important in autoimmunity (Aristimuno et al., 2012).

There are no reports of differences in B-cell counts between females and males; however, there are long-recognized differences in levels of IgM but not in other immunoglobulin isotypes, with females showing increased levels for all ages  $>6$  years (Butterworth et al., 1967; Lichtman et al., 1967). The reproductive phase of females also influences the immune system, as postmenopausal women, compared to fertile women, have fewer total lymphocytes [as a consequence of decreased numbers of B and T helper cells (Th cells)] (Giglio et al., 1994; Yang et al., 2000).

In laboratory animals, there are also sex differences in the structure of primary immune organs: in male rats the thymus is heavier, has a greater yield of cells, and contains a higher percentage of double negative CD4<sup>-</sup>CD8<sup>-</sup> cells (Leposavic et al., 1996) and catecholamine-containing cells (Pilipovic et al., 2008) than thymi of female rats. However, in humans, in autopsy studies, no difference was found between the weight of adult thymi from females or males, after correction for body weight (Narongchai and Narongchai, 2008). Possibly the differences are more clear-cut in inbred laboratory animals.

There are differences in the function of the immune system of males and females. Generally, females produce more vigorous humoral and cellular immune responses than males (Ansar et al., 1985; Weinstein et al., 1984), shown in mice in a variety of test systems such as an augmented responses to a variety of antigens (Terres et al., 1968), the ability to reject allografts more rapidly than males (Kongshavn and Bliss, 1970), and in mice and humans by better in vitro responses to mitogens (Santoli et al., 1976; Weinstein et al., 1984) and relative resistance to the induction of immune tolerance (Bebo et al., 1999). Following trauma-hemorrhage, immune functions are severely depressed in young male mice, ovariectomized and aged females but are maintained in proestrus females (Choudhry et al., 2007; Kahlke et al., 2000). The survival rate in proestrus females following trauma-hemorrhage and the induction of subsequent sepsis are significantly higher than in age-matched males and ovariectomized females.

Furthermore, females are more successful than males in resisting a variety of bacterial, viral, and parasitic infestations and this enhanced immune capability might explain, in part at least, why the life expectancy of females exceeds that of males. For example, female mice have a greater ability than male to combat various

infections, including Leishmaniasis and amebic infection with liver abscess (Lotter et al., 2006), which is thought to be due to the sex difference in Th1 and Th2 responses (Mock and Nacy, 1988). Moreover, in Wistar rats infected with *Trypanosoma cruzi*, there is less parasitemia in females than males (dos Santos et al., 2005). Of relevance to autoimmunity, there are gender differences in resistance to inflammation of the heart after Coxsackie virus infection, which are inferior in males and related to poorer Treg responses in males than females (Frisancho-Kiss et al., 2007). In immunized mice, females show greater production of the Th1 cytokine interferon (IFN)- $\gamma$  than males (Huygen and Palfiet, 1984). These differences in Th1 and Th2 response are mediated in part through IL-13 (Sinha et al., 2008).

In humans, the antibody response to a variety of vaccines and test antigens, including flagellin protein (Rowley and Mackay, 1969), influenza, hepatitis B, rubella, tetanus (Cook, 2008), and a variety of other viral vaccines (Klein et al., 2010), is more vigorous in females than in males. In women, the innate immune response is also stronger.

Another, less quantifiable, functional difference between females and males is seen in the immune response to injury, according to reports on greater degrees of immunosuppression in men than in women after physical trauma (Choudhry et al., 2005) and after abdominal surgery (Wichmann et al., 2003) as measured by B-lymphocyte, T-lymphocyte, Th cell counts, and natural killer (NK) cell counts and circulating levels of IL-6.

There are many examples of sex differences in biochemical pathways involved in immunity. Sexual dimorphism is also expressed at a cellular level, since stimulation of invariant natural killer T cells with  $\alpha$ -galactosylceramide leads to higher concentrations of IFN- $\gamma$  in the serum of female mice (Gourdy et al., 2005) and the concentration of serotonin and histamine in white blood cells and mast cells is greater in females than in male rats (Csaba et al., 2003).

## EFFECTS OF HORMONES ON THE IMMUNE SYSTEM

Sexual dimorphism in the immune system could be due to the effects of sex and reproductive hormones. These hormones have cognate receptors that are widely expressed on many cell types, including cells of the immune system. There is evidence that sexual dimorphism in immune functions in C57Bl/6 mice is dependent on puberty, which suggests that the effects of the sex hormones are important (Lamason et al., 2006). There are numerous effects of the sex hormones in human immunity (Bouman et al., 2005). The effects of the various sex hormones on immune function are summarized below.

### Estrogens

There are three estrogenic hormones, estrogen (E1), estradiol (E2), and estriol (E3), with E3 being produced only in pregnancy. As well as being present in high levels in females, estrogens are also present in males, in whom they have widespread effects (Sharpe, 1998). Estrogens act on intracellular ERs. The best known ERs (ER $\alpha$  and ER $\beta$ ) belong to the class known as ligand-regulated nuclear transcription factors (Matthews and Gustafsson, 2003). There is also a membrane-bound G-protein-coupled ER (Prossnitz et al., 2007), that is prominent on vascular tissue and has rapid "nongenomic" effects (Simoncini et al., 2004). ERs are widespread and have important effects on the growth of cells. ER $\alpha$  and ER $\beta$  are expressed on antigen-presenting cells (Nalbandian and Kovats, 2005), and at higher levels in CD4 $^+$  T cells and B cells than in CD8 $^+$  T cells; however, whereas B cells express higher levels of ER $\beta$  than ER $\alpha$ , CD4 $^+$  T cells show higher levels of ER $\alpha$  than ER $\beta$  (Pernis, 2007).

The results of many experiments indicate that estrogen can affect immune function: for example, T lymphocytes from patients with systemic lupus erythematosus (SLE), but not from healthy controls, can be activated via ER $\alpha$  and ER $\beta$  to increase expression of the T-cell activation markers CD154 and calcineurin (Rider et al., 2006). Furthermore, different types of estrogens can have differential effects (Ding and Zhu, 2008). Estrogen induces thymic atrophy by preventing the proliferation of early thymic progenitor cells (Zoller and Kersh, 2006), and this is due in part to the effects of estrogen on the membrane-bound ER (Wang et al., 2008). Estrogen has effects on dendritic cells (DCs) (Ding and Zhu, 2008), modulates the effects of lipopolysaccharide on monocytes (Pioli et al., 2007), and inhibits monocyte adhesion to endothelium (Nilsson, 2007). Such results, however, may not relate to the role of estrogens at physiological levels. Much of what has been observed *in vitro* is likely to be what occurs in high estrogen states, such as pregnancy, rather than in nonpregnant women.

Estrogen has numerous effects on the function of CD4<sup>+</sup> T cells (Pernis, 2007). Low doses of estrogen, as would occur in nonpregnant women, enhance Th1 responses whereas high levels, as would occur in pregnancy, enhance Th2 responses. Estrogen also influences chemokine production by activated splenocytes (Lengi et al., 2007) and influences T-cell trafficking. E2 can convert CD25<sup>-</sup> cells to CD25<sup>+</sup> Tregs (Tai et al., 2008). Thus enhancement of Th2 responses and induction of Treg cells by high doses of estrogens could ameliorate Th1-mediated autoimmune diseases. Estrogen enhances antibody production in response to antigen immunization (Da Silva, 1999a). This effect differs between E3 and E2 (Ding and Zhu, 2008), with E3 strongly stimulating antibody response to bacteria (Da Silva, 1999b).

There is some evidence that estrogens are more directly involved in autoimmunity. Thus in patients with myasthenia gravis, there is an alteration of expression of ER in the thymus (Nancy and Berrih-Aknin, 2005), a site wherein the disease may be generated (Hill et al., 2008). In SLE, estrogen promotes the survival of B cells with affinity for DNA (as does prolactin) (Grimaldi, 2006). Genetic studies among Japanese show that there are associations of polymorphisms in the ER in rheumatoid arthritis (Takagi et al., 2000), although not in autoimmune diabetes (Ban et al., 2000). In females with multiple sclerosis (MS) who carry HLA-DR2, carriage of an ER $\alpha$ 4 polymorphism conveys an additional risk of developing disease (Mattila et al., 2001).

## Progesterone

Progesterone is a steroid hormone that is present in the blood during the menstrual cycle and in high levels in pregnancy. Adult males have levels similar to those in women during the follicular phase of the menstrual cycle. In women, progesterone is produced in the ovary as well as the placenta during pregnancy. In males progesterone is produced by the adrenal gland and testes. The action of progesterone is mediated through cytosolic progesterone receptors, of which there are three isoforms, belonging to the nuclear hormone receptor superfamily of transcription factors. The different isoforms are widely distributed and have specific tissue expression patterns that can be modified following exposure to hormones. Ligand binding induces changes in gene expression through direct binding to promoter elements or through protein–protein interactions with other transcription factors (Tait et al., 2008). In some cells, including T cells (Dosiou et al., 2008), progesterone may also act via membrane G-coupled protein receptors that rapidly transduce hormone-induced signals across the cell membrane (BoonyaratanaKornkit et al., 2008). Since these additional phenomena do not depend on the genome, these actions are called nongenomic or extranuclear effects (Wehling and Losel, 2006).

Progesterone has immunomodulatory effects (Tait et al., 2008) which are generally antiinflammatory, including inhibition of glucocorticoid-mediated thymocyte apoptosis (McMurray et al., 2000), and reduction of nitric oxide production (Miller et al., 1996) and expression of Toll-like receptors (TLRs) (Jones et al., 2008) by macrophages. Progesterone promotes Th2 differentiation in vitro (Piccinni et al., 1995) and also influences antibody production, especially the production of antibodies that are asymmetrically glycosylated in such a way that they fail to trigger immune effector mechanisms. Such antibodies are thought to be self-protective (Canellada et al., 2002). High doses of progesterone enhance differentiation of human and mouse DCs in vitro and expression of the costimulatory molecules CD80, CD86, and CD40, as well as major histocompatibility complex (MHC) class II (Ivanova et al., 2005; Liang et al., 2006).

## Androgens

Androgens, the best known of which is testosterone, stimulate or control the development and maintenance of masculine characteristics; however, they have other functions, including maintenance of bone mass in both women and men. Androgens are also the precursors of all estrogens. In males, androgens, primarily testosterone, are present in high levels, but these decline with increasing age (Mitchell et al., 1995). In contrast, in females, lower levels of androgens (particularly the adrenal-derived androgens dehydroepiandrosterone (DHEA) and DHEA-S) persist throughout life (Davison et al., 2005). The best known androgen receptors are nuclear receptors, but nongenomic signaling also occurs (Lutz et al., 2003).

The potent and rapidly occurring immunosuppressive effects of testosterone in mice occur at least in part by induction of thymic atrophy, and cessation of testosterone production by castration of males results in thymic hypertrophy; these effects occur via interaction of sex hormones with receptors on thymic stromal cells (Hince et al., 2008). Testosterone also impairs thymocyte proliferation in response to the mitogen Con A (Yao and Shang, 2005). In men treated with medical castration, there is a reduction in levels of CD4<sup>+</sup> CD25<sup>+</sup> Tregs and in IFN- $\gamma$  production following mitogen-induced activation of CD8<sup>+</sup> T cells (Page et al., 2006).

## ROLE OF THE SEX CHROMOSOMES IN IMMUNITY

The differences between males and females are due to differences in sex chromosomes. People with a Y chromosome show masculinization, due largely to the effects of the testis forming gene, *sry*, on the Y chromosome, and the effects of high levels of testosterone. However, the other genes on the sex chromosomes play a role in sexual dimorphism, largely through epigenetic effects, and the *sry* gene also has other effects than in testis formation (Wijchers et al., 2010). We will now examine the effects of sex chromosomes in immunity.

### X Chromosome

The increased prevalence of autoimmunity in females has generated considerable interest in the X chromosome in immunity, particularly since there was shown to be a direct influence of the overall complement of X chromosomes to the female bias toward autoimmune disease (Smith-Bouvier et al., 2008). This could be related to autoimmune susceptibility genes on the X chromosome.

There are genes on the X chromosome of potential relevance for autoimmunity, including those encoding the IL-2R $\gamma$  chain (also known as the common  $\gamma$  chain because it is shared by receptors for IL-2, IL-7, IL-15, and IL-21) (Alves et al., 2007), and *Foxp3*, which is important in the development and function of Tregs (Zheng and Rudensky, 2007). Mutations of these genes lead to X-linked severe combined immune deficiency (Leonard et al., 1994) and IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome (Bennett et al., 2001), respectively. Other molecules encoded by genes on the X chromosome that might be important for autoimmunity are CD154 (CD40 ligand), which is overexpressed on CD4 $^{+}$  T cells in some autoimmune diseases (Toubi and Shoenfeld, 2004), tissue inhibitors of metalloproteinases 1–4, which are important in inflammation (Anderson and Brown, 2002), the X-linked inhibitor of apoptosis that regulates T-cell function (Zehntner et al., 2007), and the pattern recognition receptors TLR7 and TLR8, both of which are important in recognition of single-stranded RNA and which have also been associated with asthma and other inflammatory diseases (Moller-Larsen et al., 2008; Fish, 2008).

In women with Turners syndrome, who have X monosomy in all cells, there is an increased incidence of autoimmune disease overall, and especially thyroid autoimmunity (Wilson et al., 1996). Interestingly, this thyroid disease is associated with an X isochromosome, which is a condition when one arm of a chromosome is deleted and replaced with an exact copy of that arm from the sister chromosome. This means that both of these identical arms would have the same epigenetic modifications—depending on whether the arm came originally from mother or father (Elsheikh et al., 2001).

Males who have SLE in addition to Klinefelter's syndrome (wherein they have at least two X chromosomes and at least one Y chromosome) share many characteristics of the female with SLE (Lahita, 1999), including increased oxidation of androgens, suggesting that there is some role for the two X chromosomes in this process, although exactly what this role is may be is not yet known.

### Y Chromosome

The Y chromosome contains few genes. Most of the DNA is male specific and the remainder is autosomal. The Y chromosome encodes at least 27 proteins, some of which are confined to testis and some of which are more widely expressed (Skaletsky et al., 2003). The most important Y chromosome gene is *Sry*, which is the gene responsible for the formation of testes and masculine features.

There is some effect of Y chromosome genes on development of experimental autoimmune encephalomyelitis (EAE), the animal model of multiple sclerosis, since female offspring of backcross strains carrying the susceptible SJL/J Y chromosome behaved more like their male siblings than like the female mice from three other birth crosses carrying the resistant C57BL/6 Y chromosome, both in lesion severity (reduced) and clinical sensitivity to CNS damage (increased) (Teuscher et al., 2006). With increased age, male SJL/J mice show increased susceptibility to EAE, and this has been shown to be due to a polymorphism on the Y chromosome (Spach et al., 2009). Y chromosomes candidate genes potentially responsible for these effects include *Hya*, *Yaa*, and *Sry* (Teuscher et al., 2006).

Interestingly, *Yaa*, which predisposes to autoimmunity in mice, is actually a translocation of a cluster of X chromosome genes, including the gene encoding TLR7 (Subramanian et al., 2006). It has been demonstrated that even relatively modest increases in the expression of TLR7 can result in dramatic lymphocyte activation and autoimmunity in mice (Deane et al., 2007). It has been suggested that a similar effect in humans could dictate

susceptibility to SLE. However, a study of 190 male and female SLE patients and controls found no lupus-related difference in copy number of the *TLR7* gene, suggesting that human lupus is not commonly due to a *Yaa*-like mutation (Kelley et al., 2007).

## ENVIRONMENTAL EFFECTS ON SEX DIFFERENCES IN IMMUNITY

As with many issues in biology, there can be an interaction between genes and the environment. The sex differences noted above are what is observed in humans living in natural conditions, and it is possible that there is plasticity in the immune responses in response to the environment. It is theorized that the sex differences are a result of the pressures of the environment (availability of food, availability of sexual partners) and that the males and females differ in traits that limit their fitness, so the response to the environment will differ. It is possible that alteration of the environment could alter the sexual dimorphism in the immune system. In experiments with *Drosophila*, increased availability of food led to increased female immune function and increased availability of mates led to decreased male immune function (McKean and Nunney, 2005). It is possible that gender differences in human immune function could be affected by environmental and social factors. It is now known that the gut microbiota plays an important role in the shaping of the immune system, and in autoimmunity. There is evidence that there is sexual dimorphism in the interaction of the gut, nutrition, and the immune system.

## CONSEQUENCES FOR AUTOIMMUNITY OF SEXUAL DIMORPHISM IN THE IMMUNE SYSTEM

There is a marked female preponderance in many autoimmune diseases (McCombe et al., 2009; Ngo et al., 2014) and it is likely that this is due, at least in part, to the stronger female immune system. When autoimmune disease occurs in males, this could mean that these individuals have immune systems that are particularly vulnerable to disease. This theory is known as the Carter effect, which is applicable to polygenic disorders (Carter, 1969), and suggests that if a subject has an innate biological resistance to a particular disease, then there will be a greater burden of genetic risk factors required to overcome that resistance for disease to occur. Thus for a male to develop a true autoimmune disorder would require that there needs to be a much heavier load of other contributing elements, be they genetic or environmental: males who do present with diseases such as autoimmune thyroid disorder, primary biliary cirrhosis, or lupus may warrant particular scrutiny, as nonsex-related causal elements might be more readily identifiable.

There may also be other gender-specific differences that indirectly affect immune reactivity and contribute to skewing of susceptibility to autoimmune disease in females (McCombe et al., 2009; Greer and McCombe, 2011; Pan and Chang, 2012; Borchers and Gershwin, 2012; Pollard, 2012; Nussinovitch and Shoenfeld, 2012; Quintero et al., 2012). These differences could include sexual dimorphism in the vulnerability of the target organ to

**TABLE 24.1** Immune Functions that Show Sexual Dimorphism

Immune functions that show sexual dimorphism	Difference between males and females
Percentage of lymphocytes in total leukocyte population	Lower in males (Bouman et al., 2004)
Immunosenescence	Greater in males
IgM levels	Greater in females (Butterworth et al., 1967; Lichtman et al., 1967)
Allograft rejection	Greater in females (Kongshavn and Bliss, 1970)
In vitro response to mitogens	Greater in females (Santoli et al., 1976; Weinstein et al., 1984)
Resistance to the induction of immune tolerance	Greater in females (Bebo et al., 1999)
Ability to combat infection	Greater in females (Lotter et al., 2006; dos Santos et al., 2005)
Response to vaccination	Greater in women (Klein et al., 2010)
CD4 + :CD8 + ratio	Greater in women (Wikby et al., 2008; Das et al., 2008)
Th1 responses	Greater in females (Huygen and Palfriet, 1984)

autoimmune attack; epigenetic effects of the sex hormones or gender-specific environmental or lifestyle exposures on genetic risk factors; differences in genomic imprinting in males and females; and effects related to female reproduction. The future challenge is to determine which of these differences between males and females is most important in the development of autoimmunity, since understanding the influences of sexual dimorphism in autoimmune diseases is likely to provide opportunities for better therapies (Table 24.1).

Alterations in genome architecture can lead to human diseases. In autoimmune diseases, however, although strong genetic bases have been found in genome-wide association studies, no unique genetic mechanism underlying immune tolerance breakdown was identified, and the significant genetic associations described are present only in a relatively small proportion of patients. As seen in other complex disorders, linkage studies and genome-wide profiling arrays have contributed to the identification of multiple genes that may exert a combinatorial effect in predisposing individuals to develop the disease (Kochi, 2016). The largely incomplete concordance rates of autoimmune diseases in monozygotic twins strongly support other complementary mechanisms involved in gene regulation, ultimately causing overt autoimmunity (Zouali, 2009). It is, therefore, becoming increasingly evident that gene expression based on DNA sequence alterations or mutations is not sufficient to explain the variety of manifestations observed in disease states (Feil and Fraga, 2012), and that epigenetic deregulation contributes to the severity of these diseases.

## EPIGENETIC MODIFICATIONS

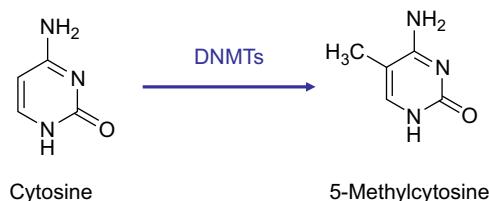

Epigenetics can be defined by the heritable changes that occur in gene expression caused by mechanisms other than alterations in the underlying DNA sequence. These modifications are based on a set of molecular processes that can activate, reduce, or completely disable the activity of particular genes or entire genomic regions: methylation of cytosine residues in the DNA, remodeling of chromatin structure through covalent modification of histone proteins, and recruitment of chromatin-associated small RNA molecules that provide the sequence specificity to target transcriptional silencing. The combination of these different modifications, commonly referred to as the “epigenetic code,” adds a layer of complexity to the information present in the genetic code.

Several observations indicate that environmental changes can produce modifications in gene expression, suggesting that epigenetics can have a potential role in environmental/genetic interactions. First, when the diet *agouti* pregnant rodents were supplemented with foods rich in methyl donors, the offsprings exhibited coat color changes, compared to mothers fed with a standard diet (Wolff et al., 1998). This observation was explained by an altered DNA methylation process that silenced the intracisternal A particle retroviral insertional element, ultimately limiting the appearance of *agouti* alleles. A second remarkable example comes from Dutch individuals who were exposed to famine during intrauterine life and childhood during World War II. Compared to nonexposed subjects, they had a well-conserved hypomethylation status of a region regulating the insulin-like growth factor 2 (IGF2) (Heijmans et al., 2008), providing an example of epigenetic imprinting in human.

### DNA Methylation

In mammals, approximately 60% of the cytosine-phosphate-guanine (CpG) dinucleotides are methylated, and DNA methyltransferases (DNMTs) control DNA methylation of CpG residues and maintenance of methylation during cell differentiation (Bird, 2011). As a regulator of transcription, DNA methylation generally occurs on cytosines in cytosine-guanosine (CG) dinucleotides located within the promoter, most often between 1 and 0.8 kb upstream of the transcription start site (Fig. 25.1).

DNA methylation results from the addition of a methyl group from *S*-adenosylmethionine (SAM) to the C5 position of a cytosine nucleotide, generally located within CpG dinucleotides. DNA sequences that are rich in CpG are called CpG islands. They map essentially to the promoter regions of many genes. Methylation generates a more condensed configuration of the DNA, which hinders the accessibility of transcription factors and attracts methyl-CpG-binding domain (MBD) proteins, thereby leading to repression of gene transcription. By contrast, a low methylation at the promoter region results in an increased transcriptional activity (Jones, 2012).

**FIGURE 25.1** DNA methylation.

Methylation of DNA at 5-position of cytosine by DNMTs that control DNA methylation of CpG residues and maintenance of methylation during cell differentiation. *DNMTs*, DNA methyltransferases; *CpG*, cytosine-phosphate-guanine.

Altered CpG island methylation may change chromatin structure, modulating promoter-transcription factor interactions within the transcription machinery. Although DNA methylation was initially thought to be a stable modification with only passive removal of methyl groups possible, accumulating evidence suggests that DNA demethylation occurs actively and appears to be key in a variety of cellular responses to environmental stimuli, including hypoxia, hormonal signaling, and viral latency and reactivation. Furthermore, aberrant hypo- and hypermethylation may occur in specific genes within the same cell, as is the case in some neoplastic cells.

The three DNMTs that catalyze DNA methylation, DNMT1, DNMT3A, and DNMT3B, have unique sequences, expression patterns, and regulatory mechanisms (Jurkowska et al., 2011). DNMT1 sustains a methylation pattern during cell division and DNA replication and is, therefore, considered a maintenance methyltransferase. The two others, DNMT3A and DNMT3B, catalyze de novo methylation, essentially during embryonic development.

DNA methylation is dynamically controlled and can be reversed through either passive demethylation, a process wherein methyl groups are lost during cell division and DNA replication, or active demethylation mediated by enzyme catalysis. In this process, methylcytosines are modified sequentially by hydroxylation, deamination, oxidation, and DNA repair (Bhutani et al., 2011). Active demethylation requires the following enzymes: the ten-eleven translocation (TET), the activation-induced cytidine deaminase/apolipoprotein B messenger RNA (mRNA) editing enzyme component 1 (AID/APOBEC), and the base excision repair (BER) (Bhutani et al., 2011). Oxidation of 5-methylcytosine (5-mC) gives rise to 5-hydroxymethylcytosine (5-hmC), which is often considered an indicator for active demethylation.

Methylated CpGs recruit transcriptional repressors, such as MBD proteins and histone deacetylases (HDACs), which introduce positive charges in the histone tail, allowing tight binding to negatively charged nucleic acids and leading to the formation of closely compact nucleosomes that prevent transcription. Importantly, these proteins play essential roles in orchestrating the interaction between DNA methylation, histone modifications, and chromatin structure. Eleven MBD members have been described: the methyl-CpG-binding protein (MeCP2), MBD1–6, SETDB1, SETDB2, BAZ2A, and BAZ2B (Baymaz et al., 2014; Hendrich and Tweedie, 2003). Of these proteins, only MeCP2 and MBD1–4 can bind to 5-mC and, therefore, are considered the core MBD proteins. However, even though MBDs are generally considered transcriptional repressors, there is evidence to indicate that these proteins also can behave as transcriptional activators (Chahrour et al., 2008). In physiological conditions, DNA methylation is required for several cellular processes, including genomic imprinting, embryonic development, cell differentiation, X chromosome inactivation, repression of repetitive elements, and maintenance of cellular identity (Martin-Subero, 2011).

## Histone Posttranslational Modifications

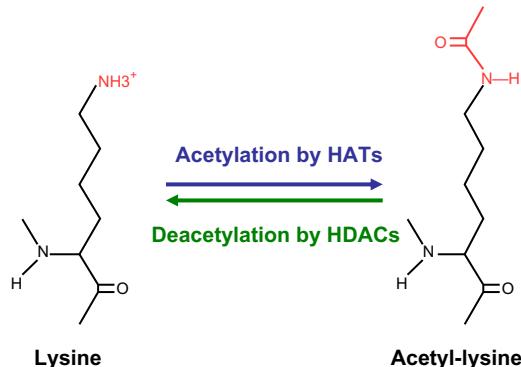

Histone proteins can undergo a number of posttranslational modifications (PTMs) that represent major epigenetic regulatory mechanisms. A variety of histone PTMs that affect chromatin structure have been described, including acetylation, methylation, phosphorylation, ubiquitination, sumoylation, and ADP ribosylation. They can be dynamically added or removed by a plethora of specific enzymes that can work to add or remove functional groups, which are, in turn, recognized by nuclear factors. Together with the diverse nucleosome composition, these modifications can cause a change in the net charge of nucleosomes, alter DNA–histone interactions, and affect chromatin structure. In addition, individual histone PTMs, or specific combinations of them that form the “histone code,” can provide signals to other proteins able to influence chromatin structure, thereby regulating gene expression by the formation of transcriptionally active or repressed states (Li et al., 2007; Berger, 2007).

Histones are highly conserved proteins that reside within nuclei of eukaryotic cells and form the nucleosome cores. They can be categorized into two main groups: (1) core histones (H2A, H2B, H3, and H4), and (2) linker histones (H1 and H5). Two of each of the core histones assemble to form an octameric nucleosome core particle by wrapping approximately 147 base pairs of DNA around the protein spool in a 1.7 left-handed super-helical turn (Luger et al., 1997), thus providing DNA condensation and organization in the nucleus and modulating DNA accessibility to the transcription machinery.

The interaction between histones and the surrounding DNA impact gene expression. Whereas a closed chromatin configuration is associated with transcriptional repression, an open chromatin conformation favors transcriptional activation. These DNA–histone interactions are affected by histone modifications that target specific amino acid residues in the side chains of histones and alter chromatin structure and accessibility. Mechanistically, specific amino acids of histone tails are the targets for several PTM, including acetylation, phosphorylation, poly-ADP ribosylation, ubiquitination, and methylation. Likewise, each histone subtype can be modified by different chemical alterations at defined amino acids, leading to transcriptional modulation and, therefore, cell cycle regulation, development, and differentiation. Acetylation of histones in the nucleosome increases their net negative charge, thereby interrupting their interaction with DNA and leading to an open chromatin conformation with negatively charged DNA—a structure permissive for recruitment of a transcriptional machinery that can initiate gene transcription and expression.

### ***Histone Acetylation and Deacetylation***

These processes are among the most important gene expression regulatory mechanisms (Strahl and Allis, 2000). They involve the conserved ε-amino group of lysine residues at the amino-terminus of nucleosomal histones (Fig. 25.2). Histone acetylation can present as mono-, di-, or tri-acetylation and, usually, occurs at lysine residues on H3 or H4. Acetylation abrogates the positive charges on the histone side chains, which reduces the interaction between the negatively charged DNA and histones, and results in an open chromatin conformation encompassing gene promoters that are more accessible to transcription factors, thereby favoring gene transcription. During histone acetylation, an acetyl group from acetyl coenzyme A is transferred to the NH<sub>3</sub><sup>+</sup> groups on lysine. This transfer is mediated by histone acetyltransferases (HATs) that include P300/CBP, PCAF, and MYST and leads to increased gene expression through transcriptional activation. For example, acetylation of lysine 27 of H3 (H3K27ac) is considered an epigenetic mark associated with transcriptional activation. Histone deacetylation, on the other hand, is catalyzed by several HDACs. According to size, subcellular expression, number of enzymatic domains, and structure, HDACs are divided into four classes. Class I HDACs (HDACs 1, 2, 3, and 8) are detected in the nucleus and ubiquitously expressed in different tissues and cell lines. Class II HDACs (HDACs 4, 5, 6, 7, 9, and 10) shuttle between the nucleus and cytoplasm and are expressed in a tissue-specific manner. For example, human HDAC4 is more abundant in skeletal muscle, brain, heart, and ovary, but undetectable in liver, lung, spleen, and placenta. HDAC5 is expressed in mouse skeletal muscle, liver, and brain, but not in spleen (Brandl et al., 2009). Class III HDACs are structurally unrelated to class I and class II HDACs, but use a unique enzymatic mechanism of action that requires the cofactor NAD<sup>+</sup> for their activity. Finally, HDAC1 is the only

**FIGURE 25.2** Acetylation and deacetylation of lysine residues in histone molecules.

Histone acetylation is catalyzed by HATs. In general, histone acetylation is linked to transcriptional activation and associated with euchromatin. HDACs introduce positive charges in the histone tail, which bind tightly to negatively charged nucleic acids and lead to the formation of closely compact nucleosomes that prevent transcription. *HATs*, Histone acetyltransferases; *HDACs*, histone deacetylases.

member of class IV HDACs, and its classification is still under debate. As a result, HATs decrease the overall positive charge of histones, thereby decreasing their affinity for negatively charged DNA and providing a platform for the binding of transcription factors to the chromatin template. Thus the transfer of acetyl groups to lysine by HATs promotes gene expression. By contrast, removal of acetyl groups by HDACs is generally associated with gene repression (Thiagalingam et al., 2003).

### **Histone Methylation**

Another form of histone PTM is histone methylation, the effects of which depend on the position of the modified lysine residue within the histone tail and on the number of methyl groups added to such residues. Depending on the number of methyl groups that are added and the location of the amino acid being methylated, this process, which occurs frequently, can either increase or decrease gene transcription. For example, whereas trimethylation of histone H3 at lysine 4 (H3K4me3) is an active mark for transcription, the triple methylation of residues 9 or 27 (H3K27me3) is repressive (Kouzarides, 2007). The methylation status of histones is under the control of histone methyltransferases (HMTs) and histone demethylases (HDMs) (Teperino et al., 2010). Three classes of HMTs have been described: (1) SET domain lysine methyltransferase, (2) non-SET domain lysine methyltransferase, and (3) arginine methyltransferase (Smith and Denu, 2009). On the other hand, HDMs have been categorized based on their demethylase domains: (1) LSD1 domain and (2) JmjC domain (Teperino et al., 2010).

Importantly, the interactions between histone modifications and readers are dynamic and exhibit a level of promixuity (Margueron et al., 2009). Each HMT or HDM can target different lysines or arginines, and each lysine or arginine can be methylated or demethylated by more than one HMT or HDM. A single domain from a reader can recognize several histone modifications (i.e., EED can read H3K9me3, H3K27me3, and H1K26me3), and several readers can recognize one histone modification (i.e., H3K4me3 has eight readers). Thus H3K27 can be methylated by EZH2, which can also methylate H1K26. H3K27 can be demethylated by UTX or JMJD3, which can demethylate H3K4.

### **Arginine Methylation**

Arginine can also be methylated/demethylated by specific enzymes (Chen et al., 1999). Methylation of arginine residue 3 on histone H4 (H4R3) and arginine 17 on histone H3 (H3R17) has been shown to induce gene activation. Remarkably, the occupancy of coactivator-associated arginine methyltransferase-1 (CARM1), known to enhance transcriptional activation by nuclear receptors, together with histone H3R17 methylation and citrullination, is regulated at the promoters of inflammatory genes in monocytes, suggesting a role for histone arginine modifications in inflammatory diseases (Miao et al., 2006). Therefore similar to histone lysine methylation, interest in histone arginine methylation is growing. Based on the current knowledge, the histone modification status of H3R17 in cells can exist in at least three modes: (1) arginine, (2) methylated arginine, and (3) citrullinated arginine. The biological meaning of the three modes—or the “H3R17 code”—is slowly emerging but needs further investigation. It seems that H3R17 methylation is associated with gene activation and that H3 arginine citrullination might be associated with the repression of nuclear receptor and NF- $\kappa$ B-regulated genes. This could suggest additional connections between arginine epigenetic markers and human diseases.

### **Ubiquitination**

Ubiquitin is a 76 amino acid protein involved in specific protein labeling. Ubiquitinated proteins are committed to proteosomal degradation, and, thus, ubiquitination controls the stability and intracellular localization of numerous proteins. Ultimately, it influences the status of histone methylation or acetylation and modulates gene expression, as in the case of the NF- $\kappa$ B pathway.

### **Writers, Readers, and Erasers of Histone Modifications**

Among the tail histone modifications described above, enzymes that add groups on histones, that is, HATs and HMTs, are called “writers” of the histone code, and those that remove groups, that is, HDACs and HDMs, are referred to as “erasers.” In addition to writers and erasers, histone modifications also can be regulated by protein effectors to control gene transcription, which are called “readers” (Musselman et al., 2012). Even though these histone readers exhibit structural differences, they have in common one or more conserved domains capable of recognizing specific histone modifications (Yun et al., 2011). Protein modular domains include bromodomains that bind to acetyl-lysines, plant homeodomain that binds methyl-lysines, and “Royal Family” of reader

modules—including Tudor, chromo, PWWP, and MBT domains—that recognize methylated lysine or methylated arginine residues (Margueron et al., 2009).

It is important to note that as a result of these PTMs histone tail modifications can be, directly or indirectly, involved in the regulation of gene expression but also in DNA repair, replication, and recombination (Bannister and Kouzarides, 2011). Thus, histone acetyltransferases mediate histone tail acetylation, resulting in an open chromatin structure that facilitates transcription (Berger, 2007). Methylation on histone tail residues also is a well characterized, but more complex, epigenetic mark that can shape chromatin conformation. Because several methylation sites are located on each histone tail, methylation of core histones H3 and H4 can be associated with either chromatin condensation or relaxation.

## Noncoding RNAs

Noncoding RNAs (ncRNAs) do not code for proteins, but they can impact gene expression through several mechanisms. On the basis of size, ncRNAs can be categorized into three groups: (1) small ncRNAs with less than 50 nt include microRNA (miRNA) and PIWI-interacting RNA; (2) medium-sized ncRNAs (<200 nt) include small nucleolar RNA and promoter-associated small RNAs; and (3) long ncRNAs (lncRNAs), the length of which exceeds 200 nt (Esteller, 2011). miRNAs and lncRNAs are the most studied in autoimmune disease pathogenesis.

Only recently has it been discovered that miRNA can regulate gene expression via mRNA degradation and translational repression (Bartel, 2004). miRNAs are small RNA molecules, the size of which ranges between 18 and 25 nucleotides that bind to the 3' untranslated region of target mRNAs and mediate their posttranscriptional regulation (Sato et al., 2011). Depending on the degree of sequence complementarity, miRNAs, which target about 60% of all genes, can lead to either degradation or translational inhibition. Their synthesis is a step-wise process, which starts with the transcription of primary miRNAs from noncoding regions of the genome (Krol et al., 2010). These longer transcripts are then processed by RNase III enzymes, that is, Drosha and Dicer, into mature double-stranded miRNAs. Subsequently, each strand of the complementary miRNA is incorporated in the RNA-induced silencing complex to promote mRNA degradation. With such a tightly regulated process, miRNAs can repress gene transcription through either mRNA degradation or repression of mRNA translation.

This group of posttranscriptional regulators is involved in several biological processes, including development, differentiation, proliferation, and apoptosis (Filipowicz et al., 2008). miRNAs are genome-encoded and transcribed by RNA polymerase II, similar to ordinary protein-coding RNAs, and it is estimated that miRNA target ~30% of the human transcriptome (Lewis et al., 2005). The role of miRNA in immunity is being explored. For example, miR-146 was identified as a key player in innate immunity (Taganov et al., 2006), and miR-181a was found to modulate adaptive immunity, particularly T-cell sensitivity and selection (Li et al., 2007). Therefore miRNAs are being investigated in autoimmune and chronic inflammatory conditions. A growing body of evidence suggests impaired expression of ncRNAs, and particularly of miRNAs, in autoimmune diseases (Liu et al., 2017).

lncRNAs are thought to make up the largest portion of the noncoding transcriptome (Mercer et al., 2009). This group of heterogeneous transcripts are over 200 nt long. They are involved in RNA silencing, but also in chromatin remodeling, transcriptional activation, posttranscriptional regulation, and DNA methylation (Schmitz et al., 2016).

## Cross Talk Between Epigenetic Regulations

It is noteworthy that epigenetic mechanisms act in concert. Two or more epigenetic mechanisms, including RNA-mediated silencing, histone modifications, and DNA methylation, can act in concert to control gene transcription, and, hence, genome-encoded functions. Thus the regulation of specific DNA methylation patterns that control gene transcription is dependent on local chromatin conformations, and histone methylation marks affect de novo DNA methylation by guiding DNMTs to specific regions of the genome (Brenner and Fuks, 2007).

DNA methylation, for its part, is mediated and maintained by DNMTs, and MBD proteins, which associate with methylcytosine, and recruit silencing complexes that participate in transcriptional repression. These latter complexes contain HDACs and HMTs, which enable a cross talk between DNA methylation, histone modifications, and nucleosome remodeling (Ehrlich and Lacey, 2013). In parallel, miRNAs frequently interact with other epigenetic mechanisms, including DNA methylation, histone modification, and other epigenetic modifiers, thereby shaping the overall gene expression profile.

## Epigenetic Stability

Maintenance of epigenetic marks during cellular division is important to maintain cell lineage commitment in progeny cells and to shape a memory of transcriptional status. Several mechanisms are required for the transmission of epigenetic information through multiple cell divisions. These mechanisms also mediate the inheritance of epimutations (alterations to epigenetic marks that can be transmitted from parents to offspring via their germ-line), which can lead to changes in chromatin structure and transcription levels of genes in disease conditions, such as cancer, imprinting disorders, and, possibly, autoimmune diseases.

Thus even though DNA methylation shows dynamic changes during developmental stages, DNA methylation marks have been initially suggested to be relatively stable over time in adult individuals (Dolinoy et al., 2007). However, human and experimental studies revealed that DNA methylation can exhibit various temporal behaviors, ranging from a nearly absolute stability of the DNA sequence to the rapid variations typical of mRNA levels (Hoyo et al., 2009). Consistently, a recent study showed that DNA methylation markers in human-blood DNA exhibit different degrees of short-term variability (Byun et al., 2012). Whether such variations can be extended to other cell types remains to be determined.

## RHEUMATOID ARTHRITIS

Like several other chronic immune-mediated diseases, the physiopathology of rheumatoid arthritis (RA) involves excessive production of inflammatory mediators, and large quantities of cytokines and chemokines are detectable in the synovial fluid. Another hallmark of RA is the hyperplasia of the synovium, with increased cell density and infiltration of inflammatory cells. The aggressive and invasive behavior of RA synovial fibroblasts (RASFs) and their increased resistance to apoptosis account for the fact that they also are referred to as cells with a “tumor-like phenotype” (Fassbender et al., 1992). Together with cell–cell contacts, the inflammatory mediators can activate stromal fibroblast–like synoviocytes (FLS), leading to the production of enzymes that degrade cartilage and bone. While there is no genetic background for these alterations, several studies suggest that epigenetic modifications could contribute to the characteristic changes of RASFs.

### Acetylation Marks in Rheumatoid Arthritis Immune Cells

Hyperacetylation and hypoacetylation are postulated to tightly regulate the production of inflammatory cytokines at multiple levels, including regulation of transcription factor access to gene promoters, posttranscriptional mRNA processing, and protein secretion. Given the complexity of histone modifications that stabilize an open or repressive chromatin state, a number of investigators focused on the expression of histone-modifying enzymes, including HDACs, particularly because they could have promising therapeutic applications. The analysis of human RA monocytes revealed that HDAC inhibitors (HDACis) are potent antiinflammatory agents (Leoni et al., 2002). More recently, RA PBMCs were found to exhibit increased HDAC activity compared to PBMCs from healthy individuals, and the increase was unaltered after 12 weeks of etanercept therapy (Gillespie et al., 2012).

### Histone Modifications in Rheumatoid Arthritis Synovial Fibroblasts

In initial studies of synovial fibroblasts, there were indications that decreased expression of HDACs in synovial tissue could contribute to RA pathogenesis, and nuclear extracts of RA synovial tissue samples showed lower HDAC activity than those of osteoarthritis (OA) tissue samples (Huber et al., 2007). In further investigations, histone hyperacetylation at the Interleukin (IL) 6 promoter was connected to increased IL-6 expression (Wada et al., 2014). In a more detailed study, significantly higher marks were found for the active H3K4me3 mark in the promoters of MMP-1, MMP-3, MMP-9, and MMP-13 and lower marks of the repressive H3K27me3 in the promoters for MMP-1 and MMP-9 of RA patients, as compared to OA (Araki et al., 2016). These epigenetic modifications could account for the heightened basal MMP levels in RASFs and their aggressive behavior.

In murine models of RA, nonselective HDACis have been used with positive results, including reduced proinflammatory cytokine expression, joint destruction, and disease severity (Lin et al., 2007). In ex vivo experiments, TSA treatment of synovial macrophages reduced the level of IL-6 production and the reduction correlated with enhanced mRNA degradation in RA macrophages and RASFs (Grabiec et al., 2010). Consistently, TSA was a potent inhibitor of TNF- $\alpha$  and IL-6 production in both RA and healthy PBMCs (Gillespie et al., 2012). By contrast,

another HDACi (MI192) inhibited TNF- $\alpha$  production at high concentrations and dose-dependently inhibited IL-6 in RA PBMCs, but not in healthy PBMCs. In parallel, HDACi were found to reduce RA FLS IL-6 production induced by cytokines and Toll-like receptor (TLR) ligands (Grabiec et al., 2012), providing a mechanistic evidence by which HDACi might suppress inflammatory cytokine production and supporting the view that HDACi may represent a novel therapeutic approach for RA.

Importantly, even though blockade of HDACs and bromodomain proteins—reader proteins of histone acetylation—generally leads to antiinflammatory effects (Klein et al., 2016), not all HDACs inhibitors exhibit antiinflammatory actions on synovial fibroblasts. However, one member of the HDCA, namely, HDAC3, represents a promising target because its inhibition was reportedly associated with a suppression of proinflammatory factors in RASFs (Angiolilli et al., 2017). Further characterization of HDACis is needed to better establish their role in the management of RA, and changes in RA acetylation patterns have to be firmly determined before molecular therapeutic targeting becomes feasible.

## DNA Methylation in Rheumatoid Arthritis Immune Cells

Defective DNA methylation also was described in other lineages, such as lymphocytes (Schwab and Illges, 2001), potentially leading to the emergence of autoreactive T- and/or B-cell clones in RA. The *CD21* and *IL-6* promoters were also demethylated in RA PBMC and synovial fluid cells (Nile et al., 2008). In further studies, DNA of monocytes from RA patients was found to be globally hypomethylated in T cells (de Andres et al., 2015). While in the latter study no change in global DNA methylation between healthy and RA B cells could be detected, genome-wide DNA methylation profiling, changes between healthy and RA B cells were described, even in treatment-naïve RA patients (Glossop et al., 2014; Glossop et al., 2016).

In epigenetic studies of PBMCs, the potential confounding effects of differences in the cellular composition cannot be excluded. As a result, the identification of cell-specific epigenetic changes requires that the data must be corrected for differences in the amount of the various cell types present in PBMCs. In one such study, the authors described various DMRs that mapped essentially to the major histocompatibility complex (MHC) region associated with RA genetic risk (Liu et al., 2013). Investigation of the function of regulatory T cells (Tregs) in RA patients disclosed a specific region within the *CTLA-4* promoter that was hypermethylated in Tregs from RA patients, as compared to healthy controls. This DNA hypermethylation could prevent the binding of a transcription factor (NF-AT2), thereby leading to a lower *CTLA-4* expression (Cribbs et al., 2014). In addition to showing that changes in methylation have the potential to subvert cellular function, these epigenetic marks could have therapeutic applications.

## Genomic DNA Hypomethylation and the Activated Phenotype of Rheumatoid Arthritis Synovial Fibroblasts

Converging observations support the hypothesis that progressive loss of methylation marks may give rise to the activated phenotype of RASFs. For example, methylation of CpG islands in the promoter region of the death receptor 3 of RASFs results in a higher resistance to apoptosis (Takami et al., 2006). In further experiments, hypomethylated nuclei were reportedly present in the synovial tissue of RA patients, and RASFs retained their demethylation profile ex vivo (Karouzakis et al., 2009). Chronic treatment of normal synovial fibroblasts with the DNMT inhibitor 5-AZA (5-aza-2'-deoxycytidine) changed the cellular profile into a RASF-like phenotype. Overall, the data support the hypothesis that genomic hypomethylation could account for the activated phenotype of RASFs, in particular with respect to their destructive potential. This hypomethylation could also explain the increased expression of multiple receptors, adhesion molecules, and matrix-degrading enzymes, which play a role in RA. It remains unclear whether the epigenetic modifications of RASFs can contribute to RA chronicity and can be responsible, at least in part, for the fact that current therapies are not effective in all patients.

To determine whether the differentially methylated CpGs in RASFs also are differentially methylated in peripheral blood subsets from RA patients, 371 genome-wide DNA methylation profiles were recently measured in  $CD14^+$  monocytes,  $CD19^+$  B cells,  $CD4^+$  memory T cells, and  $CD4^+$  naïve T cells (Rhead et al., 2017). Of 5532 hypermethylated RASF candidate CpGs, 1056 were hypermethylated in naïve T cells from RA. In addition, 1 significantly hypermethylated CpG in memory T cells, 6 hypomethylated, and 12 hypermethylated CpG were observed in naïve T cells, indicating that DNA methylation signatures of peripheral cells could represent useful risk biomarkers for RA.

## Aberrant SUMOylation

In addition to DNA and histone modifications, posttranslational processes can have direct or indirect effects on epigenetic events. Thus ubiquitin and a related family of proteins, the small ubiquitin-like modifiers (SUMOs), have been shown to impact the potential of RASFs to react to Fas-induced apoptosis. In RA, SUMO is overexpressed in synovial tissue and synovial fibroblasts (Meinecke et al., 2007). However, despite the availability of chemical modulators of ubiquitination and SUMOylation, a better understanding of the molecular mechanisms that underlie these modifications must be achieved before clinical applications can be considered.

## miRNA and the Destructive Potential of Rheumatoid Arthritis Synovial Fibroblasts

Accumulating evidence implicates an important role of miRNAs in the regulation of immune responses and the development of autoimmunity, and recent observations suggest that altered expression and function of miRNAs may also be involved in RA pathogenesis. In one study, treatment of RASFs with TNF- $\alpha$ , IL-1 $\beta$ , lipopolysaccharide, or poly(I-C) led to an upregulation of miR-155 and miR-146, and these two miRNAs were constitutively more highly expressed in RASFs than in synovial fibroblasts of OA patients (Stanczyk et al., 2008). Peripheral blood monocytes of RA patients also displayed higher levels of miR-155. Furthermore, enforced expression of miR-155 repressed the levels of matrix metalloproteinase-3 (MMP-3) and reduced the induction of MMP-3 and MMP-1 by TLR ligands and cytokines (Stanczyk et al., 2008). The repressive effect of miR-155 on MMPs may suggest that miR-155 plays a role in the modulation of the destructive behavior of RASFs (Stanczyk et al., 2008). This conclusion is supported by another study showing an enhanced expression of miR-146 in RA synovial tissue (Nakasa et al., 2008). In that study, the expression levels of miR-146 in RASFs were increased upon stimulation with TNF- $\alpha$  and IL-1 $\beta$ . Consistently, the investigation of 33 RA patients revealed that synovial fluid and peripheral blood CD4 $^+$  T cells exhibit upregulation of miR-146a and downregulation of miR-363 and miR-498 (Li et al., 2010). Moreover, the levels of miR-146a expression were positively correlated with those of TNF- $\alpha$ , and miR-146a overexpression was found to suppress T-cell apoptosis, suggesting a role for miR-146a in RA pathogenesis (Li et al., 2010).

Further evidence for the involvement of miR-146a in inflammation and cytokine production comes from the observation that the expression of miR-146a was associated with that of IL-17 in the PBMC and synovium of RA patients, and that the increased expression of both molecules correlated with disease activity (Niimoto et al., 2010). A parallel survey further demonstrated that a polymorphism in the 3'-UTR of IL-1 receptor-associated kinase (IRAK1), a target gene of miR-146a, is associated with RA susceptibility (Chatzikyriakidou et al., 2010). Since the overexpression of miR-146a was found to significantly deregulate the function of Th1 cells, and because miR-146a treatment ex vivo could induce protein expression of key proinflammatory cytokines (Guo et al., 2010), the results support the hypothesis that miR-146a may be directly involved in the pathogenesis of RA and, possibly, other inflammatory diseases. Thus in reports from different research groups, miR-146a and miR-155 have been consistently found to be upregulated in RASFs, PBMCs, synovial fluid, PBMC-derived CD4 $^+$  T cells, and Th17 cells from patients with RA when compared with healthy controls or OA patients (Stanczyk et al., 2008; Li et al., 2010; Pauley et al., 2008).

In more recent investigations, miRNA-155 was described to be a regulator of chemokine and proinflammatory chemokine receptor expression in RA monocytes (Elmesmari et al., 2016). The fact that its levels were in correlation with tender and swollen joint counts could indicate that it is an active player in promoting inflammation in the RA synovium. In addition to playing a role in innate immunity, miRNA-155 seems to be required for adaptive immune responses that lead to autoimmune arthritis. In one study, miR-155 was found to target a transcription factor, PU.1, implicated in early B-cell commitment and upregulated in memory B cells at an early stage of RA (Elmesmari et al., 2016). Because blockade of endogenous miRNA-155 in B cells of RA patients restored PU.1 levels and decreased antibody production (Elmesmari et al., 2016), this miRNA could represent a promising therapeutic target.

In line with the observation that the expression of both miRNA-146a and miRNA-155 is characteristically abnormal in peripheral naïve and Treg subsets from RA patients (Simmonds et al., 2014), injection of miRNA-146a into CIA mice could inhibit osteoclastogenesis, prevent joint destruction, but, only partially, ameliorated inflammation (Nakasa et al., 2011). miRNA-124/miRNA-124 is another regulator of osteoclastogenesis that acts through downregulation of NFATc1. When injected into the ankles of rats, it ameliorated adjuvant-induced arthritis (Nakamachi et al., 2016). Also overexpressed in synovial fibroblasts, T cells, monocytes, synovial fluid, and serum of RA patients are miRNA-223 (Ogando et al., 2016). It targets aryl hydrocarbon receptor nuclear translocator and acts as an antiinflammatory factor by reducing the production of inflammatory cytokines (Ogando et al., 2016).

## AUTOIMMUNE THYROID DISEASES

Both Graves' disease (GD) and Hashimoto's thyroiditis (HT) are organ-specific autoimmune diseases characterized by lymphocytic infiltration of the thyroid gland, with evidence of humoral and cellular immune system hyperactivation and female preponderance (Weetman, 2001). Whereas in GD the autoimmune process results in the production of thyroid-stimulating antibodies that lead to hyperthyroidism, in HT the immune response is destructive and leads essentially to hypothyroidism (Brix and Hegedus, 2012). In patients with autoimmune thyroid diseases (AITD), there is a significant increased risk for the occurrence of other autoimmune diseases (Fallahi et al., 2016). The investigation of genetic risk factors has revealed that some genes are unique for GD or HT, while others are common to both diseases and, sometimes, shared by other autoimmune diseases (Tomer, 2014).

### DNA Methylation in Autoimmune Thyroid Diseases

Epigenetic profiling of blood samples, lymphocytes, and thyrocytes from patients revealed impaired DNA methylation in AITD. In one study of peripheral blood mononuclear cells (PBMCs) from three GD patients and three age- and gender-matched controls, 82 hypermethylated and 103 hypomethylated genes were reported (Cai et al., 2015). Some of these genes had been previously associated with GD or other autoimmune diseases, including the immunoregulatory factor *ADRB2*, *ICAM1* that codes for a cell surface glycoprotein, and *B3GNT2* that plays a role in the regulation of lymphocyte activity. In addition, the transcription of the genes coding for both DNMT1 and the MBD protein MECP2 was significantly decreased in GD patients compared with normal controls (Cai et al., 2015). In another study of CD4<sup>+</sup> and CD8<sup>+</sup> T cells from 38 GD patients and 31 matched controls, 365 and 3322 differentially methylated CpG sites were described in CD4<sup>+</sup> and CD8<sup>+</sup> T cells, respectively (Limbach et al., 2016). Some of the hypermethylated CpG sites are present on genes involved in T-cell signaling, including *CD247*, *LCK*, *ZAP70*, *CD3D*, *CD3E*, *CD3G*, *CTLA4*, and *CD8A* (Limbach et al., 2016). Interestingly, the first intron of the thyroid-stimulating hormone receptor (*TSHR*) gene, known to contain several GD-associated polymorphisms, was hypermethylated (Limbach et al., 2016). A third study showed abnormal DNA methylation of the *ICAM1* gene promoter in the thyrocytes of 35 AITD patients, as compared to 35 sex- and age-matched controls (Liu et al., 2017).

### Histone Tail Modifications in Autoimmune Thyroid Diseases

One study of PBMCs from GD patients showed reduced global histone H4 acetylation levels and increased levels of HDACs, as compared to healthy controls (Yan et al., 2015). In an analysis of CD4<sup>+</sup> and CD8<sup>+</sup> T cells, also from GD patients, there was a decreased expression of H3K4me3 (histone 3 lysine 4 trimethylation) and H3K27ac (histone 3 lysine 27 acetylation), two epigenetic marks usually present on the vicinity of active promoters (Limbach et al., 2016). Together with the DNA methylation studies, it appears that the gene promoter methylation observed in cells from GD patients is associated with changes in chromatin structure that allow silencing of gene expression.

### Noncoding RNAs in Autoimmune Thyroid Diseases

Several studies probed miRNAs expression in AITD. For example, the expression of miR-154\*, miR-376b, and miR-431\* was found to be suppressed in PBMC from initial GD patients, as compared to healthy controls (Qin et al., 2015). In studies attempting to decipher the biological significance of miRNA deregulation, it has been suggested that increased miR-155 and decreased miR-146a could promote ocular inflammation and proliferation in Graves' ophthalmopathy (Li et al., 2014). Similarly, a decreased expression of miR-125a-3p was suggested to upregulate IL-23 receptor expression in patients with HT (Peng et al., 2015). In other investigations, there was a differential expression of 23 miRNAs in thyroid tissue of GD patients, resulting in the upregulation of 1271 mRNAs and in downregulated expression of 777 mRNAs (Qin et al., 2015). Further evidence for a possible involvement of miRNAs in AITD pathogenesis also comes from studies linking miRNA gene polymorphisms to increased risk of thyroid disease (Cai et al., 2017). However, given the variability in miRNA expression, additional studies are required to discriminate between miRNAs that are deregulated in a given disease.

## TYPE-1 DIABETES

Whereas type-2 diabetes is associated with a relative lack of insulin, most commonly due to the failure of the beta cells to compensate for insulin resistance caused by obesity, type-1 diabetes (T1D) is associated with absolute insulin deficiency due to selective destruction of beta cells. Affecting more than 30 million people worldwide, T1D is a complex autoimmune disease caused by a combination of genetic and nongenetic factors, leading to immune destruction of insulin-secreting islet cells.

It is thought that the destructive process causing T1D is immune-mediated and involves a destructive autoimmune reaction. The fact that predisposing susceptibility loci map at immune response genes and that other autoimmune diseases share common genetic risk factors supports the view that the disease has an immunological basis. In T1D, the associated genes code for proteins that exhibit four broad functions, namely, decreased T-cell signaling, antigen presentation and T-cell repertoire formation, increased type-1 interferon (IFN) responses, and cytokine signaling (Li et al., 2015).

Several lines of evidence suggest that T1D could be subject to nongenetically determined components (Salvetti et al., 2000). First, MZ twins exhibit a high discordance rate, particularly when they are aged over 15 years at diagnosis. Thus even though MZ twins are genetically identical, only approximately 50% of the twins of T1D-affected cotwins will develop the disease (Leslie and Delli Castelli, 2004; Redondo et al., 2001; Hyttinen et al., 2003). Second, over recent years, the risk of developing T1D has increased at a rate that cannot be accounted for solely by genetic changes. Third, the risk for an offspring of a father with T1D is higher than that of an offspring of a mother with T1D, that is, 6% versus 1%, respectively. Fourth, it is the age at diabetes onset, and not the haplotype, that accounts for diabetes risk, suggesting that epigenetic/environmental factors can accelerate T1D progression. Factors that could contribute to the etiology of this complex autoimmune disease include viral infections, dietary factors, or vitamin D deficiency (Knip et al., 2005).

### DNA Methylation Profiling in Type-1 Diabetes

To determine whether epigenetic variation can underlie some of the nongenetic components of T1D etiology, an epigenome-wide association study was devised (Rakyan et al., 2011). To rule out genetic differences and to establish the temporal origins of T1D-associated epigenetic variation, the study combined T1D–discordant MZ twins with longitudinally sampled pre-T1D singletons. Genome-wide DNA methylation profiling led to the identification of 132 different CpG sites at which the direction of the intra-MZ pair DNA methylation difference significantly correlated with the diabetic state, that is, T1D-associated methylation variable positions (T1D–MVPs). Since these T1D–MVPs were found in MZ twins, they cannot be due to genetic differences. Additional experiments revealed that some of these T1D–MVPs are found in individuals before T1D diagnosis, suggesting that they arise very early in the process that leads to overt T1D and that they are not simply due to postdisease associated factors, that is, medication or long-term metabolic changes. However, the origin of these T1D–MVPs remains unclear. First, given that stochastic epigenetic variation in humans is more common than previously appreciated, as demonstrated by genome-scale analysis of DNA methylation profiles in 114 MZ and 80 dizygotic (DZ) twins (Kaminsky et al., 2009), these T1D–MVPs could be of early life stochastic origin. Second, since disease-relevant environmental factors can operate in early life to influence disease-risk (Knip et al., 2010), the T1D–MVPs could have been induced environmentally in MZ twins who were exposed to similar, but not identical, environments. The analysis of individuals before they present with autoantibodies should establish whether T1D–MVPs are valuable disease biomarkers, capable of augmenting the predictive power of autoantibodies and genetic variants.

In a second genome-wide DNA methylation quantitative trait locus, the analysis of human pancreatic islets using 574,553 SNPs with genome-wide DNA methylation data of 468,787 CpG sites from 89 donors, 383 CpG sites showed significant associations after correction for multiple testing, including known diabetes loci (Olsson et al., 2014). Importantly, functional analysis revealed that the identified candidate genes, that is, GPX7, GSTT1, and SNX19, could affect chief biological processes that include proliferation and apoptosis in pancreatic beta cells. Thus genome-wide genetic and epigenetic variations have the potential to interact in a manner that impacts gene expression, islet function, and potential T1D risk.

DNA methylation of promoter regions is generally inherited and exhibits high concordance rates in identical twins, indicating that twin pairs discordant for a particular disease represent an optimal opportunity to probe epigenetic differences that might be involved in that disease. In an epigenome-wide association study of T cells,

B cells and monocytes from 52 monozygotic twin pairs discordant for T1D, a striking concordance between twins of each pair was observed (Paul et al., 2016), consistent with a strong shared genetic/nongenetic effect on CpG methylation in DNA promoter regions. While this observation could suggest that epigenetic changes can contribute to disease pathogenesis, it is also possible that the epigenetic changes could result from other abnormalities that arise in T1D. It will be important to focus on prediabetic subjects and interrogate distal enhancer regions.

### Chromatin Remodeling and Histone Acetylation in Type-1 Diabetes

HDAC inhibition is known to modify innate and adaptive immune responses. In monocytes isolated from patients with T1D or T2D, histone H3 was hyperacetylated in the promoters of TNF- $\alpha$  and the inflammatory-associated enzyme cyclooxygenase (COX)-2 (Miao et al., 2004), suggesting a potential importance of HATs and HDACs in the expression of proinflammatory genes.

A more recent study was based on the view that environmental factors can trigger epigenetic changes and that variations in histone PTMs at the promoter/enhancer regions of T1D susceptible genes may be associated with T1D (Miao et al., 2012). Likewise, histone PTM variations at known T1D susceptibility genes were evaluated in blood cells from T1D patients versus healthy nondiabetic controls, and key histone PTMs were profiled. Marked variations in H3K9 acetylation (H3K9Ac) levels were observed at the upstream regions of *HLA-DRB1* and *HLA-DQB1* in T1D monocytes relative to controls (Miao et al., 2012). Additional experiments demonstrated increased expression of *HLA-DRB1* and *HLA-DQB1* in response to IFN- $\gamma$  and TNF- $\alpha$  treatment that was accompanied by changes in H3K9Ac at the same promoter regions. These results suggest that the H3K9Ac status of *HLA-DRB1* and *HLA-DQB1*, two loci highly associated with T1D, may be relevant to their regulation and transcriptional response toward external stimuli. Thus the promoter/enhancer architecture and chromatin status of key susceptible loci could be important determinants in their functional association with T1D susceptibility. In summary, the findings point to inappropriate chromatin remodeling and histone acetylation as important pathogenetic factors in diabetes.

### Histone Deacetylase Inhibitors in Type-1 Diabetes Preclinical Studies

In ex vivo experiments, increased histone acetylation can be induced by high-glucose concentrations and HDACis in monocytes from diabetics (Miao et al., 2004). Similarly, production of the inflammatory cytokines IL-1 $\beta$  and TNF- $\alpha$  was induced by high-glucose concentrations through the activation of NF- $\kappa$ B (Shanmugam et al., 2003), suggesting that hyperacetylation is a consequence of hyperglycemia or other metabolic aberrancies of diabetes, rather than a cause. Such studies suggest that acetylation favors insulin expression and that HDAC activity decreases insulin expression. In support of this view, TSA and sodium butyrate (NaB) increase histone H4 acetylation and enhance insulin expression at low glucose levels (3 mmol/L), supporting a repressive role of HDACs on pre/proinsulin transcription (Mosley and Ozcan, 2003). Of note, TSA and NaB do not potentiate acetylation of H4 after exposure to high concentrations (30 mmol/L) of glucose (Mosley and Ozcan, 2003). A stimulatory effect of sodium valproate (VPA) on insulin release has also been reported in human islets incubated in low glucose concentrations (2.8 mmol/L). In contrast, accumulated insulin release from rat islets incubated in 11 mmol/L glucose was unaffected by SAHA and the HDACi ITF2357, but was slightly inhibited by TSA (Lundh et al., 2010).

Overall, converging observations indicate that there is evidence for genetic association between diabetes and HDACs, and that HDACs are involved in several biological pathways relevant for the etiology and pathogenesis of not only T1D, but also T2D. The observations that HDACi can promote  $\beta$ -cell development, proliferation, differentiation, and function; prevent  $\beta$ -cell inflammatory damage; improve insulin resistance; and positively affect late diabetic microvascular complications provide a strong rationale for continuing preclinical studies, with the aim of testing the clinical utility of HDACi in diabetes. On the basis of the preclinical evidence, inhibition of various HDACs represents a promising novel therapeutic principle to correct the insulin-resistant state. However, further studies are needed to clarify the differential importance of various HDAC subtypes and, thereby, different HDACi, and to optimize the concentrations of HDACi to be used. The use of more specific HDACi, along with careful titration studies, should provide even more encouraging preclinical results. Lastly, the enigma of how HDAC inhibition, an apparently nonspecific treatment, can exert therapeutic benefits in so many diverse disorders needs to be unraveled.

## MULTIPLE SCLEROSIS

In this chronic, inflammatory and demyelinating neurological disease of the central nervous system, the precise mode of inheritance is not established. Even though the prevalence of multiple sclerosis (MS) in Europe and the United States approximates 0.1%, the disease frequently affects young adults at the age range of 20–45 and leads to considerable economic burden. Approximately 15%–20% of the patients have one or more affected relatives, and first-, second-, and third-degree relatives are more likely to develop the disease than the general population (Sadovnick et al., 1988). If genetic information were the sole determinant for MS susceptibility, one would expect that MZ twins, who are genetically identical, should display the same risk for developing the disease. By contrast, in MS the concordance rate for MZs is only 20%–30% (Hansen et al., 2005; Willer et al., 2003), implying a multi-factorial etiology, with interactions among genetic, environmental and stochastic factors (Dyment et al., 1997). The disease is almost two times more prevalent in women rather in men, implicating the involvement of epigenetic mechanisms in MS development, a disparity that could be due to an epigenetic deregulation of the X chromosome in females.

Environmental risk factors for the development of MS include smoking, which has been documented to impact DNA methylation, histone acetylation, and miRNA expression (Allione et al., 2015). Low serum levels of vitamin D and Epstein–Barr virus infection also have been proposed to act on the epigenome of susceptible patients. Thus vitamin D could alter gene expression by recruiting histone acetyltransferases or HDACs (Fetahu et al., 2014).

### DNA Methylation and Multiple Sclerosis

DNA isolated from the white matter of MS brains contained only about one-third of the amount of methylcytosine found in DNA from normal subjects (Mastronardi et al., 2007). This decreased methylation of cytosines in CpG islands was not the result of decreased DNMT activity, but rather the result of a twofold higher DNMT activity (Mastronardi et al., 2007). Importantly, it was specific for MS because DNAs from the thymus of the same MS patients and from patients with Alzheimer's, Parkinson's, and Huntington's diseases were normally methylated, and the DNMT activity was unaffected (Mastronardi et al., 2007). An important target of this hypomethylation in MS brains is the activation of the PAD2 locus. Its promoter has a 74% GC content, and sequence analysis revealed that this region is hypomethylated in MS brains compared to controls (Mastronardi et al., 2007). Together with the findings of increased DNA demethylase, the data suggest that specific genes are reactivated in MS brains, due to epigenetic modulation. It is, for example, possible that the hypomethylated PAD2 promoter underlies overexpression of PAD2 in the normal-appearing white matter (NAWM), which could be responsible for citrullination of MBP (Baranzini et al., 2010). In addition to cellular DNA, relapsing-remitting MS (RRMS) patients exhibit unique disease- and state-specific methylation abnormalities of cell-free plasma DNA, an observation that could be useful for developing new MS biomarkers (Liggett et al., 2010).

Genome-wide DNA methylation profiling of CD4<sup>+</sup> T cells from monozygotic twin pairs discordant for MS showed differences in DNA methylation patterns (Baranzini et al., 2010). Consistently, the analysis of approximately 485,000 CpG sites throughout the whole genome of peripheral blood CD4<sup>+</sup> T cells from patients with MS and healthy controls disclosed 74 significantly different methylated CpG sites in MS, as compared to controls (Graves et al., 2014). Among these CpG sites, 30 mapped to genes that were previously associated with MS, including IL-32 and the T-cell antigen receptor. Another genome-wide methylation analysis of NAWM from MS patients showed 319 significantly hypermethylated and 220 significantly hypomethylated regions (Huynh and Casaccia, 2013). Hypermethylation and hypomethylation targeted genes known to be involved in oligodendrocyte survival and immune responses, respectively.

### Histone Modifications in Multiple Sclerosis

HATs and HDACs fine-tune cellular acetylation, targeting not only histones but also a variety of proteins with key roles in cell metabolism, signaling, and death. Several observations indicate that, within neural cells, aberrant regulation of acetylation homeostasis may represent a common pathogenetic mechanism underlying neurodegeneration in neurological diseases (Sweet et al., 2012). In an animal model of MS, experimental autoimmune encephalomyelitis (EAE) in SJL mice, the HDACi sodium phenylbutyrate and its metabolite sodium phenylacetate (SPA) almost completely abrogated the development of adoptive transfer of EAE (Dasgupta et al., 2003).

Similarly, SPA suppressed neurological impairment in MBP-primed T-cell recipient mice. Both SPA pretreatment of donor EAE mice *in vivo* or MBP-primed T cells *ex vivo* were able to reduce adoptive EAE symptoms and neuropathology in recipient mice (Dasgupta et al., 2003). In C57BL/6 mice immunized with the myelin oligodendrocyte glycoprotein peptide MOG35–55, injection of TSA reduced neurological impairment (Camelo et al., 2005). In that study, increased histone acetylation levels in the spinal cord of TSA-treated EAE mice correlated with reduced levels of caspase 3 and 9. In addition, TSA treatment reduced transcripts for IL-2 receptor, IL-8 receptor, IL-12, and the costimulatory molecule CD28 in the spleen of EAE mice, and T-cell proliferation to MOG35–55 as well as to nonspecific T-cell activators (Camelo et al., 2005). The findings indicate that TSA treatment during EAE severely affects the development of the autoimmune response.

Other studies demonstrated that immunological functions of dendritic cells (DCs), Th1, Th17, and Tregs, as well as glial cells, are affected profoundly by HDACi. For example, exposure of *ex vivo*–generated human DCs to the HDACis valproic acid or entinostat (MS-275) impaired cell differentiation and immunogenicity (Nencioni et al., 2007). Likewise, DC production of proinflammatory cytokines (IL-6, IL-12, TNF- $\alpha$ ) was reduced by the two HDACi. Consistently, two other HDACis (SAHA and ITF2357) reportedly suppressed IL-6, IL-12, and TNF- $\alpha$  expression by mouse bone marrow–derived DCs challenged with different activators (Reddy et al., 2008). The two HDACi also impaired costimulatory molecule expression by DCs as well as their T-cell stimulatory capacity. In addition to the HDACi-dependent DC suppression, which might be relevant to MS therapy during different disease phases, different HDACi are able to impair Th1 and Th17 cell actions. Thus the HDACis TSA and SAHA could reduce the amount of IL-12 and IL-23 (two key cytokines necessary for DC-dependent polarization of T cells toward Th1 and Th17 cells) produced by human DCs *ex vivo* or mouse DCs *in vivo* (Bosisio et al., 2008).

Further underscoring the therapeutic relevance of HDACi to MS therapy, several lines of evidence indicate that HDACs negatively regulate Treg generation and function. Whereas Treg transfer affords protection from EAE in rodents (Kohm et al., 2002), reduced numbers and functional deficiency of Treg have been reported in MS patients (Zhang et al., 2004). In further studies, TSA was found to assist proliferation of Treg as well as their suppressive function on effector T cells *in vivo* (Tao et al., 2007). These effects are due to inhibition of HDAC9-dependent Foxp3 transcription factor deacetylation. Additional evidence indicates that the functional enhancement also is prompted in freshly isolated and expanded human Tregs by several HDACi, and the promotion of Treg functions by HDACi seems to be due to increased expression of the negative immune regulator CTLA-4, also called CD152 (Akimova et al., 2010).

Inhibitors of HDACs might exert protection from the autoimmune response to the nervous system via both immunosuppressive effects and the promotion of neuronal survival. The preclinical evidence suggests that pharmacological inhibition of HDACs is a promising therapeutic strategy for the treatment of neurological disorders, including MS. However, based on preclinical data, the drugs also might exert detrimental effects that may contribute to MS pathogenesis. In light of the emerging role of drug-induced remyelination in protection from EAE, for example, the observation that HDACi can impair remyelination in cuprizone-treated mice (Taveggia et al., 2010) may reduce the therapeutic potential of these compounds in MS. It is also worth noting that the various HDACi used in preclinical studies are pan-HDACis with off-target effects (Kazantsev and Thompson, 2008). It is, therefore, hoped that isoform-selective HDACi will be available shortly.

Mitochondrial changes, including decreased expression of electron transport chain subunit, have been described in MS, but their relevance to MS pathogenesis remains the focus of the investigation. In studies of histone H3 methylation in the gray matter from postmortem MS and control cortical samples, reduced betaine homocysteine methyltransferase levels in cortical neurons from MS patients were in correlation with altered methylation of H3K4me3 (Singhal et al., 2015), which could account for the downregulation of oxidative phosphorylation genes and, consequently, respiratory defects in the MS cortex. It remains to be seen whether dietary betaine supplementation could support mitochondrial respiration in the clinic.

## Generation of Neo-Epitopes

It is possible that environmental factors can break tolerance through PTMs and molecular mimicry to induce self-antigen modifications that, subsequently, can trigger a range of immune responses. In MS, episodes of neuroinflammation lead to myelin loss and multifocal loci of demyelination, called “plaques,” that are often characterized by the appearance of new myelin at the lesion edge. Pathological studies of postmortem tissue obtained from MS brains revealed that the composition of myelin in the NAWM is different from that of non-MS brains (Moscarello et al., 1994). The coexistence of multiple cell populations in the NAWM and the observation

that HDAC is necessary for the definition of an epigenetic signature of oligodendrocytes in developing rodents (He et al., 2007) led to the proposal that, as a result of a deregulated “epigenetic identity,” disease progression may result from the generation of neo-epitopes.

Further evidence that epigenetic deregulation could lead to the emergence of immunogenic forms of MBP comes from studies of PAD2, a peptidylarginine deiminase that catalyzes the conversion of the guanidino group of arginine to citrulline in MBP. PAD2 levels are elevated in MS and in a transgenic animal model of the disease (Mastronardi et al., 2007). While in normal brains only a very small proportion of MBP is citrullinated, in chronic MS, citrullinated MBP comprises approximately 40% of the total MBP (Moscarello et al., 1994). The observation that there was over 90% citrullination of MBP in a rare acute Marburg’s form of MS suggested a relationship between the amount of citrullinated MBP and MS severity. The conversion of the majority of arginines into citrullines resulted in a visible apparent mass change of MBP, and in a net reduction of its positive charge, thereby affecting the interactions of MBP with other myelin components, and leading to an aberrant localization of the citrullinated form of MBP in human brain white matter biopsies (Wood et al., 1996). Altogether, citrullination of MBP caused by epigenetic deregulation of PAD2 could lead to the release of modified and/or highly immunogenic forms of MBP, which may affect disease progression (Mastronardi et al., 2007; Tranquill et al., 2000; Musse and Harauz, 2007). In one scenario, citrullination could increase the generation of immunodominant peptides, due to increased autocleavage of the protein. Alternatively, citrullination could disrupt the physicochemical properties of MBP and thereby affect its localization within the myelin membrane. Finally, the importance of sex hormones in MS suggests that sex steroids could epigenetically modulate PAD2 gene expression by affecting chromatin components and transcriptional complexes (Kaminsky et al., 2006).

## MicroRNAs in Multiple Sclerosis

A number of research groups reported different expression profiles of miRNAs in whole blood, peripheral blood-derived lymphocytes, or serum from MS patients, but discordant profiles were found. These discrepancies could be due to differences in sample types, cell populations, numbers of miRNAs surveyed, or the techniques used.

Since epigenetic modifications, including miRNA expression profiles, are unique to each cell subset, evaluation of miRNA expression in purified cell populations, instead of heterogeneous cells contained in PBMCs, would be optimal to pinpoint aberrant miRNA profiles in MS patients.

In a study of CD4<sup>+</sup> T cells isolated from peripheral blood, significantly different expression patterns of 85 miRNAs were found in samples from MS patient, as compared to control subjects (Guerau-de-Arellano et al., 2011). Also of interest is the profiling of 368 miRNA in the plasma samples from MS patients (Gandhi et al., 2013). It revealed specific patterns of 29 miRNAs in RRMS patients and 35 miRNAs in secondary progressive MS (SPMS) patients. Remarkably, in RRMS patients, miR-92a-1 expression correlated with disability score and disease duration.

## SYSTEMIC LUPUS ERYTHEMATOSUS

In lupus, there is strong evidence that the presence of one risk allele can influence other risk alleles across different loci. With the identification of a number of gene–gene epistatic interactions (Hughes et al., 2012), it is becoming clear that epigenetic factors play a key role in systemic lupus erythematosus (SLE) pathogenesis. Likewise, interactions between environmental and genetic factors have been proposed to explain why certain individuals develop the disease while others do not, and to account for the discordance rates for the disease in MZ twins (Zouali, 2005; Gourley and Miller, 2007; Zouali, 2011).

## DNA Methylation in Systemic Lupus Erythematosus

This epigenetic modification has emerged as an important contributing factor in lupus. Patients exhibit global T-cell hypomethylation (Richardson et al., 1990) and the changes correlate with increased disease activity (Deng et al., 2001). T-cell DNA hypomethylation has been implicated in the development of drug-induced lupus by hydralazine and procainamide, and in the pathogenesis of lupus-prone MRL-lpr mice (Yung et al., 1997).

Interruption of the ERK signaling pathway in T cells and subsequent inhibition of DNMT1 induces anti-dsDNA antibody production and a lupus-like gene expression profile in mice (Sawalha et al., 2008).

The *CD40LG* gene, located on the X chromosome, is hypomethylated in T cells from healthy men, while healthy women have one methylated and one hypomethylated allele (Lu et al., 2007). Treatment of CD4<sup>+</sup> T cells with the DNA methylation inhibitor 5-azacytidine demethylated *CD40LG* and doubled its expression in normal healthy women, but not men (Lu et al., 2007; Zhou et al., 2009). These findings suggest that hypomethylation of the normally inactivated and silenced X chromosome might be related to the higher prevalence of lupus in women. Indeed, men with Klinefelter's syndrome (47, XXY) have a similar risk to develop lupus as normal women (46, XX) and approximately a 14 times higher risk to develop lupus compared to normal men (46, XY). This gene–dose effect may be achieved by hypomethylation of the X chromosome, making more than one X chromosome available for transcription (Scofield et al., 2008).

Other abnormally methylated genes include the *ITGAL* (CD11a), which is important for cell–cell adhesion (Lu et al., 2002), *TNFSF7* (CD70); which is required for T-cell proliferation, clonal expansion and promotion of effector T-cell formation (Oelke et al., 2004), and *CD40L*; and which stimulates IgG overproduction (Lu et al., 2007). Other factors include the gene encoding perforin 1 (PRF1) (Kaplan et al., 2004), which contributes to autoreactive killing of macrophages and release of apoptotic material, CD3  $\zeta$  chain, CTLA4, IL-2, IL-4, IL-10, and IFN- $\gamma$  (Kaplan et al., 2004; Richardson et al., 1992; Lu et al., 2005; Mishra et al., 2001; Lee et al., 2002; Thomas et al., 2005; Januchowski and Jagodzinski, 2005; Schmidl et al., 2009). In resting SLE B cells, the E1B promoter of the *CD5* gene was reportedly hypomethylated (Lu et al., 2002). These data show that DNA methylation and chromatin structure can influence the expression of SLE-related genes. In mice, demethylating drugs can trigger overexpression of these same molecules and induce both autoreactive T cells and a lupus-like syndrome (Yung et al., 1997).

The observation that several susceptibility genes (*STAT4* or *MECP2*) bear connections with DNA methylation and the existence of polymorphisms in genes that can influence DNA methylation prompted further investigation of epigenetic changes in lupus. Initial candidate gene studies revealed several pathways in which aberrant gene expression due to DNA demethylation was linked with SLE development (Huck and Zouali, 1996). Abnormal hypomethylation of CD4<sup>+</sup> T-cell DNA could contribute to the pathogenesis of lupus-like diseases (Ballestar et al., 2006), and this phenomenon was associated with reduced expression and activity of DNMT1 in patient CD4<sup>+</sup> T cells (Deng et al., 2001; Dubroff and Reid, 1980; Balada et al., 2008; Lei et al., 2009). In a genome-wide DNA methylation study, 236 hypomethylated and 105 hypermethylated CG sites were identified among 27,578 CG sites located within the promoter regions of 14,495 genes in lupus CD4<sup>+</sup> T cells, as compared to normal controls (Jeffries et al., 2011). Among the hypermethylated genes identified, several genes are overrepresented in gene ontologies of metabolic pathways and responses to micronutrients, suggesting a link between environmental factors and epigenetic modifications. They also suggest that DNA methylation changes in specific loci correlate with lupus disease activity.

Studies of T cells from lupus patients also showed reduced expression of DNMT1 and DNMT3a, as compared to normal subjects, but other investigations did not reveal such differences (Balada et al., 2008). These disparities could be due to the inclusion of distinct ethnic groups of patients or different disease activities. It is also possible that an mRNA expression was not a reflection of protein activity of the DNMTs. Mechanisms that could contribute to reduced DNMT1 expression include increased expression of protein phosphatase 2A, known to suppress ERK signaling and DNMT1 activity (Sunahori et al., 2013). Altered activation of protein kinase C delta also can reduce activation of extracellular signal-regulated kinases (ERKs) and impair DNMT1 activity, which could result in reduced DNA methylation and overexpression of costimulatory molecules (CD11A, CD70, and CD40L), proinflammatory cytokines (IL-17A) and IFN-regulated genes (Gorelik et al., 2015).

Because lupus PBMCs express high levels of IL-10 mRNA and protein, and since the serum levels of the potent B-cell stimulator IL-10 correlate with disease activity and severity, it has been hypothesized that the Th2 cytokines IL-10 and IL-13 may be upregulated in SLE due to an aberrant DNA methylation of their promoter regions in CD4<sup>+</sup> T cells, thereby contributing to the activation of the humoral immune arm and triggering lupus disease activity. In one study, methylation of C/G pairs within the IL-10 and IL-13 promoters was found to be significantly reduced in T cells from SLE CD4<sup>+</sup> T cells, as compared with healthy control samples, and the methylation status was inversely correlated with the levels of IL-10 and IL-13 transcripts and proteins, as well as with disease severity (Zhao et al., 2010). Furthermore, treatment of healthy CD4<sup>+</sup> T cells with the methylation inhibitor 5-azacytidine triggered IL-10 and IL-13 expression to levels similar to those observed in SLE CD4<sup>+</sup> T cells, suggesting an important role of DNA methylation in regulating the expression of Th2 cytokines in SLE. These findings may provide a basis for the design of a new therapy aimed at reversing the epigenetic alterations of gene expression in SLE patients.

## Histone Modifications in Systemic Lupus Erythematosus

In addition to altered DNA methylation, abnormal histone marks are thought to contribute to the pathophysiology of SLE. Global H3 and H4 hypoacetylation characterizes CD4<sup>+</sup> T cells from SLE patients (Hu et al., 2008). In one study, significant clusters of aberrantly expressed genes were found in SLE, including those coding for chemokines, which are strongly associated with altered H4 acetylation (Zhang et al., 2010). Other investigators reported that patient T cells exhibit permissive modifications in histone proteins at the IL-17 locus (increased H3K18ac and reduced levels of H3K27me3), which could contribute to the uncontrolled expression of proinflammatory IL-17A (Hedrich et al., 2012). In parallel, the same research group found that the *IL-2* gene undergoes epigenetic silencing in T cells from lupus patients, with histone modifications, impaired histone acetylation and increased methylation being repressive (Hedrich et al., 2012). It is possible that these histone modifications contribute to shape the effector phenotype of T cells from lupus patients.

Overexpression of the CD70 receptor on lupus CD4<sup>+</sup> T cell was proposed to be due to the hypomethylation of the promoter of its encoding gene, *TNFSF7*. Yet studies of lupus CD4<sup>+</sup> T cells also indicated that, in addition to DNMT inhibitors, HDAC inhibitors, such as TSA, could impact CD70 overexpression. Consistently, permissive histone modifications (H3K4 hypoacetylation and H3K4 dimethylation) are frequently increased in lupus patients and are in correlation with disease activity. Thus both deregulated histone marks and DNA hypomethylation within the *TNFSF7* promoter likely contribute to lupus pathogenesis by the promotion of CD70 expression (Yang et al., 2015).

## MicroRNA in Systemic Lupus Erythematosus

miRNAs play an important role at different stages of cell activity, and in lupus, several observations suggest that miRNA expression could represent an indicator of disease progression. In a study of 23 SLE patients and 10 healthy controls, seven miRNAs (miR-196a, miR-17-5p, miR-409-3p, miR-141, miR-383, miR-112, and miR-184) were downregulated and nine miRNAs (miR-189, miR-61, miR-78, miR-21, miR-142-3p, miR-342, miR299-3p, miR-198, and miR-298) were upregulated in patients, as compared with healthy controls (Dai et al., 2007). In further studies using pilot expression profiling, underexpression of miR-146a was identified in PBMCs from SLE patients (Tang et al., 2009), and miR-146a was found to negatively regulate type-I IFN induction by TLR-7 signaling. The strong association between miR-146a levels and clinical disease activity suggested that it may serve as a new disease biomarker and that miRNA could serve as a therapeutic target for SLE treatment (Tang et al., 2009). In another study, miR-125a was found to be reduced, and the expression of its predicted target gene, KLF13 (encoding a transcription factor) that regulates the expression of the chemokine (C-C motif) ligand 5 (CCL5) in T lymphocytes was increased (Zhao et al., 2010). In addition, miR-125a negatively regulated RANTES expression by targeting KLF13 in activated T cells. In another study, screening of approximately 1000 human miRNAs indicated altered expression that was related to disease development and activity (Amarilyo and La Cava, 2012). Methylation profiling also revealed that *IL-10* and *IL-1R2* genes exhibit decreased methylation levels in SLE, as compared to healthy controls, and these decreases correlated with greater disease activity (Lin et al., 2012). It is intriguing that *IL-6* gene hypomethylation was proposed to play a role in lupus kidney damage. Consistently, hypomethylated *IL-6* and *IL-6* overexpression were found to correlate with the presence of autoantibodies and immune complexes.

In SLE, as well as in the antiphospholipid syndrome (APS), there is an increased tissue factor (TF) expression in monocytes and endothelial cells (ECs). The fact that, in several web databases and algorithm target predictions, miR-19b and miR-20a were reported to target TF expression led to a study that tested whether miRNA levels may influence TF levels in patients. In APS, the levels of these two miRNAs were decreased in comparison with monocytes from healthy controls. In monocytes from SLE, miR-20a levels were also lower than those from healthy subjects (Teruel et al., 2011). In addition, the reduced expression of miR-19b and miR-20a was inversely correlated with TF cell surface expression.

In line with these findings, one investigation disclosed that among the 11 miRNA that showed increased or decreased expression in SLE CD4<sup>+</sup> T cells, miR-126 was significantly overexpressed, and its upregulation was inversely correlated with DNMT1 protein levels (Zhao et al., 2011). miR-126 reportedly could directly inhibit DNMT1 translation by interacting with its 3'-UTR, leading to a significant reduction in DNMT1 protein levels. This observation suggests that overexpression of miR-126 can cause demethylation and upregulation of genes encoding LFA-1 (CD11a) and CD70, two receptors that have been linked to disease activity. Importantly, knocking down miR-126 in SLE CD4<sup>+</sup> T cells reduced their autoactivity and their stimulatory effect on IgG production

in cocultured B cells (Zhao et al., 2011). This link between miRNA126 expression and reduced MAPK activity, which could subsequently result in reduced DNMT1 expression in lupus T cells (Zhao et al., 2011), illustrates how epigenetic alterations can influence the expression of ncRNA.

Recent investigations suggest that, in SLE, miRNAs also can regulate DNA methylation by targeting the DNA methylation machinery. In one study, miR-21 and miR-148a were found to be upregulated in CD4<sup>+</sup> T cells from both patients with lupus and in MRL-*lpr* mice (Pan et al., 2010). Whereas miR-21 indirectly downregulated DNMT1 by targeting its upstream regulator (Ras guanyl-releasing protein 1), miR-148a directly downregulated DNMT1 by targeting the protein-coding region of its transcript, leading to a derepression of autoimmune-associated methylation-sensitive genes in CD4<sup>+</sup> T cells, such as CD70 and LFA-1 (CD11a). An alleviation of hypomethylation could also be induced in CD4<sup>+</sup> T cells from lupus patients by transfection with miR-21 and miR-148a inhibitors (Pan et al., 2010).

## SJÖGREN'S SYNDROME

In this disease, studies have focused on analyzing DNA methylation alterations in mechanotransduction, a mechanism that allows the conversion of mechanical stimuli into chemical activity. By translating mechanical forces and deformations into biochemical signals, mechanotransduction enables cells to sense their physical three-dimensional environment. In turn, these signals can adjust cellular and extracellular structures. Experimental evidence suggests that a physical continuum directly connects the extracellular matrix (ECM) to the cellular nucleus (Herrmann et al., 2007). An example of a mechanotransduction-mediated mechanism is the production of lactotransferrin by glandular cells: high levels of lactotransferrin mRNA have been detected in a cell fraction enriched in epithelial cells from salivary glands of patients with Sjögren's syndrome (pSS), together with an altered distribution of  $\alpha 6\beta 4$  integrin and an acinar cell shape (Perez et al., 2009). Increased transcription of the lactotransferrin gene suggests a role of mechanotransduction-signaling pathways in pSS etiopathogenesis.

### DNA Methylation in Sjögren's Syndrome

The role of epigenetic processes in the development of glandular damage was investigated through hemidesmosome (HD) organization–mediated mechanisms. HDs are protein complexes that mediate epithelial cell adhesion to the ECM and are composed of an  $\alpha 6\beta 4$  integrin dimer that binds to laminin, plectin, and other proteins (bullous pemphigoid antigens BP180 and BP230). Suggestive of epigenetic control, reduced levels of BP230 mRNA were found in epithelial cells of patients with pSS in comparison with controls, and, in contrast, an accumulation of BP230 on the basal surface of acini was documented (Gonzalez et al., 2011). The reduced levels of BP230 mRNA could be related to an increased methylation index of CpG islands. In addition, differential methylation changes of the *BP230* gene promoter may explain the up- and downregulations detected in patients with pSS. It is of related interest that CD70 expression was elevated, and the changes correlated with a decrease in TNFSF7 promoter methylation in pSS CD4<sup>+</sup> T cells compared to controls (Yin et al., 2010). As for SLE, demethylation of the CD70 promoter regulatory elements could contribute to CD70 overexpression in pSS CD4<sup>+</sup> T cells and, thereby, to autoreactivity.

More recently, genome-wide DNA methylation profiles were analyzed in CD4<sup>+</sup> T cells and CD19<sup>+</sup> B cells from female pSS patients (Miceli-Richard et al., 2016). Remarkably, methylation alterations were mainly detected in B cells, with an enrichment of genes with differentially methylated positions (DMPs) in at-risk loci, including Interferon regulated genes. In addition, DFPs were overrepresented in B cells from patients with active disease.

In another genome-wide DNA methylation study of human labial salivary glands (LSGs) from 28 female pSS patients, 7820 DMPs associated with disease status were reported, including 5699 hypomethylated and 2121 hypermethylated DMPs (Cole et al., 2016). The investigators identified 57 genes, the promoters of which were enriched for DMPs and implicated pathways previously thought to be involved in disease-related processes. However, since the basal DNA methylation level in lymphocytes is lower than in epithelial cells, it remains possible that lymphocyte infiltration could account, at least partly, for the aberrant methylation described in LSG tissues.

## miRNAs in Sjögren's Syndrome

Studies of miRNAs in pSS pathogenesis have centered on analyzing miRNAs from salivary exosomes. Thus miRNA profiling of salivary glands of healthy controls and patients with pSS who were classified according to a high or a low focus score revealed patterns that could distinguish control subjects and the two pSS groups (Alevizos et al., 2011). In particular, the expression of two miRNAs (768-3p and 574) was inversely correlated with the focus score, and downregulation of the mir-17–92 cluster was observed in half of the pSS patients with a high focus score (a “focus” refers to a cluster in a LSG biopsy of at least 50 lymphocytes, based on survey of at least 4 lobules). Here, it is remarkable that previous studies had associated downregulation of the mir-17–92 cluster with an accumulation in pro-B cells and a marked reduction of pre-B cells, which have been associated with lymphoproliferative and autoimmune diseases (Mendell, 2008; Xiao et al., 2008). However, a large number of studies are required to validate the usefulness of miRNAs in salivary glands as diagnostic markers of pSS.

## SYSTEMIC SCLEROSIS

Systemic sclerosis (scleroderma, SSc) is a multisystem disorder of unknown etiology. The disease is characterized by vascular injury, immune activation, and skin fibrosis. Tissue fibrosis of internal organs often leads to organ dysfunction, causing morbidity and mortality. Because of the complex nature of the disease, there is no efficacious treatment for SSc. Its pathogenesis is believed to involve four cell types, namely, microvascular ECs, lymphocytes, macrophages, and fibroblasts, and to require three self-amplifying events, namely, microvascular alterations, immune activation, and fibrosis in multiple organs. The disease has a genetic component. For example, having a family history of SSc represents a high-risk factor for developing the disease (Arnett et al., 2001); but environmental factors, such as silica, organic solvents, welding fumes, viruses, and drugs, are thought to be involved in triggering SSc. It is possible that these factors are able to affect gene expression through epigenetic mechanisms that could contribute to the onset, disease severity, and response to medication of scleroderma.

## DNA Methylation in Scleroderma

DNA methylation studies revealed that global hypomethylation is common among various cell types, and a number of genes are differentially methylated. Early studies showed a significant reduction in DNMT1, MBD3, and MBD4, possibly leading to a reduction of DNA methylation in CD4<sup>+</sup> T cells (Lei et al., 2009). Similarly, overexpression of CD40L in CD4<sup>+</sup> T cells of female SSc patients was suggested to be due to DNA hypomethylation of CD40L promoter and enhancer (Lian et al., 2012). In parallel, DNA methylation was proposed to account for perturbation of X chromosome inactivation (Selmi et al., 2012), supporting the view that epigenetic mechanisms could indeed contribute to the gender bias in SSc.

On the other hand, studies of fibroblasts indicated upregulation of a number of epigenetic mediators in SSc, as compared to normal fibroblasts (Wang et al., 2006; O'Reilly et al., 2016). In a genome-wide level DNA methylation analysis covering over 485,000 CpG sites in the entire genome, a total of 2710 and 1021 differentially methylated CpG sites were identified in diffuse SSc and limited SSc, respectively, with a large proportion of them being hypomethylated (Altorok et al., 2015). Remarkably, this unbiased approach led to the identification of genes that code for collagen, ECM, transcription factors, and those that are involved in the TGF- $\beta$  pathway and the Wnt pathway. In addition, there were significant differences in DNA methylation patterns between diffuse and limited SSc patients, suggesting that these two different disease subsets are epigenetically distinct.

## Histone Modifications in Scleroderma

As regards histone modifications, aberrant expression of histone writers and erasers, together with histone codes in different cell types were reported. In one study, hypermethylation of CpG islands and deacetylation in the FLI-1 promoter region in SSc fibroblasts and skin biopsy specimens were found to be associated with an increased production of type I collagen (Wang et al., 2006). Treating the cells with both the DNMT inhibitor 5-aza-2'-deoxycytidine and the HDACi TSA resulted in decreased collagen levels. Remarkably, there was a direct influence of DNMT3A on the degree of histone modification; and a reduced DNMT3A expression resulted in an enhanced histone acetylation, further underlining the repressive nature of DNMT3A on acetylation of core histones. The beneficial therapeutic use of HDACi has been shown in an animal model of SSc. Knockdown of

HDAC7 in skin fibroblasts and treatment of bleomycin-induced skin fibrosis in mice with TSA remarkably reduced the accumulation of ECM proteins and fibrosis (Huber et al., 2007).

More recently, studies of SSc B cells showed global H4 hyperacetylation and H3K9 hypomethylation, together with expression changes in JHDM2A, HDAC2, HDAC7, and SUV39H2 (Wang et al., 2013). Whereas global H4 acetylation correlated with disease activity, HDAC2 expression negatively correlated with skin thickness, which may suggest that these histone modifications could be pathogenic. Examining the impact of histone modifications on SSc fibrosis, other investigators reported an increase in HDAC4 and HDAC5 expression in SSc ECs and a reduction in HDAC6 expression (Tsou et al., 2016). In addition, levels of EZH2 and H3K27me3 were upregulated in SSc ECs, as compared to normal ECs (Tsou et al., 2016). It is possible that by repressing proangiogenic genes or activating antiangiogenic genes, EZH2 inhibits angiogenesis in SSc ECs.

## MicroRNAs in Scleroderma

A number of studies were devoted to probing ncRNAs in different cell types and tissues from SSc patients. In the investigation of vascular dysfunction, miR-193b was found to be significantly downregulated in SSc fibroblasts and skin (Iwamoto et al., 2016). Interestingly, manipulation of this miRNA in SSc dermal fibroblasts altered urokinase-type plasminogen activator (uPA) expression, which may suggest a role of this pathway in SSc pathogenesis. Not only uPA induced vascular smooth muscle cell proliferation, but it also inhibited cell apoptosis. Since downregulation of miR-193b led to increased uPA production, this pathway could contribute to the proliferative vasculopathy seen in SSc.

The TGF- $\beta$  pathway is thought to be a key regulator of fibrosis, and a number of ncRNA studies focused on activation of this pathway and its downstream signaling effectors. In one study, miR-150, which targets integrin  $\beta$ 3 and activates the latent form of TGF- $\beta$ , was downregulated in SSc skin and dermal fibroblasts (Honda et al., 2013). In addition, miR-21 can be regarded as an enhancer that amplifies the effect of TGF- $\beta$  in SSc fibrosis (Zhu et al., 2013). Specifically, the induction of miR-21 by TGF- $\beta$  could downregulate Smad7, which inhibits profibrotic signals of TGF- $\beta$ .

miR-29 exerts a classical antifibrotic potential, and several studies support the conclusion that it plays an antifibrotic role in SSc (Iwamoto et al., 2016; Maurer et al., 2010). Its overexpression, which can be modulated by TGF- $\beta$ , decreased type I and type III collagen expression in SSc dermal fibroblasts. In addition to miR-29a, TGF- $\beta$  also can negatively modulate miR-196a and let-7a expression in fibroblasts and modulates the expression of their target, type I collagen.

Beside TGF- $\beta$ , miR-155 reportedly enhanced Wnt/b-catenin and Akt signaling pathways in SSc fibroblasts by directly targeting casein kinase 1a (CK1a) and src homology 2-containing inositol phosphatase-1 (SHIP1) (Yan et al., 2016). Consistently, mice deficient in miR-155 showed reduced skin fibrosis and inhibition of the Wnt/b-catenin and Akt pathways.

In more recent studies, miRNA profiles were determined in serum and their relevance to disease was assessed. For example, a statistical model was built from 26 circulating miRNAs derived from 120 SSc individuals to distinguish healthy controls, SSc, and SLE patients (Steen et al., 2015). A combination of the miR-17–92 cluster could discriminate between the control and diseased groups, indicating that analyzing a cluster of circulating miRNA could represent a promising strategy for disease classification and prediction.

## ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODIES—ASSOCIATED VASCULITIS

In this pathology of blood vessel walls, inflammation can lead to heterogeneous clinical manifestations. The activation of neutrophils represents a hallmark of antineutrophil cytoplasmic autoantibodies (ANCA)—associated vasculitis. It results in an increased adherence and transmigration to the vascular endothelium, where neutrophils produce reactive oxygen species and release granule constituents, including proteolytic enzymes (Kallenberg et al., 2006). To account for this activation, it has been proposed that the major neutrophil granule protein ANCA autoantigens—proteinase 3 (PR3) and myeloperoxidase (MPO)—are aberrantly expressed in mature neutrophils of ANCA patients (Ohlsson et al., 2005). In contrast, silencing mechanisms would maintain normal expression of PR3 and MPO in mature neutrophils of healthy controls. Support to this view comes from observations showing that aberrant expression of proteolytic enzymes in ANCA disease patients could result from active gene transcription, suggesting a failure in normal gene silencing (Ciavatta et al., 2010). Specifically, at the PR3 and MPO loci, levels of H3K27me3, a mark of transcriptionally silent chromatin, were reduced in

neutrophils of ANCA patients relative to those of healthy controls. This reduced H3K27me3 signature was associated with altered histone modification mechanisms, that is, an overexpression of the H3K27me3 demethylase jumonji C domain-containing protein 3 (JMJD3) in patients. The decreased histone methylation could result from a defective recruitment of the H3K27 methyltransferase enhancer of zeste homolog 2 (EZH2). A potential additional silencing mechanism may be DNA methylation because a CpG island in the *MPO* gene was found to be unmethylated in patients, and there was a significant increase in methylated DNA at this CpG island in healthy controls (Ciavatta et al., 2010). Overall, the evidence suggests that the transcriptional regulation of *PR3* and *MPO* genes may involve an epigenetic process in normal neutrophils that is perturbed in neutrophils of ANCA-associated patients. A decreased histone methylation and an increased histone demethylation would give rise to a permissive chromatin structure at the *MPO* and *PR3* genes.

## EPIGENETICS OF IMMUNE TOLERANCE TO SELF

### Dysruption of B Cell Tolerance to Self

In the B cell compartment, immune tolerance operates through several mechanisms (Zouali, 2007). Their epigenetic regulation has been discussed (Zouali, 2013). In the B-cell compartment, self-tolerance operates by several processes, including deletion, anergy and receptor editing, a powerful mechanism that allows autoreactive B cells to revise their receptors and to escape apoptotic death (Radic and Zouali, 1996). Several studies found that receptor editing is impaired in SLE and RA and that this abnormality could account for the ineffective silencing of B cells that have acquired autoreactive receptors (Bensimon et al., 1994; Suzuki et al., 1996; Samuels et al., 2005; Yurasov et al., 2005; Faber et al., 2006; Zouali, 2008). Further insight into the molecular basis of inefficient editing as a potential cause of autoimmunity comes from studies based on different approaches. One line of evidence comes from studies on drug-induced lupus. This autoimmune disease can be induced by more than 40 medications, such as the antihypertensive drug hydralazine (Zouali, 2011). Interestingly, aromatic amines and hydralazine derivatives can be found in a wide variety of compounds used in agriculture and industry, and commercial applications. Hydralazine itself also occurs in tobacco and tobacco smoke, and a lupus-like syndrome has been reported in individuals who have been in contact with these agents (Reidenberg et al., 1993). To test the hypothesis that drugs that alter DNA methylation and trigger a lupus-like syndrome can disrupt the mechanisms that maintain B cell tolerance, the effects of hydralazine on receptor editing were investigated in mice harboring human transgenic immunoglobulins. The studies revealed that by disrupting the ERK signaling pathway, hydralazine alters DNA methylation, reduces receptor editing in B lymphocytes, and contributes to the generation of pathogenic autoreactivity (Mazari et al., 2007). The data also support the view that epigenetic alterations contribute to exacerbated activation or deregulation of the mechanisms that maintain tolerance to self-antigens. Future studies will determine whether other drugs and xenobiotics that trigger autoimmunity in humans also can act through similar mechanisms.

For T cells, central tolerance takes place in the thymus through negative selection, where developing thymocytes are deleted if they react too strongly with self-antigens presented by the MHC. However, since not all peripheral self-antigens are adequately presented in the thymus, central tolerance is incomplete, and self-reactive T cells escape negative selection, and migrate to secondary lymphoid organs. In the periphery, autoreactive lymphocytes must be inactivated by deletion or by suppression by Tregs, and/or by cell-intrinsic programs that lead to a state of functional unresponsiveness, called anergy. Understanding the regulatory mechanisms that maintain or break T-cell tolerance to self-antigens is required to prevent autoimmunity.

### Epigenetic Regulators of Tolerant T Cells

Studies of histone acetylation in vitro and ex vivo suggested that immune tolerance is under epigenetic influences. A variety of HDACis, such as butyrate or trichostatin A (TSA) and suberoylanilide hydroxamic acid (SAHA), induce anergy in Th1 cell cultures (Edens et al., 2006), as characterized by an inhibition of proliferation accompanied by a reduction of IL-2 production. The effect was attributed to chromatin remodeling at the IL-2 promoter, as well as to acetylation of transcription factors, such as NF- $\kappa$ B (Matsuoka et al., 2007).

To identify genes and pathways critical for maintenance of unresponsiveness, an in vivo mouse model was used to perform a microarray analysis of naïve (N), memory (M), and tolerant (T) T cells (Schietinger et al., 2012). The study revealed that T cells harbor a tolerance-specific gene signature markedly distinct from that of N and M cells, and 164 genes were identified as “tolerance-specific” gene sets representing uniquely overexpressed genes,

including negative regulators of cell signaling and proliferation, transcription factors, and phosphatases. Genes modulating cell cycle, cell division, nucleosome assembly, mitosis, and DNA replication were also highly over-represented and upregulated in T cells. Thus T cells “remember” the tolerance program established during the initial encounter(s) with self-antigen in the periphery, raising the question of how such memory is encoded. The fact that transcripts of numerous genes regulating chromatin modification were enriched in T cells (e.g., *Jmjd3*, *Dnmt1*, *Hat1*, *Hdac2*, *Hdac3*) supports the view that epigenetic factors are involved. Consistently, genome-wide miRNA profiling revealed that N, M, and T cells had distinct miRNA expression patterns (Schietinger et al., 2012). Thus these insights into the regulatory mechanisms that maintain or break self-tolerance may lead to new epigenetic strategies for the treatment of autoimmunity.

## DNA Methylation in Treg Development and Function

*Foxp3* is a member of forkhead/winged-helix family of transcription factors that act as a “master” regulator for the development and suppressive function of Tregs. Its constitutive expression is necessary for the suppressive function of Tregs, and mutation or deficiency of *Foxp3* leads to the development of autoimmune diseases. Genetic defects in *Foxp3* cause the *scurfy* phenotype in mice and IPEX syndrome (immune dysfunction, polyendocrinopathy, enteropathy, X-linked syndrome) in humans (Khattari et al., 2003). In the thymus, a subset of CD4<sup>+</sup>CD25<sup>+</sup> T cells develops into Foxp3<sup>+</sup>CD4<sup>+</sup> T cells, known as natural Tregs (nTregs). However, in peripheral lymphoid organs, TGF-β can induce naïve CD4<sup>+</sup>CD25<sup>-</sup> T cells to develop into Foxp3<sup>+</sup>CD4<sup>+</sup> T cells, known as adaptive or induced Tregs (iTregs). Ex vivo culture of peripheral naïve CD4<sup>+</sup>CD25<sup>-</sup> T cells in the presence of TGF-β induces expression of *Foxp3* and provides a method to generate Foxp3<sup>+</sup> Tregs ex vivo. Importantly, nTregs and iTregs exhibit different functional characteristics (Tran et al., 2007), and nTregs are more stable than iTregs, a feature that may be related to the epigenetic regulation of *Foxp3* (Lal et al., 2009; Polansky et al., 2008).

Early studies showed that the differentiation of T helper cells is under epigenetic regulation through CpG methylation (Lee et al., 2001; Wilson et al., 2009). As regards Tregs, different regulatory *cis*-elements are present in the *Foxp3* locus, upstream of the transcriptional start site (−600 to −1 bp) at the proximal promoter where the methylation status of the CpG residues plays an essential role in *Foxp3* expression. Thus 10%–45% of the CpG sites in the *Foxp3* proximal promoter (−250 to +1) are methylated in naïve CD4<sup>+</sup>CD25<sup>-</sup> T cells, whereas all are demethylated in nTregs (Kim and Leonard, 2007), and TGF-β induces demethylation of CpG at this site in CD4<sup>+</sup>CD25<sup>-</sup> T cells. That methylation of the proximal promoter is an important regulator of *Foxp3* expression also is supported by the observation that this region is ≈70% methylated in human CD4<sup>+</sup>CD25<sup>lo</sup> cells compared with ≈5% in CD4<sup>+</sup>CD25<sup>hi</sup> T cells (Janson et al., 2008). Further support comes from the fact that CpG residues in an intronic region (+4201 to +4500) are completely methylated in naïve CD4<sup>+</sup>CD25<sup>-</sup> T cells and fully demethylated in mouse (Polansky et al., 2008; Kim and Leonard, 2007) and human nTregs (Baron et al., 2007). Also, an upstream enhancer (−5786 to −5558 bp) is methylated in naïve CD4<sup>+</sup>CD25<sup>-</sup> T cells, activated CD4<sup>+</sup> T cells, and iTFoxp3<sup>+</sup> Tregs but is demethylated in nTregs (Lal et al., 2009). Together, these reports demonstrate that *Foxp3* is regulated by complex mechanisms where many extracellular signals control transacting factors as well as chromatin remodeling through covalent modification of CpG DNA. Understanding these signals and their cumulative intracellular effects on *Foxp3* *cis*-elements at different T-cell developmental stages will be a key for therapeutic manipulation of T-cell responses.

## Impacts of Histone Acetylation on Development and Function of Regulatory T Cells

In addition to DNA methylation, Treg development and function are under influences of histone acetylation. For example, following TCR stimulation of murine T cells, class II HDACs are mainly expressed in Tregs (Tao et al., 2007). On the other hand, HDACi enhances *Foxp3* expression in both CD4<sup>+</sup>CD25<sup>-</sup> and CD4<sup>+</sup>CD25<sup>+</sup> T cells, suggesting that deacetylation directly regulates *Foxp3* expression and enhances Treg suppressive functions (Tao et al., 2007; Tao et al., 2007; Lucas et al., 2009). Another class II HDAC, HDAC9, interacts with *Foxp3* and down-regulates its acetylation. Treatment with the class I and II HDACi TSA enhances *Foxp3* acetylation and Treg function (Li et al., 2007). In mice, administration of pan-HDACi increased *Foxp3* gene expression, as well as the production and suppressive function of Tregs in vitro. In addition, HDAC9 proved particularly important in regulating *Foxp3*-dependent suppression, as demonstrated by studies in HDAC9-knockout mice (Tao et al., 2007). At the molecular level, optimal functions of Tregs required acetylation of several lysines in the forkhead domain of *Foxp3* (Wang et al., 2009).

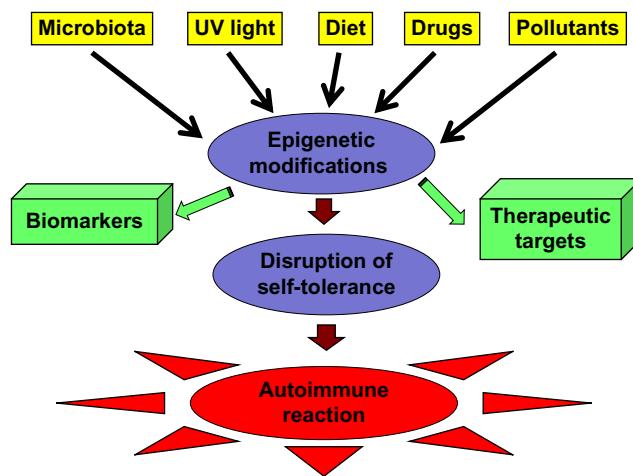

## Epigenetic Modulation of Regulatory T-Cell Stability

Several observations indicate that  $\text{Foxp}3^+ \text{CD4}^+$  Tregs encompass a heterogeneous population in mice (Komatsu et al., 2009) and humans (Miyara et al., 2009) and that their phenotype and functions are not as stable as initially thought (Zhou et al., 2009; Lee et al., 2009). For example, a fraction of  $\text{Foxp}3^+ \text{CD4}^+$  nTregs adoptively transferred to lymphopenic mice converted into  $\text{Foxp}3^-$  T cells (Komatsu et al., 2009). Under inflammatory conditions,  $\text{Foxp}3^+$  Tregs lose  $\text{Foxp}3$  expression and suppressive functions in an IL-6-dependent manner (Pasare and Medzhitov, 2003). The fact that different subsets of Tregs exhibit different levels of CpG DNA methylation at the  $\text{Foxp}3$  locus suggests that Treg instability may be under epigenetic controls (Miyara et al., 2009). Thus the increased methylation of CpG at the  $\text{Foxp}3$  locus was linked with a lower  $\text{Foxp}3$  expression, decreased Treg stability, and reduced suppressive Treg function (Lal et al., 2009; Miyara et al., 2009). In addition, nTregs possess demethylated CpG at the  $\text{Foxp}3$  locus and show stable  $\text{Foxp}3$  expression, whereas TGF- $\beta$ -induced Tregs show methylated CpG and do not maintain constitutive  $\text{Foxp}3$  expression after restimulation in the absence of TGF- $\beta$ . It is of further interest that HDACi can modulate Th cellular phenotypes. In one study, the HDACi TSA could induce a profound negative effect on the emergence of IL-17-producing cells from Tregs (Koenen et al., 2008). Whereas sorted Tregs could be polarized from the Treg phenotype to Th17 cells in a defined cytokine milieu, this could be prevented by the presence of TSA (Koenen et al., 2008). Finally, while it is known that various cross talks between histone methylation and acetylation exist, their impact on T-cell polarization is being addressed. Investigators identified a highly conserved CpG island within a FoxP3 enhancer region that is methylated in peripheral CD4 $^+$  T cells, but not in nTreg (Lal et al., 2009). This region was histone H3 acetylated and bound by Sp1 and TGF-inducible early gene-1 (TIEG1). Removing this methylation in non-Tregs resulted in an increased and stable FoxP3 expression. This effect is similar to other reported modulations of FoxP3 expression via methylation (Polansky et al., 2008).

## GENETIC AND EPIGENETIC INTERACTIONS IN AUTOIMMUNE DISEASES

It is plausible that genetic and nongenetic effects interact to induce complex diseases. This scenario is likely to true for autoimmune diseases. For example, exposure of females who are slow acetylators—a genetically determined trait—and bear the HLA-DR4 genotype to hydralazine, an antihypertensive, demethylating drug, can trigger SLE (Russell et al., 1987). Similarly, subjects who carry the HLA-DR4 risk allele and smoke are at increased risk of developing RA (Meng et al., 2017). Specifically, DNA methylation of the CpG promoter site cg21325723 can mediate gene-environment interactions between the RA-associated single-nucleotide polymorphism rs6933349 and smoking. Remarkably, this interaction imparts the risk of developing RA-associated anti-trullinated peptide autoantibodies and has been observed in both Caucasian and Asian subjects (Meng et al., 2017). Thus interactions resulting from altered gene expression linked to epigenetic changes and nongenetic factors have the potential to trigger an autoimmune process that leads to autoimmune disease (Fig. 25.3).

Direct comparison of identical twins represents a unique approach to test “environmental epigenetics” because DNA sequence differences, including single-nucleotide polymorphisms, which would be abundant in singleton-based studies, cannot interfere. Not surprisingly, twin studies demonstrated the existence of genome-wide epigenetic differences that potentially could explain phenotypic differences (Kaminsky et al., 2009; Fraga et al., 2005). They demonstrated how epigenetic differences between MZ twins become more pronounced with age, supporting the notion that “epigenetic drift” plays a role in the divergence of MZ phenotypes (Fraga et al., 2005). More recently, a collection of identical twins discordant for SLE and two other related systemic autoimmune diseases (RA and dermatomyositis) was used to perform a high-throughput analysis of DNA methylation changes (Javierre et al., 2010). Only SLE samples exhibited significant changes in the DNA methylation status at both the global and sequence-specific levels in comparison with their healthy, discordant twins and compared with unrelated matched normal controls. Comparison of SLE twins with their corresponding healthy twins showed a decrease in global 5-methylcytosine content and a change in DNA methylation status of the CpG-rich region of the ribosomal DNA repeat, which contains the transcribed 18S and 28S genes. The study also yielded a list of epigenetically deregulated DNA sequences in SLE. Importantly, gene ontology analysis revealed an enrichment in categories associated with immune function, and individual analysis confirmed the relevance of DNA methylation changes in genes to SLE pathogenesis, supporting the notion that epigenetic alterations may be critical in the clinical manifestations (Zouali, 2011; Javierre et al., 2010). The results reinforce the notion that, for a particular genetic background, environmental factors can modulate SLE onset. However, it remains unclear whether

**FIGURE 25.3** A current trend of linking epigenetics to autoimmune diseases.

In genetically susceptible individuals (single nucleotide polymorphisms, copy number variation, etc.), the complex interplay between the environment, the epigenome, and the genome can lead to a variety of epigenetic modifications. The list of environmental factors covers a range of not only deleterious factors (toxic materials, radiation, drugs, and pollution) but also lifestyle (diet, smoking, and stress). The resulting epigenetic alterations can affect normal gene expression and lead to loss of immune tolerance to self in both the B- and T-cell compartments. This tolerance break could account for the emergence and/or progression of autoimmune diseases. The abnormal epigenetic marks identified in this group of disorders could allow the discovery of biomarkers for disease diagnosis and monitoring, and, possibly, the design of novel therapeutic strategies.

environmental factors caused the epigenetic changes observed, or whether environmental factors cause disease by some unknown mechanisms, possibly associated with inflammatory and immune responses that give rise to epigenetic changes.

## EPIGENETICS CHANGES ASSOCIATED WITH ENVIRONMENT TRIGGERS IN AUTOIMMUNITY

It is possible that a close interplay between environmental triggers, epigenetic, and genetic factors is responsible for the loss of immunological tolerance to self, leading to autoimmune disease. There is evidence to suggest that the environment can subvert epigenetic regulatory pathways, causing overexpression of normally silenced genes. Environmental factors that could play a role include exposure to ultraviolet (UV) light, toxic chemicals, dietary components, drugs, and infection.

### Exposures to Ultraviolet Light

In SLE, up to 73% of the patients develop photosensitivity, and UV light has long been associated with disease exacerbation (Wysenbeek et al., 1989). UV irradiation is known to lead to specific demethylation events during subsequent rounds of replication (Wysenbeek et al., 1989; Kastan et al., 1982). It reduces DNMT1 mRNA expression and impairs DNA methylation in T cells from SLE patients (Zhu et al., 2013). Yet, it remains unclear how UV-B affects disease by altering DNA methylation.

### Drugs

Over 40 drugs are able to induce a lupus-like syndrome, including procainamide, hydralazine, propylthiouracil, sulfonamides, D-penicillamine, isoniazid, phenytoin, carbamazepine, methyldopa, quinidine, captopril, acebutolol, and chlorpromazine (Rubin, 2005; Tsay and Zouali, 2008). The mechanisms of drug-induced lupus remain unknown, and several possibilities have been put forward. Two drugs, in particular, are high-risk inducers: procainamide, an antiarrhythmic drug, and hydralazine, an antihypertensive medication. Hydralazine-induced antihistone antibodies are characterized by anti-H3 and anti-H2 IgM antibodies, and procainamide-induced antihistone antibodies by anti-H2a/H2b complex antibodies. Both drugs inhibit DNMT1. Procainamide

acts as a competitive inhibitor, and hydralazine as an indirect inhibitor through its action on the ERK that controls DNMTS transcription. In an experimental model, hydralazine was documented to be able to subvert B cell tolerance to self and to trigger autoantibody production (Mazari et al., 2007).

## Toxic Chemicals

Experimental studies and clinical observations showed that autoimmune disease may be triggered by chronic exposure to various chemicals, including xenobiotic organic and inorganic compounds, silica dust, organic solvents, and petroleum (Pollard et al., 2010). Notorious among them is hydrazine and its derivatives present in a variety of compounds and used in agriculture and industry, including herbicides, photographic supplies, textiles, synthesis of plastics, anticorrosives, rubber products, preservatives, dyes, and pharmaceuticals. Hydrazine is present in mushrooms, penicillium, tobacco, and tobacco smoke; and smokers exhibit a significant increased risk to develop SLE and RA (Klareskog et al., 2007).

In experimental animals, tetramethylpentadecane (TMPD), commonly known as pristane, can trigger autoimmune phenomena. In the test tube, TMPD, which can be found in processed food for human consumption, induces chromatin changes, and, potentially, changes in gene expression (Garrett and Cuchens, 1991). Also of interest is the common industrial solvent trichloroethylene (TCE), known to be able to exacerbate autoimmunity (Cai et al., 2008). This compound was found to alter DNA methylation patterns (Palbykin et al., 2011). Exposure to heavy metals, which have been postulated to be able to trigger autoimmune diseases, can modify gene expression by a variety of epigenetic mechanisms (Martinez-Zamudio and Ha, 2011).

## Microbiome Epigenetics

Recent evidence indicates that the gut microbiome is perturbed in several autoimmune diseases, including SLE, RA, inflammatory bowel disease (IBD), and T1D. Since environmental signals can impact gene expression through epigenetic mechanisms, the human microbiome, as an environmental component inside the human body, could influence host gene expression by epigenetic modifications. Several studies showed that the changes of the composition and/or the function of the human microbiome could have effects on the status of the human epigenome. Translocation of microbial epigenetic enzymes or ncRNAs of the microbiome into host cells could influence the expression of host genes. On the other hand, microbial metabolites can impact the activity of epigenetic enzymes. For example, short-chain fatty acids (SCFAs) can act as HDACis, leading to suppression of inflammation in PBMCs (Vinolo et al., 2011), macrophages (Chang et al., 2014), T cells (Arpaia et al., 2013), and DCs (Singh et al., 2010).

Importantly, the interplay between epigenetics and microbiome is bidirectional. That is, human epigenetic changes can, in turn, result in dysbacteriosis. For example, miRNAs, which are detectable in host feces in the form of extracellular vesicles, can enter bacteria and impact bacterial gene expression. Neonatal mice do not develop a conventional gut microbiota when their Dicer, the cleaving enzyme required for miRNA formation, was inactivated (Liu et al., 2016).

There are examples of the relationship between dysbacteriosis and epigenetic changes in some autoimmune diseases. Thus an inverse correlation between miR-30C and miR-130A levels and autophagy-related proteins was reported in ileal biopsy samples of patients with Crohn's disease, which may suggest that microbiome regulation of miRNA expression and autophagy could be important for IBD pathogenesis (Nguyen et al., 2014). In an experimental model of T1D, pathological changes and gut dysbacteriosis in virus-induced LEW1.WR1 rats could be reversed by HDACis (Hara et al., 2014). However, convincing evidence for the association between microbiome and epigenetics in autoimmune diseases is still missing. It is possible that future work based on the analysis of multiomics of the microbiome and the epigenome could lead to the identification of biomarkers and novel therapeutic targets for autoimmune diseases.

## Dietary Components and Nutri-Epigenomics

A significant increase in the incidence of autoimmune diseases, such as diabetes and MS, in the industrialized countries has led to the hypothesis that diet is a potential environmental risk factor for such disorders. In parallel, studies of the role of dietary influences on gene expression have led to the emergence of a new discipline termed

nutri-epigenomics. It is, for example, conceivable that DNA methylation events and dietary practices, such as micronutrient intake, can influence disease induction and/or progression.

Importantly, epigenetic marks, such as DNA and histone modifications, are dependent on diet-derived substrates and/or intermediary metabolism products. For example, levels of SAM, which plays a pivotal role as a methyl donor in a myriad of biological and biochemical events, including DNA methylation, are dependent on dietary micronutrients, including vitamins B2, B6 and B12, folate, methionine, zinc, and choline (Oaks and Perl, 2014). Since methyl groups from SAM are needed for DNA methylation, diets with insufficient sources of methyl groups can impair SAM synthesis and lead to global DNA hypomethylation (Selhub, 2002).

In lupus patients, there is a reduced global DNA methylation, which could result from alterations of the SAM cycle and/or expression of the gene encoding DNMTs. Patients who have low DNMT1 levels due to environmental exposures, that is, UV light, smoking or infections, could be sensitive to a diet poor in methyl donors. Levels of S-adenosylhomocysteine (SAH), an inhibitor of transmethylation reactions, are often increased, and transmethylation micronutrient levels are decreased in patients with active lupus (Wu et al., 2012). Experimentally, dietary micronutrients that affect DNA methylation could exacerbate or ameliorate disease in a transgenic mouse lupus model (Strickland et al., 2013). It is, therefore, possible that nutritional intakes able to restore a balanced SAM could be useful in the management of disorders exhibiting reduced global DNA hypomethylation.

## TRANSLATIONAL APPLICATIONS OF EPIGENETICS

As in other disorders, epigenetic marks are thought to represent potential therapeutic targets and/or diagnostic markers for disease progression and/or response to treatment.

### Potential Disease Biomarkers

In several autoimmune diseases, differentially methylated regions in the genome were proposed to represent putative disease markers. In RA, for example, peripheral naïve T cells were found to share hypermethylation sites with FLS (Rhead et al., 2017). It will be of interest to confirm that the epigenetic signatures identified can represent valuable biomarkers for the risk of RA or for disease status.

miRNAs are detectable and stable in a variety of body fluids (blood, plasma, synovial fluid, etc.) and are relatively easy to quantify using accessible experimental approaches. In lupus nephritis (LN), miR-26a and miR-30b have been proposed to play an important role. Their expression is downregulated in renal tissues and urine of LN patients (Costa-Reis et al., 2015). In addition, the expression of miR-26a is increased in urinary exosomes, which are cell-derived vesicles that play a key role in intercellular signaling (Ichii et al., 2014). In parallel, miR-29c expression was reported to be predictive of lupus kidney damage (Sole et al., 2015), suggesting that miR-26a and miR-29c could serve as biomarkers of early LN progression. The fact that the expression levels of miRNAs in the serum are generally stable suggests that they could be used as disease biomarkers. However, despite their abnormal expression in SLE, whether miRNAs could serve as biomarkers in stratifying lupus disease remains uncertain.

Caution should be exercised for data interpretation (Churov et al., 2015). First, miRNA expression is under the influence of sex, lifestyle, and environmental factors (Vrijens et al., 2015; Khalifa et al., 2016). Second, data analysis requires using appropriate reference samples and needs to be standardized. Third, the specificity of the changes observed needs to be expressed relative to other inflammatory disorders. Recent observations made during a clinical trial illustrate some of these limitations in using miRNAs as disease biomarkers. In a discovery cohort of RA patients treated with either adalimumab (anti-TNF antibody) or etanercept (a recombinant protein encompassing the TNF receptor and the constant end of the IgG1 antibody), the predicted miRNAs that were targeted by the treatment could not be validated (Cuppen et al., 2016). These disappointing results call for validation of miRNA candidates in independent cohorts, and standardization of tests that would make them suitable for implementation into clinical practice.

### Epigenetic Therapy

It is clear that epigenetic regulation plays a role in disease pathogenesis. However, it remains unresolved whether the epigenetic abnormalities are a consequence of altered disease pathways or the true trigger of the

pathogenesis. Within this limitation, targeting epigenetic pathways for therapeutic purposes could be an attractive approach for treating autoimmune diseases.

The use of drugs to correct epigenetic defects, referred to as epigenetic therapy, is a new and rapidly developing area of pharmacology. Compared to genetic defects, which are permanent, epigenetic defects are more easily reversible with pharmacological intervention. Therefore epigenetic therapy could give rise to agents capable of controlling and, possibly, preventing various diseases (Egger et al., 2004). This offers the possibility of using epigenetic drugs to reverse patterns of epigenetic alterations and to relieve particular conditions, and several drugs initially approved for cancer treatment could, hopefully, possess beneficial properties for multiple autoimmune diseases.

### **Targeting DNA Methylation**

For this epigenetic mark, only an all-or-nothing targeting is possible. The prototypic inhibitor 5-azacytidine was developed as a cytotoxic agent and, subsequently, has been discovered to possess a potent DNMT inhibitor activity. Since the drug is converted into nucleotide triphosphates and is incorporated in place of cytosines into replicating DNA, it is more active in the S-phase of cells. Because it binds both RNA and DNA, it both interrupts mRNA translation and inhibits methylation by trapping DNMTs. In animal models, DNMT inhibitors, such as 5-aza-2'-deoxycytidine, reversed the aberrant hypermethylation of DKK1, SFRP1, and FLI1 in fibroblasts from SSc patients, and normalized Wnt signaling and type I collagen expression (Dees et al., 2014). In mice with EAE, a model of the human demyelinating disease MS, 5-aza-2'-deoxycytidine treatment increased the immunosuppressive function of  $\text{Foxp3}^+$  Tregs, prevented EAE development and suppressed CNS inflammation (Vojinovic et al., 2011; Chan et al., 2014).

However, DNA methylation inhibitors exhibit double-edged effects on the immune system. For example, 5-azacytidine could promote Treg function via demethylation of FOXP3 but, at the same time, promoted increased IgG production by B cells (Lal et al., 2009; Wang et al., 2014), making its potential effects difficult to predict in autoimmune patients whose cells already often exhibit global hypomethylation.

The disadvantages of azanucleosides (instability in aqueous solutions and toxicity) might be overcome by the use of other analogs, such as zebularine, procainamide (used to treat cardiac arrhythmia), 5-fluoro-2'-deoxycytidine, and hydralazine (used to treat hypertension). Several natural products derived from tea and sponges, such as epigallocatechin-3-gallate, also show DNMT inhibitory activity (Fang et al., 2003). Clinical trials that target DNMT1 are underway in tumors (<http://clinicaltrials.gov>).

In human autoimmune diseases, inhibiting DNA methylation would not be the optimal therapeutic option because the changes identified to date are hypomethylation, but not hypermethylation. Furthermore, DNA demethylating agents such as hydralazine have been shown to subvert B lymphocyte tolerance and to contribute to the generation of pathogenic autoreactivity (Mazari et al., 2007). Likewise, in autoimmune diseases exhibiting a global DNA hypo methylation (SLE and RA), drugs should be designed to specifically increase the DNA methylation without triggering undesirable hypermethylation-related tumorigenesis.

It is of related interest that in clinical settings, the epigenetic effects of some drugs may account for their effectiveness. For example, methotrexate can induce depletion of SAM, a substrate of DNMTs during DNA methylation, and thereby reduces DNMT1 activity (Nihal et al., 2014). In RA patients, treatment with methotrexate was found to reduce DNA hydroxymethylation (de Andres et al., 2015). Similarly, cyclophosphamide treatment can perturb the activity of DNMT1 and increase DNA methylation (Zhang et al., 2011).

### **Histone Deacetylase Inhibitors**

HDAC and HAT enzymes play an important role in regulating gene transcription through chromatin remodeling, which comprises histone protein–DNA complexes that tightly package to form chromosomes. HATs promote the transcriptionally active “decondensed” chromatin state by catalyzing the addition of acetyl groups onto the N-terminal tails of histone lysine residues, causing spatial distortion and allowing transcription factor and RNA polymerase complex recruitment. On the other hand, HDACs catalyze the removal of acetyl groups from lysine tails and restore the transcriptionally inactive “condensed” state.

The development of HDACis is relatively advanced. They show promising antiinflammatory properties, as demonstrated in an increasing number of animal and cellular models of inflammatory diseases (Halili et al., 2009). As indicated by their name, the molecular function of HDACs was thought to be restricted to histone deacetylation, but recent advances in phylogenetic analysis suggested that HDACs regulate the activity of a wide range of nonhistone proteins; and 3600 acetylation sites (of which only 61 were on histones) were found on 1750 proteins, including cytoplasmic proteins. Thus the impact of acetylation in terms of posttranslational regulation

is comparable to that of phosphorylation. A growing number of HDACi are being developed for the treatment of an expanding range of conditions, from cancer to neurodegenerative and other inflammatory diseases.

To date, HDACi, such as SAHA and TSA, have proved to be useful for relieving lupus disease in mice (Ballestar et al., 2006). The effects of TSA on human T cells are predominantly immunosuppressive and reminiscent of the signaling aberrations that have been described in patients with SLE (Hasler and Zouali, 2001; Zouali and Sarmay, 2004). Since global histone acetylation is reduced in T cells from SLE patients, increased histone acetylation was suggested to be beneficial in SLE. HDACi, such as suberoylanilide hydroxamic acid (SAHA) and TSA, have been reported to induce clinical improvement of lupus disease in animal models (Mishra et al., 2003; Reilly et al., 2008). However, valproic acid, used to treat bipolar mood disorder and seizures, also inhibits HDAC. In epilepsy patients, it was found to sometimes result in lupus-like symptoms (Mau and Yung, 2014). Such adverse reactions may limit the potential of epigenetic treatments.

In juvenile idiopathic arthritis, HDAC inhibition provides beneficial effects (Vojinovic et al., 2011). In studies of experimental diabetes, acetylation is recognized to regulate NF- $\kappa$ B, the master transcription factor in inflammation, the activation of which is critical in IL-1 $\beta$ -induced  $\beta$ -cell death. As a result, HDAC inhibition exerts protective effects on  $\beta$  cells exposed to toxicity-mediating cytokines.

In SSc, the HDACi TSA has demonstrated inhibitory effects on fibroblast activation by restoring the expression of FLI1, a negative regulator of collagen expression (Wang et al., 2006). The inhibition of HDAC7 by TSA down-regulated the expression of the fibrosis-related genes COL1A1 and COL3A1 (Hemmatazad et al., 2009). In RA synoviocytes, TSA impaired the stability of IL-6 mRNA and disrupted inflammatory cytokine production (Grabiec et al., 2012). In T cells from SLE patients, TSA reversed the aberrant increase of CD40L and IL-10 expression and the skewed IFN- $\gamma$  expression (Mishra et al., 2001).

In a clinical trial of 17 patients with systemic juvenile idiopathic arthritis, the orally active pan-HDACi givinostat, also called ITF2357, gave rise to six adverse events in three patients, while two-thirds of the patients achieved significant therapeutic benefit after 12 weeks, particularly in terms of the arthritic component of the disease (Vojinovic et al., 2011). This therapeutic benefit could be due, in part, to decreased production of IL-6 by givinostat. Currently, selective HDACi are being developed to increase therapeutic efficacy and limit toxicity (Lee et al., 2015).

Studies of chemically induced experimental colitis that mimics human ulcerative colitis also show a similar trend. For example, inhibition of HDAC in trinitrobenzene- and oxazolone-induced colitis resulted in amelioration (Glauben et al., 2006; Glauben et al., 2008). HDACi of different classes (the hydroxamic acids SAHA and ITF2357 as well as the SCFA valproic acid) suppressed the inflammatory parameters in acute dextran sulfate sodium-induced colitis, and ameliorated weight loss, bleeding, and colon shortening (Glauben et al., 2008). These macroscopic data were paralleled by a reduction of proinflammatory cytokines at the site of inflammation in colon cultures and by a reduced histological inflammation score (Glauben et al., 2006).

However, since each HDAC can target several genes, it can potentially alter the expression of other genes and lead to unacceptable toxicity (Kroesen et al., 2014). As a result, HDACi could behave as a double-edged sword in epigenetic therapy. A similar reasoning applies to the use of DNMT inhibitors in the clinic. Therefore investigations should be performed to identify safer therapeutic targets.

### **MicroRNAs-Targeting Therapeutics**

miRNAs have been demonstrated to represent potential diagnostic biomarkers for autoimmune diseases. Therefore the modulation of miRNA expression using miRNA mimics or inhibitors could represent an attractive therapeutic avenue for autoimmune diseases. Antisense oligonucleotides that target miRNA (anti-miRs) are highly complementary to the target miRNA. Upon delivery to cells in culture, anti-miRs specifically suppress the function of the target miRNAs and can even induce degradation of the targeted miRNAs.

In studies of collagen-induced arthritis, injection of recombinant lentiviral vectors silencing miR-223 to mice led to amelioration of the score and the incidence of arthritis, and bone erosion in the joints (Li et al., 2012). In a clinical trial of five SLE patients who had high IFN scores, manipulation of miR-146a levels reduced expression of selected genes, suggesting that this approach could provide a therapeutic benefit to SLE patients (Tang et al., 2009).

Inhibition of miRNA expression can be achieved using antisense oligonucleotides, small-molecule inhibitors, and miRNA sponges. This latter vector-based strategy is based on mRNA sequences containing multiple artificial miRNA-binding sites that can act as a decoy or a sponge. Transfection of a vector encoding a sponge into cells in culture selectively depletes endogenous miRNAs, allowing translation of the target mRNAs (Ebert et al., 2007). In studies of MS, in vivo silencing of miR-326 by miRNA sponges reduced Th17 cell numbers and disease severity,

suggesting that miR-326 plays a role in Th17 polarization during the pathogenesis of this disease (Du et al., 2009). Thus the antisense oligonucleotide approach could open up new avenues for treating autoimmune diseases.

### ***Epigenetic Generation of Regulatory T Cells***

A variety of methods can be used to generate Tregs expressing Foxp3 protein, which is generally considered a specific Treg marker. Since the stability of Foxp3 expression in Tregs is important for their therapeutic use, conversion of antigen-specific Tregs into effector T cells can have detrimental effects and limit their clinical applicability (Roncarolo and Battaglia, 2007). In addition to Foxp3 activity, the development and function of stable Tregs also are governed by epigenetic mechanisms, including DNA methylation, histone modifications, nucleosome positioning, chromatin remodeling, and miRNA expression (Arvey et al., 2015; Huehn and Beyer, 2015).

Therefore epigenetic regulation may be an effective therapeutic strategy to generate stable, suppressive Tregs. In vivo injection of HDAC9, a member of the class II HDACi, increases Treg numbers and function in mice (Tao et al., 2007) and in rhesus monkeys (Johnson et al., 2008). Remarkably, pan-HDACi, but not class I-specific HDACi, increased the function of Foxp3<sup>+</sup> Tregs and prevented and reduced established colitis in mice. These pan-HDACi-mediated effects were associated with increased numbers of Foxp3<sup>+</sup> Tregs within the lamina propria.

As regards DNMT inhibitors, they induce strong Foxp3 expression, but with cell toxicity as well as induction of Th1 and Th2 cytokines, which limits their use (Lal et al., 2009). Similarly, DNA methyltransferase inhibitors were found to strongly induce Foxp3 expression but are associated with high toxicity and induction of Th1 and Th2 cytokines, which also hampers their clinical use.

In humans, an epigenetic approach was followed to generate enhanced Foxp3<sup>+</sup> suppressive Tregs that could be used in cell therapy (Lal et al., 2009). Human Foxp3<sup>+</sup>CD4<sup>+</sup> T cells are very heterogeneous, based on CD25, CD62L, CD45RA, HLA-DR, and ICOS expression, but they can be divided into three different subsets of Foxp3<sup>+</sup>CD4<sup>+</sup> T cells in the peripheral blood (Miyara et al., 2009). CD45RA<sup>+</sup>Foxp3<sup>lo</sup> resting Tregs and CD45RA<sup>-</sup>Foxp3<sup>hi</sup> activated Tregs show completely demethylated CpG at the proximal promoter (-256 to -16 bp) and more than 85% demethylation of the intronic region promoter (+3824 to +3937 bp), and are suppressive (Miyara et al., 2009). However, CD45RA<sup>-</sup>Foxp3<sup>lo</sup> Tregs show less than 50% demethylation at the intronic region, secrete cytokines such as IL-2 and IFN- $\gamma$  and do not show suppressive functions (Miyara et al., 2009). These findings suggest that epigenetic mechanisms may help designing better approaches to generate suppressive human Tregs. Stabilization of the activity of Foxp3 and Treg function by epigenetic mechanisms could open up development of novel therapeutic strategies for autoimmune diseases.

---

## CONCLUSIONS AND FUTURE PROSPECTS

---

As summarized above, autoimmune disease concordance rates in monozygotic twins range from 13% to 61%, suggesting that environmental factors play a direct or indirect role in the pathogenesis of autoimmune diseases. They include drugs, such as the methyl donor hydralazine, vaccination and antibiotics, iodine levels, cigarette smoking, increasing wealth, temperate, decreased infection rates, increased hygiene, UV irradiation, wheat consumption, and gut microbiota. Some of these factors have the potential to induce epigenetic changes that have been reported in cells from patients with autoimmune diseases. It will be important to further define the role of environmental factors and to decipher how they influence gene expression in autoimmune diseases. There is a need for additional investigations to confirm the observed alterations and, hopefully, relate them to abnormal pathways that could be unique to a given disease. In addition, it would be essential to pinpoint common pathways in several autoimmune diseases that could account for the occurrence of different autoimmune phenotypes in family members.

The above hypothesis-driven studies are being complemented by resource-generating activities. Thus the International Human Epigenome Consortium makes available comprehensive sets of reference epigenomes relevant to health and disease (Bujold et al., 2016). It will be important to compare epigenome maps of model organisms relevant to human health and disease and to encompass a variety of human cell and tissue types from a variety of disease states, including autoimmune diseases. This could lead to the discovery and validation of epigenetic markers for diagnostic use and for the development of novel and more efficacious treatments.

A better understanding of the paths involved in disease pathogenesis should open up avenues for potential diagnostic and prognostic tools, and, possibly, for epigenetic interventions based on miRNA silencing and/or

chromatin remodeling agents. Progress in understanding epigenetic deregulation in autoimmune diseases invites investigations aiming at identifying biomarkers for early diagnosis and to develop novel therapeutic approaches. In experimental animals, several therapeutic agents have been found to modify the epigenome. However, since the epigenetic modifications reported in autoimmune diseases are complex, treatment strategies that target the epigenome are limited by off-target effects, and may result in undesirable effects or may cause severe adverse events. Despite encouraging preclinical observations, epigenetic therapy may have limitations. Because of lack of specificity, DNMT and HDACi may activate oncogenes, potentially resulting in accelerated tumor progression. In addition, once corrected, epigenetic states may revert to the original state because of the reversible nature of DNA methylation patterns. Finally, the findings that crosstalk mechanisms between DNA methylation, histone modification, and miRNAs regulate the expression of epigenome would suggest that epigenetic targeting for therapeutic purposes and using epigenetic modifications as biomarkers will not be of use in the short term in autoimmune diseases.

## MAJOR HISTOCOMPATIBILITY COMPLEX

Evolution of pathogens including viruses, bacteria, and parasites provides the biggest threat to human survival. The human immune system has evolved to combat the invading pathogens via innate immunity which is the first line of defense. However, specific response to various pathogens and memory to clear a second infection by the same pathogen required an adaptive immunity. The main feature of the adaptive immunity is its diverse nature of immune response. The major players for adaptive immunity are the genes encoded within the major histocompatibility complex (MHC). While everybody is exposed to infections at some point in their life, the response generated to infectious pathogens varies among individuals. The MHC plays a very important role in generating the immune response to clear invading pathogens. Human MHC is divided into three main regions, human leukocyte antigen (HLA) class I, II, and III. HLA class I and class II genes are most polymorphic genes in human genome. The high polymorphism in the MHC region can be attributed to strong selection pressure as the human population moved to different parts of the world and encountered new infections leading to diversity in MHC genes through mutation, gene duplication, or gene conversion. A population with diverse HLA class I and II alleles leads to herd resistance to infection and have a survival advantage.

The MHC is the most gene-dense region in human chromosome. Human MHC molecules are called HLA that are homologous to the H-2 of mice. The HLA complex is located on the short arm of chromosome 6 in humans and chromosome 17 in mice and is 3500 kb long. HLA class I molecules contain one heavy chain of 44 kDa and one non-MHC encoded nonpolymorphic  $\beta 2$  microglobulin of 12 kDa. The heavy chain consists of 3 extracellular domains of 90 residues each. The polymorphic residues in class I molecules are located on  $\alpha 1$  and  $\alpha 2$  domains of the heavy chain. There are three class I genes designated HLA-A, HLA-B, HLA-C that are expressed on all nucleated cells. Class I molecules can bind 8–10 amino acids long peptides that have been processed endogenously.

HLA Class II molecules are present as heterodimers on the cell surface consisting of an alpha chain (32–34 kDa) and a  $\beta$  chain (29–32 kDa) each with two extracellular domains of about 90 amino acid long ( $\alpha 1$ ,  $\alpha 2$  and  $\beta 1$ ,  $\beta 2$ ). The beta chains of three major histocompatibility complex class II genes, HLA-DR, DQ, and DP are highly polymorphic, while alpha chains are generally nonpolymorphic. The class II molecules are expressed on antigen-presenting cells such as B lymphocytes, macrophages, dendritic cells, endothelial, and other organ-specific antigen presenting cells (APCs). In general, class II molecules can accommodate peptides up to 10–25 residues. In humans, DR, DQ, and DP are in linkage disequilibrium and are inherited en bloc as a haplotype. MHC genes are expressed codominantly in each individual. Crystal structures of the DR and DQ genes have shown that MHC molecule has a single peptide-binding cleft, which can accommodate a variety of peptides, which depends on the charge, stability, and binding affinity.

## MAJOR HISTOCOMPATIBILITY COMPLEX AND AUTOIMMUNITY

During evolution, HLA alleles offering an advantage during reproductive years have been selected and occur in populations with much higher frequency compared to other alleles. Abundance of HLA-DR2/DQ6, DR4/DQ8, and DR3/DQ2 haplotypes in various populations suggesting the importance of these haplotypes in clearing infections and survival of the species. It has been hypothesized that HLA class II molecules may be involved in autoimmunity due, in part, to their selection of T cells capable of producing cytokines such as IFN $\gamma$ , IL-4, and IL-17 (Mangalam et al., 2013). These cytokines are required for clearing pathogens, extracellular and intracellular,

as well as parasitic infections. While Th1 (IFN $\gamma$ ) can provide protection from intracellular pathogens, Th17 (IL-17) producing CD4 T cells are required for extracellular pathogens (Mangalam et al., 2013). Polymorphism in HLA class II has been associated with immune responses to vaccinations (Poland et al., 2008). HLA-DRB1\*0401 was found to be increased in individuals with seroprotective response to influenza vaccine (Moss et al., 2013). Involvement of class II molecules and CD4 T cells in clearing influenza has been shown (Miller et al., 2015). Although these haplotypes offered a survival advantage in terms of fighting infection, they can also generate an autoreactive response, thus predisposing to a number of autoimmune diseases. Even though there are more than 450 DRB1 alleles and 75 DQB1 alleles with the possibility of generating thousands of haplotypes, only few alleles of these 3 haplotypes are associated with most of the autoimmune diseases. DRB1 has the maximum allelic diversity suggesting a rapidly evolving region due to positive or negative selective pressures. Thus nature leads to the selection of alleles offering advantage over other alleles. Studies have suggested that HLA heterozygosity has an advantage over homozygosity in the generation of immune response. HLA diversity evolves via mutations, gene conversion, and genetic recombination. The most conserved haplotype, B8-DR3-DQ2, has been associated with autoimmunity suggesting this haplotype provides an advantage over other haplotypes and is supported by a high gene frequency of HLA-DR3 in centenarians. Most of the autoimmune diseases show association with HLA class II alleles except the HLA-B27 associated spondyloarthropathies.

## THE MYSTERY OF HUMAN LEUKOCYTE ANTIGEN-B27 AND SPONDYLOARTHROPATHIES

Ankylosing spondylitis (AS) is a joint disease that affects the spine, the sacroiliac joints, and shoulders. In 1973 Brewerton in England showed that the MHC gene, HLA-B27, is linked to susceptibility to ankylosis spondylitis (Brewerton et al., 1973). While B27 was found in 5% of the general population, 95% of the AS patients were HLA-B27 positive. This was the first MHC gene found to be associated with an autoimmune type disease. Eventually, several other closely related diseases such as psoriatic arthritis, arthritis associated with inflammatory bowel disease, and reactive arthritis were also linked to HLA-B27, although at a much lower frequency (Allen et al., 1999b). Several enterobacteria were found to be implicated in the onset of the disease (Kvien et al., 1994). These diseases are now referred to as spondyloarthropathies. In order to understand the role of HLA-B27 in these diseases, Taurog et al. developed a transgenic rat expressing human HLA-B27 gene from an AS patient (Hammer et al., 1990). Transgenic rats developed spontaneous symptoms characteristic of spondyloarthropathy (SPA), but the disease only developed in high gene copy number rats.

### Human Leukocyte Antigen-B27 Transgenic Mice

Mice, expressing intact HLA-B27 on the cell surface, developed normally and showed no disease symptoms. Assuming the disease may require the human  $\beta$ 2m gene, we initiated studies to replace mouse  $\beta$ 2m with human  $\beta$ 2m. During this process, we noticed that mice lacking  $\beta$ 2m altogether showed some symptoms of spondyloarthropathies (Khare et al., 1995). We found that these mice expressed about 10% of  $\beta$ 2m free B27 heavy chains on their cell surface. Free heavy chains of class I molecules are rarely seen on the cell surface. This suggested that B27 may be a unique class I molecule capable of reaching the cell surface as free heavy chains. The frequency of symptoms increased after the mice were brought outside the pathogen-free barrier facility, suggesting that environmental factors may play a role. Studies with B27+ CD4– and CD8– mice indicated that CD4 T cells were critical for the disease process. Computer simulation studies indicated that the pocket of a  $\beta$ 2m free class I heavy chain may resemble a class II molecule with open ends that can load long exogenous peptides. Studies in Strominger's laboratory confirmed that some human B27 molecules were bound with 14–16 amino acid peptides rather than 8–9 amino acid peptides normally found in most class I molecules (Madden et al., 1991). Transporter-associated proteins (TAPs) interact with a unique class I confirmation, whereas calnexin associates with multiple class I forms. Spontaneous inflammatory disease in HLA-B27 transgenic mice does not require TAP (Khare et al., 2001) and is independent of class II molecules, suggesting a direct role for B27 heavy chains and not B27-derived peptides (Khare et al., 1998).

On the basis of our studies with the HLA-B27 transgenic mice, we proposed the following hypothesis. HLA-B27 is a unique class I molecule that can be expressed on the cell surface as free heavy chains. They can load

14–16 amino acids long exogenous bacterial peptides and activate autoreactive CD4 T cells. Activated CD4 T cells migrate to a target tissue and destroy cartilage causing various symptoms related to spondyloarthropathies.

### Human Leukocyte Antigen-B27 and Autophagy

In B27 transgenic rats, free heavy chains of B27 were suggested to accumulate in endoplasmic reticulum causing stress and leading to unfolded protein response (Colbert et al., 2010). However, it was difficult to prove the unfolded protein response (UPR) in patients with AS. The patients with AS were shown to have abnormal autophagy in the gut, which would suggest that misfolded protein is not cleared. Endoplasmic reticulum-associated degradation protein deficiency is linked to autophagy. In addition, altered endoplasmic reticulum aminopeptidase 1 (ERAP1) and ERAP2 have been shown to lead to an aberrant trimming of peptides causing abnormal peptide presentation by B27 and triggering an inflammatory response by stimulating IL-17 production. Thus the aberrant presentation of peptides due to variants may lead to the activation of inflammatory pathways.

### Human Leukocyte Antigen-B27 and AIDS

A major breakthrough came in the HLA-B27 field when it was identified as one of a very few HLA class I genes that protected HIV-infected individuals from progressing to full-blown disease (McMichael and Klenerman, 2002). The HLA-B27 molecules were able to bind and present multiple viral epitopes to generate a robust T-cell response to clear infection (Streeck et al., 2007). The CD4 T-cell level remained high and there was an efficient B cell response also. Further proof came when it was shown that B27+ individuals were also protected against hepatitis C infections and endemic malaria (Mathieu et al., 2008).

Andrew McMichael and his group at the University of Cambridge became interested in the role of HLA-B27 in clearing viral infection. They initiated in-depth studies to understand how the B27 molecule is processed and loaded with peptides in human cells. When they tried to generate B27 tetramers for their studies, they noticed that B27 heavy chains were reaching the cell surface in the absence of  $\beta 2m$  and peptide. Further studies showed that these free chains were actually dimers of heavy chains (Allen et al., 1999a). This confirmed the findings on the HLA-B27 transgenic mice. The McMichael group expanded their studies to analyze the expression of HLA-B27 molecule in patients with spondyloarthropathies.

### Human Leukocyte Antigen-B27 and Peptide Binding

There are several critical residues in an HLA-B27 molecule that may influence protection versus susceptibility against viral infection as well as autoimmunity. One such residue is at position 97 in the floor of the peptide-binding pocket (McMichael and Jones, 2010). While most HLA class I molecules have arginine at this position, HLA-B27 has asparagine. Arginine is known to be a hindrance for peptide binding in the groove. HLA-B27 molecules in the thymus bind to multiple peptides, but there is a major difference in the affinity of the binding. While B27 bind very few peptides with high affinity, they bind many peptides with low affinity. Thus fewer self-reactive T cells are deleted in the thymus, resulting in the positive selection of autoreactive T cells. On the other hand, they may select virus-specific T cells to broader fine specificity that could reduce virus options to escape by mutations, thus enhancing viral clearance.

Another key residue on the HLA-B27 molecule is at position 67 where B27 molecules have free cysteine (Bird et al., 2003). This residue enables the formation of dimers of the free heavy chains. The homodimer formation is dependent upon disulfide bonding through Cys67. Such bonding would require unwinding of the  $\alpha 1$  helix, enabling binding of longer peptides in a class II-like groove.

The HLA-B27 molecules have several other unique characteristics. The HLA-B27 molecules continue to be associated with calnexin after making a complex with  $\beta 2$  microglobulin unlike other HLA molecules. However, they can be expressed on the cell surface in the absence of TAP and tapasin, which are involved in the loading of peptides into the class I molecule. We have previously shown that B27 mice in the context of the TAP (knockout) still get spontaneous disease, suggesting that TAP may not be involved.

Thus HLA-B27 can be expressed on the cell surface in many different forms: as an intact molecule loaded with an endogenous peptide, or as  $\beta 2m$  free heavy chains, homodimers or multimers either loaded with peptide or as empty molecules. CD4 T cells have been found to recognize HLA-B27 either as homodimers or heterodimers

when they are devoid of peptide (Boyle and Hill Gaston, 2003). HLA-B27 reactive CD4+ T cells have been identified in HLA-B27+ AS patients.

### Human Leukocyte Antigen-B27 and Natura Killer Cells

We had shown a potential role of natural killer cells on HLA-B27 associated arthritis (Marietta et al., 2000). Introduction into T cells of NKB1, an allelic form of KIR3DL1, produces severe arthritis in HLA-B27 transgenic mice. Thus the interaction of free MHC heavy chains with MHC receptors could play a role in the development of arthritis in our HLA-B27 transgenic mice. Killer cell immunoglobulin-like receptors (KIR family) are expressed on Natural Killer (NK) cells, T cells, and NK T cells. KIR is polymorphic and demonstrates allele-specific recognition with a cognate KIR for HLA-B27 being the 3 domain, KIR3DL1. Our work in the mice was confirmed by Kollnberger et al. (2002) who showed that HLA-B27 heavy chain homodimers and receptors for HLA-B27 homodimers are expressed on populations of peripheral blood, B and T lymphocytes, and synovial monocytes from patients with spondyloarthritis. Thus the interaction of HLA-B27 heavy chain with immunoreceptors on cells of the myelomonocytic cell lineage or lymphocytes might also be involved in the pathogenesis of spondyloarthritis.

### Human Leukocyte Antigen-B27 and Evolution

If HLA-B27 was a bad gene causing all these diseases, it should have been eliminated during evolutionary time. On the contrary, HLA-B27 is one of the oldest MHC class I genes and has survived thousands of years. It is found on every continent, every geographical area, and in all ethnic and racial groups. It has one of the highest gene frequencies and is very polymorphic with over 50 subtypes. These facts suggest that HLA-B27 gene was positively selected during evolution and had to be a good gene.

The main function of MHC molecules is to clear infection. During thousands of years of evolution, HLA-B27 emerged as a class I molecule capable of presenting multiple epitopes of infectious agents to activate T cells to clear infection as well as to generate cytotoxic T cells and help B cells to generate antibodies to clear infection. This could have happened by many different mechanisms. Key mutations in the peptide-binding pocket could enable more promiscuous binding of multiple peptides for presentation to T cells. Mutations could have also enabled the B27 molecule to be expressed on the cell surface as free heavy chains, capable of loading exogenous peptides and activating CD4 T cells. Thus B27+ individuals would have survived many infectious episodes and bottlenecks, spread all over the world, and reproduced.

Unfortunately, HLA-B27 molecules can also generate adverse effects. The free chains of HLA-B27 are also expressed in the thymus where they can bind many self-peptides with low affinity and activate autoreactive CD4 T cells. These autoreactive CD4 T cells in the periphery can be activated by various mechanisms including molecular mimicry to cause autoimmunity.

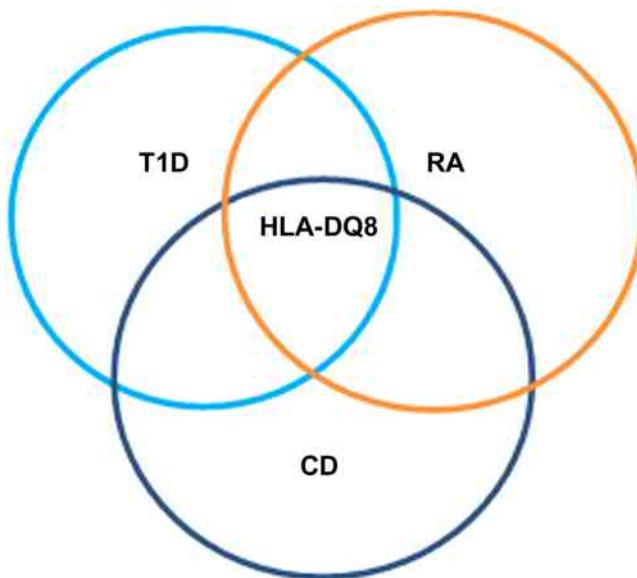

In conclusion, the many forms of HLA-B27 can activate many different T-cell populations. An intact B27 molecule would activate CD8 T cells. A free heavy chain or a homodimer loaded with an exogenous peptide will activate a CD4 T cell. B27 homodimers in complex with KIR molecules can activate NK cells. Finally, the  $\beta 2m$  free heavy chains may be able to directly interact and activate antigen-presenting cells such as B cells. Thus the HLA-B27 molecule can generate a robust immune response against infectious agents to clear infections and maintain the health of the individual. On the other hand, the aberrant activation of an autoreactive CD4 T cell could result in autoimmune diseases.

## HUMAN LEUKOCYTE ANTIGEN CLASS II ASSOCIATION WITH AUTOIMMUNE DISEASES

The first studies showing an association between MHCII and autoimmunity came from the studies from Noel Rose who suggested a connection between MHCII and autoimmune experiential thyroiditis induced in the mouse and spontaneously model in the chicken (Vladutiu and Rose, 1971; Bacon et al., 1974). This was followed by a collagen-induced model showing that MHCII predicted arthritis susceptibility (Wooley et al., 1981). Similar to experimental models, susceptibility to the majority of autoimmune diseases is associated with the presence of certain HLA-DR and -DQ alleles (Table 26.1). Despite the presence of a high degree of polymorphism, only a few HLA class II alleles and their linked haplotypes are associated with autoimmune diseases. Type 1 diabetes,

**TABLE 26.1** Association of Various Autoimmune Diseases With Human Leukocyte Antigen Class II Alleles and Haplotypes

Disease	Alleles	Haplotype
Rheumatoid arthritis	DRB1*04, DQB1*0302	DRB1*04\ DQB1*0302 DRB1*04\ DQB1*0301 DRB1*10\ DQB1*0501
Insulin-dependent Type I diabetes	DRB1*03, DRB1*04 DQB1*0302	DRB1*04\ DQB1*0302 DRB1*0301\ DQB1*02
Multiple sclerosis	DRB1*15 DRB1*0301	DRB1*1501\ DQB1*0602 DRB1*0301\ DQB1*0201
Celiac disease	DRB1*0301, DRB1*0701 DQB1*0302	DRB1*0301\ DQB1*02 DRB1*0701\ DQB1*02
Graves' disease	DRB1*0301, DQB1*02	DRB1*0301, DQB1*02
Autoimmune thyroid disease	DRB1*0301	DRB1*0301, DQB1*02
Myasthenia gravis	DRB1*03	DRB1*0301, DQB1*02

**FIGURE 26.1** Many autoimmune diseases share the predisposing HLA allele. HLA-DQ8 has been associated with predisposition to T1D, RA, and CD. *HLA*, Human leukocyte antigen; *T1D*, type 1 diabetes; *RA*, rheumatoid arthritis; *CD*, celiac disease.

rheumatoid arthritis (RA), and celiac disease (CD) are all associated with the presence of HLA-DQ8 suggesting it to be an autoimmune predisposing allele (Fig. 26.1). Although HLA class II genes are the strongest genetic factors associated with the development of autoimmune diseases, the exact role of these molecules in disease etiology is still being deciphered.

## PREDISPOSITION

In the thymus, T cells are positively selected based on their ability to bind to self-MHC molecules expressed in the thymus; T cells binding to self-peptide-MHC molecules with moderate affinity are selected, while T cells binding self-peptide-MHC complex with strong affinity or weak affinity are deleted (von Boehmer and Kisielow, 1990; Huang et al., 2004). Although effective, there is some leakiness as some T cells binding with weak affinity to self-peptide-MHC complex escape the negative selection and circulate into the periphery. In most individuals, these autoreactive T cells are kept in check through peripheral tolerance.

However, in some individuals, these autoreactive T cells can get activated through unknown mechanism and lead to the onset of autoimmune disease. Such a mechanism might explain the selection of a T-cell repertoire that is protective or susceptible to autoreactivity. The elution of peptides from HLA class II molecules suggests that some of these peptides may indeed be derived from HLA molecules themselves (Chicz et al., 1994). Thus HLA molecules not only function in the thymus by presenting other peptides but can also serve as a donor of self-peptides. This intricate relationship between MHC, self-peptides, and the T-cell receptor (TCR) could determine the specificity of T cells in the periphery. Thus the peripheral pool of T cells can recognize nonself-antigen to clear infection, recognize self-antigens to cause autoimmunity, or can become tolerant/anergic. However, studies to resolve these issues in humans have been hampered by the lack of knowledge of "culprit" autoantigens as well as the difficulty in obtaining samples from affected organs. The other confounding problem has been the linkage disequilibrium of HLA class II alleles—DR and —DQ making it difficult to interpret the association of a disease with a haplotype or specific allele. Despite this risk of autoimmunity in certain individuals, nature persisted with these HLA class II alleles due to the survival advantage associated with these genes. Thus autoimmunity is a price that we have to pay in order to control widespread infections and maintain the survival of human population. Based on the observations in animal models, it was hypothesized that autoimmune-associated HLA alleles positively select T cells programmed to produce inflammatory cytokines when activated, thereby influencing autoreactive response (Mangalam et al., 2013; Mangalam et al., 2008). This was recently confirmed in mice expressing arthritis-susceptible and -resistant genes, where susceptible mice generated Th17 response and also harbor memory T cells reactive to autoantigens (Luckey et al., 2014).

## ONSET

Among the individuals carrying disease predisposing HLA allele/haplotype, only a small percentage develops autoimmune disease. This indicates that the precipitation of disease requires a second hit in addition to genetic predisposition. Interestingly, besides genetic factors, most of the autoimmune diseases also show association with environmental factors. A number of environmental factors, both infectious and noninfectious, have been shown to play an important role in the onset of disease in genetically predisposed individuals (Klareskog et al., 2006). One mechanism could be molecular mimicry between infected agents and self-molecules activating autoreactive T cells. Till now extraintestinal infections were considered to be the culprits, but recent observations demonstrating an association between gut microbes and autoimmunity suggest that opportunistic commensals can also lead to autoreactive response. Another mechanism by which pathogens can cause autoreactivity is when posttranslational modification of proteins occurs to clear infections, it may inadvertently lead to activation of self-reactive T cells.

## ENVIRONMENTAL FACTORS

Genome-wide association studies (GWAS) have shown that the presence of a genetic factor, linked to an autoimmune disease, does not necessarily lead to the development of autoimmunity. Oftentimes, autoimmune disease in patients can be linked to environmental factors that they have been exposed to (Goris and Liston, 2012). Some examples of these environmental factors include infections, smoking, food, drugs, and bacteria (Symmons et al., 1997; Campbell, 2014; Vassallo et al., 2014; Luckey et al., 2013; Lunemann et al., 2007). Further complicating this idea is the fact that environmental and genetic contribution can interact in an additive or even synergistic manner, resulting in higher disease rates (Marietta et al., 2015). This complex association is highlighted in RA patients, where there exists an association between smoking and HLA class II alleles, resulting in higher disease rates of RA patients who smoke as compared to their nonsmoking counterparts (Klareskog et al., 2006).

## INFECTIOUS AGENT

Among all the infectious agents associated with autoimmune diseases, such as RA, multiple sclerosis (MS), and systemic lupus erythematosus, the strongest association had been reported with the presence of viruses, especially Epstein–Barr virus (EBV) (Pender, 2003). The EBV is a ubiquitous virus found in populations all over

the world. After the primary infection, virus resides in memory B cells and secretes latent protein such as EBV nuclear antigen (EBNA). After an unknown period of latency, the virus reactivates and goes into lytic phase infecting more cells. It has been hypothesized that EBV may cause autoimmunity by the activation of autoreactive T cells either through molecular mimicry or bystander activation and release of proinflammatory cytokines. There is strong evidence that EBV plays a central role in the etiology of autoimmune diseases including RA and MS (Alspaugh et al., 1981; Lunemann et al., 2008).

A pathophysiological link between EBV and RA was first described when 67% of the patients with RA were shown to produce antibodies to EBNA (Alspaugh et al., 1981; Baboonian et al., 1989). Also, EBV-encoded protein gp110, a major replicative phase glycoprotein required for infection, shares sequence similarities with the QKRAA amino acid motif (the “shared epitope”) of HLA-DRB1\*0401, suggesting that molecular mimicry may be one-way EBV could be involved in the pathogenesis of RA. In addition, the presence of HLA-DR4 is associated with 10-fold high synovial EBV DNA loads compared to controls and low T-cell response in RA patients. A clonal expansion of CD8+ EBV specific T cells that are suggested to be dysfunctional has also been observed in RA patients. Patients with RA have higher numbers of circulating EBV-reactive B cells compared to controls (Tosato et al., 1984). Thus a combination of impaired T-cell response and presence of antibodies could lead to an immune complex disease.

The mechanism linking MS and EBV is not well understood but could involve a pathological role of antibodies to EBV antigens and activation of CNS myelin-specific T cells by cross-recognition of EBV specific T cells. Patients with MS have increased antibody reactivity against several EBNA domains, of which antibodies against EBNA-1 in HLA DRB1\*1501 positive individuals were associated with a 24-fold increase in risk for MS (Sundstrom et al., 2009). Further, MS patients show a selective increase of CD4+ T-cell response to the EBNA1 which also cross-reacted with myelin antigens (Lunemann et al., 2008). These reports indicate that EBNA1-specific antibodies and/or myelin cross-reactive CD4+ T cells in the presence of a susceptible HLA class II allele (HLA-DRB1\*1501) could potentially contribute to the development of MS. These reports suggest that molecular mimicry may be one way that EBV-derived protein could cause pathogenesis in autoimmune diseases.

## SMOKING AND AUTOIMMUNITY

Several retrospective and prospective studies have shown the association between cigarette smoking and susceptibility to a number of autoimmune diseases such as RA, MS, Type I diabetes (T1D), thyroiditis, primary biliary cirrhosis, and Crohn’s disease (Wingerchuk, 2012). This has led to the emergence of smoking as a risk factor linked to the onset and the clinical development of these autoimmune diseases in genetically predisposed individuals. Although these studies show an association, there is no experimental proof of a direct link between smoking and autoimmune diseases, RA and MS. Numerous studies have provided evidence suggesting an association of smoking with the development of RA. Smoking has been associated with extraarticular features of RA-like nodules and lung disease, which is the third major reason for mortality in arthritis patients (Harel-Meir et al., 2007). An interaction between smoking and DRB1 alleles has been suggested to confer an increased risk of anti-citrullinated protein antibodies (ACPA)-positive RA. An increase in the presence of citrulline-modified proteins observed in the lungs of smokers may be due to an increase in the peptidyl arginine deiminase (PAD) enzyme (Makrygiannakis et al., 2008). Although the mechanism of interaction between the RA-susceptible class II alleles and environmental factors such as smoking has not been elucidated, it is thought that RA onset may occur later in life (median age for RA onset is around 60 years), but the process of autoreactivity starts earlier. This is supported by the fact that autoantibodies in shared epitope positive individuals precede clinical disease, suggesting a role for smoking in triggering antibody production. Cigarette smoke exposure in humanized mice showed an exacerbation of disease in mice expressing DQ8 that was associated with Th17 response in lungs and enhanced antibody production to citrullinated proteins (Vassallo et al., 2014). On the other hand, DRB1\*0401 mice showed a suppression of arthritis after an exposure to cigarette smoke. Most human data shows an association with DRB1\*0401 and smoking; this study suggested that host haplotype interaction with cigarette smoke may determine the overall immune response. This was further supported by recent observations where enhanced immune response to citrullinated Vimentin was shown in mice expressing RA-susceptible, \*0401, as well as RA-resistant, \*0402, alleles confirming previous observations that an overall Th response may determine the outcome (Bidkar et al., 2016; Ummarino, 2016). A recent study using multinational QUEST-RA database showed no significant differences in the clinical profile of RA patients that are smokers and nonsmokers except for an increase in the presence of

nodules in the smoker group (Naranjo et al., 2010). A study with a 3-year follow-up of patients with current smokers showed fewer swollen joints and no difference in radiologic damage suggesting smoking may be contributing to disease by the production of autoantibodies (Harrison et al., 2001). Cigarette smoking is the most characterized environmental factor associated with the pathogenesis of RA and suggests that the onset of RA may begin at a site other than joints.

Cigarette smoke can interact with other environmental factors such as EBV to increase the risk of MS, as smokers were twice as likely to have MS with high titers of anti-EBNA antibody compared to nonsmokers (Simon et al., 2010). Smoking can increase the risk of MS through a number of pathways such as (1) modulation of systemic immune response; (2) increasing the blood–brain barrier permeability; and (3) direct injury to CNS by neurotoxic chemicals present in smoke.

## PORPHYROMONAS GINGIVALIS AND RHEUMATOID ARTHRITIS

*Porphyromonas gingivalis*, a Gram-negative facultative anaerobe, is the major cause of an inflammatory condition of oral cavity called periodontitis (McGraw et al., 1999). Smoking has been shown to be the leading susceptibility factor for periodontitis (Klareskog et al., 2006; Lundberg et al., 2010). Further, an association between the presence of HLA-DR4 and periodontitis has been described indicating similarities with RA. *P. gingivalis* is present in more than 80% of the RA patients. Recent epidemiology studies have shown an association between periodontal disease and RA (Farquharson et al., 2012). Antibodies to *P. gingivalis* are increased in RA patients and correlate with ACPAs. The potential role of *P. gingivalis* in RA pathogenesis has been suggested to be due to the presence of bacterial PAD enzyme, even though there is no similarity with human PAD (Farquharson et al., 2012). These enzymes can deiminate an arginine residue to citrulline in antigens, thus changing their binding affinity to HLA molecules. Further, more than 40% of the RA patients are positive for antibodies to an immunodominant peptide, citrullinated alpha-enolase peptide 1, that bears sequence similarity and cross-reactivity with enolase from *P. gingivalis* (Lundberg et al., 2010). These studies suggest that molecular mimicry and immune response to a bacterial epitope may result in the production of antibodies. Recent studies have shown that bacterial PAD enzyme can deiminate host fibrinogen peptides (Wegner et al., 2010), which may lead to the generation of new epitopes, so triggering of an immune response in a genetically predisposed individual. The presence of antibodies to *P. gingivalis* in patients was associated with smoking and DRB1, suggesting that it could be a trigger for RA (Kharlamova et al., 2016).

Besides oral microbiota, recent studies have shown that intestinal microbiota is perturbed in patients with RA and could also contribute to pathogenesis (Marietta et al., 2016; Scher et al., 2013; Zhang et al., 2015).

## GENETIC FACTORS, GUT MICROBIOME IN AUTOIMMUNE DISEASES

Recently, the role and importance of the microbiome have been realized by researchers, as the microbes in the gut are involved in the homeostasis of immune response and any changes to the microbiota can disrupt this immune response. The human intestine is colonized by a large number of microorganisms, including around  $10^{14}$  types of bacteria that are involved in various functions. The colonization of the gut begins at birth and stabilizes by year 3 but changes throughout the life based on various factors, forming a unique intestinal microbiota for each individual. The gut microbiota forms a protective barrier between the environment and the intestine and helps maintain a healthy gut. A mutualistic relation exists between the host and gut microbiota (Backhed et al., 2005). The composition of an individual's gut microbiota is influenced by many factors including diet, geographical location, genetics, age, and gender (Marietta et al., 2015; Gomez et al., 2012, 2015). Most of the autoimmune diseases are sex-biased with a higher prevalence in women. The major factors in sex-bias have been suggested to be the expression of X-linked immune genes such as FoxP3, CD40L, TLR7, and hormones. Since genetic factors and hormones impact gut microbiota, it is possible that the gut is involved in the pathogenesis of autoimmune diseases. Although sex-biased microbiota has been shown in mice (Gomez et al., 2012), human data has been inconsistent (Schnorr et al., 2014; Mueller et al., 2006; Arumugam et al., 2011) probably due to lifestyle differences.

Recent studies have shown alterations in the gut microbiota, also called dysbiosis, in patients with various autoimmune diseases including diabetes, MS, lupus, and RA among others. T1D, an autoimmune disease, has been associated with reduced diversity and a decrease in Bacteroidetes:Firmicutes ratio, 2 of the main phyla, in human gut (Brown et al., 2011). Similarly, RA and MS have also been associated with dysbiosis

(Zhang et al., 2015; Chen et al., 2016; Jangi et al., 2016). Since these autoimmune diseases have strong genetic predisposition, the question arose if the gut microbiota is under the control of host genetic factors. Analysis of gut microbiota in monozygotic and dizygotic twins showed greater similarity between MZ twins compared to DZ twins (Benson et al., 2010). Many host genetic factors have been shown to influence gut microbial composition including HLA genes, Mediterranean fever, resistin-like molecule  $\beta$ , and obese genes (Marietta et al., 2015). Certain genes are involved in limiting bacterial interaction with the epithelium lining of the intestine. Mucin gene (MUC-2) is involved in protection via mucus layer, and MyD88 (myeloid differentiation primary response gene 88) pathway regulates the production of antimicrobial peptide Reg III $\gamma$  (Bergstrom et al., 2010; Vaishnava et al., 2011; Asquith et al., 2010). Yet other genes can control microbial composition. Receptors such as Toll-like receptors (TLRs) and nucleotide-binding oligomerization-domain protein-like receptors (NLRs) act as sensors for microbe-associated molecular patterns. Recent studies have shown a role of these receptors in controlling microbial composition and their association with arthritis. TLRs can bind structurally conserved molecular patterns of microbes and activate innate immune system. Nonobese diabetic (NOD)-like receptor family pyrin domain containing 6 (NLRP6) is expressed in cytosol and can bind procaspase 1 leading to the activation of inflammasomes. Mice deficient in these receptors have altered intestinal microbiota suggesting that microbial interaction with various host proteins may control colonization (Elinav et al., 2011; Oh et al., 2014). Moreover, inflammasomes have been associated with various autoimmune diseases such as MS, RA, and diabetes (Guo et al., 2015). A role of gut microbiome was further supported by mouse models. Humanized mice expressing RA-associated gene showed a loss of age-driven changes in the gut microbiota, while mice expressing RA-resistant HLA gene showed a dynamic change in the gut microbiota suggesting immunogenetic control of the microbiota (Gomez et al., 2012). A correlation between segmented filamentous bacteria and protection from diabetes and susceptibility to arthritis reaffirms a role of gut microbiome in the pathogenesis of and protection from autoimmune diseases (Wu et al., 2010).

## HUMAN LEUKOCYTE ANTIGEN, MICROBIOME, AND RHEUMATOID ARTHRITIS

The mechanism by which HLA genes control intestinal microbial composition is unknown. However, one can speculate that the role of HLA molecules in immune response may determine the colonization of the species in the intestine. Another mechanism by which HLA class II alleles influence microbial colonization could be by the HLA-mediated presentation of bacterial polysaccharides (PSA) by dendritic cells. Indeed the presentation of PSA of *Bacteroides fragilis* generates immunoregulatory response (Surana and Kasper, 2012) that may influence colonization in the gut. Autoimmune predisposing HLA class II alleles may lead to the colonization of opportunistic bacteria in the gut, which under certain inflammatory conditions can lead to break in tolerance. In addition to class II alleles, a role of HLA class I has also been suggested in bacterial colonization as bacterial adhesion protein called curli has been shown to bind immunoglobulin-like domain of the heavy chain and  $\beta 2m$  as well as fibronectin and lead to the production of cytokines (Johansson et al., 2001).

Recent studies have shown perturbed gut and oral microbiome in patients with RA (Zhang et al., 2015; Chen et al., 2016). Patients showed dysbiosis with reduced microbial diversity. RA was characterized by an abundance of rare taxa of phylum Actinobacteria, *Collinsella aerofaciens* and *Eggerthella lenta*, with a decrease in the presence of *Faecalibacterium prausnitzii* (Chen et al., 2016). Fecal microbiota analysis of naive humanized mice expressing RA-susceptible DRB1\*0401 showed the difference from DRB1\*0402 expressing mice (Gomez et al., 2012). Interestingly, naïve DRB1\*0401 mice lost sex-dependent microbial differences while \*0402 mice showed significant gut microbial composition between male and female mice. Moreover, naïve \*0401 mice showed an increase in gut permeability as they aged. MHC molecules have been suggested to regulate diseases by determining cytokine profile by the selection of T cells (Mangalam et al., 2013). HLA class II provides the strongest risk factor for autoimmune diseases. One can envisage that by controlling the immune system, HLA genes can control the colonization of microbes in the gut. It's possible that autoimmune-associated HLA class II molecules generate an environment in the gut that is favorable for microbes that, if present in abundance, can cause inflammation. Intestinal microbial composition is influenced by other factors associated with autoimmune diseases such as smoking and infections. However, since not all individuals carrying the autoimmune-susceptible HLA alleles develop disease, it would appear that another insult to immune system via gut may lead to dysbiosis and inflammation that breaks tolerance. In patients who do not carry the autoimmune-prone HLA genes, other intestinal bacteria or bacterial products may be involved. Interestingly, *E. lenta*, observed with abundance in RA, is involved in ornithine metabolic pathway resulting in the production of citrulline (Chen et al., 2016). While citrulline generated may not be directly involved in the citrullination process, it is transported out of the intestine and

converted into arginine that is again utilized for protein synthesis. Also, microbes can lead to the differentiation of T cells into T follicular cells resulting in the formation of germination centers in the gut and the production of antibodies (Taneja, 2017). Thus an abundance of a taxa or species can generate an abundance of certain byproducts, and based on the specific species, it can cause a significant increase of the byproducts. As many microbes may be able to perform a similar function, metabolites produced as byproducts of pathways microbes are involved in or bacterial products may provide targets for treatment.

## VITAMIN D IN AUTOIMMUNE DISEASES

Epidemiological studies have suggested that vitamin D deficiency is associated with a number of autoimmune diseases. Patients with autoimmune diseases such as RA, MS, T1D as well as lupus have decreased serum levels of vitamin D3. However, clinical trials for supplementation with vitamin D in various autoimmune conditions including, RA, MS, T1D, and CD have elucidated minor improvements in some studies, while others show no effect (Dankers et al., 2016). In MS, there are both a strong north-to-south gradient and high altitude areas with low sunlight (decreased levels of vitamin D) that are associated with an increased disease incidence (Hogancamp et al., 1997; Kurtzke, 2005). African-American patients are three times more likely to develop lupus as compared to Caucasian populations carrying a similar genotype. Together, these studies point toward an important role of vitamin D in predisposition to autoimmune diseases. Cells involved in immune response express vitamin D receptors. Since vitamin D shows a strong immune-modulatory effect, it's hypothesized that vitamin D suppresses autoimmune disease by inhibiting disease promoting proinflammatory response and maintaining immune tolerance (Wen and Baker, 2011). Induction of regulatory T cells and suppressor macrophages by vitamin D had been suggested to play an important role in maintaining homeostasis of the immune system.

Interaction between environmental and genetic factors in etiology of autoimmune diseases can be explained by a "Causal Pie Model" (van der Mei et al., 2011), where MHC represents the major fixed slice, while other slices represent one or another individual components (genetic or environmental) and these can interact to cause disease. To develop an autoimmune disease such as MS or RA, a person must complete the pie, though different people or groups of people might have different slices in their pie. In RA patients an inverse relationship has been described between disease activity and levels of vitamin D metabolites (Patel et al., 2007). Further, an association between a polymorphism of the vitamin D receptor and onset of RA has been observed (Gomez-Vaquero et al., 2007). Vitamin D metabolites have been shown to inhibit the production of IL-17A and stimulate IL-4 production in early RA patients (Colin et al., 2010). Thus a deficiency of vitamin D may lead to proinflammatory conditions. Patients carrying susceptible genotypes may require one or more factors, such as smoking, infection, or deficiency in vitamin D, to precipitate RA.

Similarly, in a subset of MS patients carrying the HLA-DRB1\*1501 allele, immune reactivity to EBV and smoking might complete the pie, leading to clinical disease. In other individuals, vitamin D and smoking or EBV and vitamin D might complete the pie and cause the precipitation of disease (Ascherio and Munger, 2007). EBV may cause MS through molecular mimicry as T/B cells against the EBV antigen have been shown to cross-react with myelin antigen, leading to a break in tolerance. Smoking can also increase immune reactivity to viruses such as EBV, and T cells specific to EBV antigen can further activate myelin-specific T cells through molecular mimicry (Lunemann et al., 2008). These interactions might lead to MS-related immune dysregulation that involves the activation of T cells, the modulation of dendritic cell (DC) function, and blood–brain barrier permeability.

## POSTTRANSLATIONAL MODIFICATIONS IN AUTOIMMUNITY

Posttranslational modifications of proteins occur *in vivo* frequently. In most cases, this process enables the clearance of infection and malignant cells. For example, the modification of viral antigen could enable its binding to MHC molecules for the activation of T cells. Similarly, malignant self-tissue could be modified to make them more antigenic. This process also occurs occasionally in normal proteins (Gyorgy et al., 2006; Greer and Shi, 2012). Unfortunately, the posttranslational modification of self-antigen could activate autoreactive cells, for example, posttranslational modification of synovial or joint-related antigen could trigger an immune response that would activate autoreactive T cells in the genetically predisposed individuals. There are many types of posttranslational modifications (PTMs). Modifications that change an amino acid include phosphorylation, methylation, and glycosylation while enzymatic conversions include deamidation and deimination.

## Deimination

The enzymatic process by which citrulline, a noncoded amino acid, is inserted in proteins is called deimination. PAD is the enzyme required for catalytic deimination of peptidyl arginine to citrulline, a process called citrullination, first described by [Fearon \(1939\)](#). Citrullination of proteins occurs under many conditions; however, an aberrant B cell response to citrullinated proteins is specific to RA. The presence of ACPA has been shown to be specific to RA patients.

Rheumatoid arthritis is associated with the presence of DRB1\*0401. GWAS using genotyping for single nucleotide polymorphisms of RA patients have confirmed the association of DRB1 with RA ([Harel-Meir et al., 2007](#)). Studies in some populations have shown an association of RA with the PADI4 gene encoding for PAD isotype 4 ([Suzuki et al., 2003](#)). The peptide-binding region of \*0401 has a positive charge; thus antigens with positive-charged arginine cannot bind. Citrullination of arginine changes the charge to neutral, enabling the antigen to bind DRB1\*0401 molecules for the generation of an immune response. This is supported by studies suggesting that ACPAs in RA sera strongly associate with the presence of DRB1 shared epitope alleles. In RA patients, the presence of ACPAs is used for clinical diagnosis in association with rheumatoid factor (RF). Sera from RA patients have been shown to carry antibodies to citrullinated synovial proteins that include CII, fibrinogen, vimentin, and fibronectin. Citrullination of these proteins can potentially alter their antigenicity and function; and in genetically predisposed individuals, this might lead to an autoreactive immune response. Studies using DR4.1E transgenic mice have shown that citrullinated fibrinogen can induce arthritis although no significant difference was observed in T-cell response to citrullinated and native fibrinogen. In DR4+ RA patients, T cells reactive to citrullinated vimentin-derived peptides rather than native peptides have been described, suggesting a crucial role of citrullinated vimentin in RA pathogenesis. Thus posttranslational conversion of peptidyl arginine to peptidyl citrulline by PAD enzymes appears to be an essential feature of many autoantigens in RA. A recent study utilizing humanized mice showed that RA-resistant \*0402 can also present citrullinated Vimentin and generate response suggesting that this phenomenon is not unique for \*0401 ([Bidkar et al., 2016](#)). However, immune response generated to citrullinated vimentin was different by RA-susceptible and resistant strains. In addition to HLA-DR molecules, it has been shown that DQ8 can also present citrullinated peptides ([Vassallo et al., 2014](#)) suggesting both \*0401 and DQ8 as haplotype may have an additive effect on the presentation of citrullinated proteins leading to abnormal immune response.

Estrogen can increase the production of the PAD enzymes required for citrullination of proteins ([Senshu et al., 1989](#)). A primary risk factor for the production of ACPAs in RA is the presence of the DRB1 shared epitope. Immunization with native CII-derived peptides that are nonresponders in native form in DRB1\*0401 mice followed by challenge in vitro with citrullinated peptide generated a higher response in female mice compared to males ([Behrens et al., 2010](#)). A higher antigen presentation has been shown by splenic cells and epithelial cells during proestrus when estrogen is high. One can speculate that the increased expression of PAD enzyme during estrous cycle could cause an increase in the citrullination of peptides, not only in the uterus, but other tissues including synovial tissue. This could result in the citrullination of multiple synovial specific autoantigens and their presentation by DRB1\*0401 molecule leading to the activation of autoreactive CD4 T cells and autoimmunity. This could be one of the reasons for a higher incidence of autoimmune diseases in females.

## Deamidation

Around 90% of proteins undergo some form of PTMs, which increases the structural and functional diversity of proteome. PTMs such as deamidation have been shown to be associated with autoimmunity. Deamidation is a chemical reaction in which an amide functional group is removed from a protein leading to the degradation of the protein because it damages the amide-containing side chains of the amino acids. Asparagine (Asn) and, to a lesser extent, glutamine (Gln) are prone to spontaneous deamidation changing them to aspartic/isoaspartic acid and glutamic acid, respectively. The rate at which Asn and Gln residues are deamidated is dependent on the neighboring residues in the peptide. The presence of glycine and serine as neighboring residues to Asn and Gln has a destabilizing effect, making them a target for deamidation.

In addition to spontaneous deamidation, enzymatic deamidation also occurs and requires transglutaminase (TG2). Transglutaminase is a calcium-dependent enzyme that is involved in the deamidation of glutamine side chains. Enzymatic deamidation of glutamine converts it to glutamic acid. Tissue transglutaminase (tTg) is widely distributed and is ubiquitously present in the cytosol and the extracellular space within many connective tissues and is involved in many functions. Deamidation by tTg is dependent on the presence of either a proline residue

or a hydrophobic amino acid such as C-terminal Phe of the target glutamine. In CD patients, an immune response to a wheat-derived protein, gliadin, can generate an autoimmune response. CD is a good example of how modified proteins induce an immune response even though the initiating antigen may not involve a self-protein. T cells of patients with CD recognize peptides of gliadin that are deamidated (Glu to Gln).

CD is associated with the presence of HLA-DQ2 in the majority of patients, and the remaining patients are generally positive for DQ8. Deamidation of gliadin peptides changes the charge leading to a better binding of peptides to DQ2 and DQ8 and the generation of an immune response. Studies in CD have shown that tissue transglutaminase enzymes can deamidate peptides of gliadin that are presented by DQ8 or DQ2 leading to gluten sensitivity.

## HUMANIZED ANIMAL MODELS OF AUTOIMMUNITY

The advent of transgenic mice lacking endogenous class II molecules ( $A\beta^0$ ) but expressing human HLA-DR and HLA-DQ genes has significantly advanced the understanding of the role of individual HLA class II molecules (Mangalam et al., 2008; Taneja and David, 2010). The introduction of HLA class II transgenes in  $A\beta^0$  mice led to the expression of functional HLA class II molecules and reconstituted the CD4 T-cell compartment, thus resulting in CD4 restricted immune response to various peptides. The HLA transgene in these mice is self and so they are tolerant to it. Experimental data from various laboratories have shown that the HLA class II molecules in these mice function in a way similar to that in humans. The first evidence came from in vivo and in vitro studies done with super antigens in HLA transgenic mice. Bacterial super antigens (SAg) have a lower affinity for mouse

MHC class II than for human MHC class II molecules. Because of this biological characteristic, SAg-induced toxicity is much lower in mouse models than it is in humans. When immunized with lower concentrations of SEB, HLA-DR3 transgenic mice respond vigorously, activate multiple T cells, and secrete higher levels of proinflammatory cytokines than wild-type mice (DaSilva et al., 2002). The response to super antigens in transgenic mice can result in toxic shock and is dependent on the polymorphism of HLA class II alleles.

The second evidence comes from the peptide presentation by HLA class II molecules in transgenic mice. The HLA transgenic mice respond to similar epitopes as observed in humans. In a comparison study, DR3.  $A\beta^0$  mice recognized only one epitope comprising aa 1–20 for heat shock protein 65 of *Mycobacterium tuberculosis* as observed with human DR3-restricted T cells (Geluk et al., 1998). The response was specific in DR3 mice as DQ8 mice did not respond to this peptide. These studies suggest that processing and presentation of the antigens in the context of class II molecules is similar in transgenic mice and humans.

The third evidence that HLA transgenes in mice function similar to humans comes from studies with experimental autoimmune myasthenia gravis in DR3 transgenic mice (Infante et al., 2003). The wild-type mice show a highly conserved TCR-BV gene usage and CDR3 sequences in response to acetylcholine receptor (AChR), an autoantigen for myasthenia gravis patients. However, DR3-restricted murine hybridomas generated from DR3 mice immunized with AChR expressed a diverse set of TCR  $\beta$  chains, similar to that observed in humans. The TCR-BV sequences from human MG patients were homologous to DR3-restricted murine clones, suggesting that human and mice can recognize similar epitopes and use similar CDR3 sequences for the recognition of the same peptide/MHC complex. Thus transgenic mice can provide an important insight into peptide presentation by different class II alleles and the resulting pathogenesis.

## COLLAGEN-INDUCED ARTHRITIS

Collagen-induced arthritis has been used as a model for inflammatory arthritis where the immunization of susceptible strains of mice with type II collagen leads to the development of arthritis with features similar to those of human inflammatory arthritis. The first model of autoimmunity to determine the role of human class II molecules in arthritis was established by using DQA1\*0301, DQB1\*0302 (DQ8) transgenic mice. DQ8 occurs in linkage disequilibrium with DR4 and has been shown to be associated with RA in certain ethnic groups (Taneja et al., 1992). Collagen-induced arthritis, an animal model for RA, was studied in vivo in  $A\beta^0$ .DQ8 mice. The immunization of  $A\beta^0$ .DQ8 mice with heterologous type II collagen led to a pathogenic autoimmune CD4 mediated response leading to severe arthritis and antibodies to self-type II collagen (Nabozny et al., 1996). Both CD4 T cells and B cells are required for the development of arthritis in transgenic mice (Taneja et al., 2005, 2007b). This

is the first model where arthritic mice produced RF, one of the major features in patients with RA (Taneja et al., 2002). The scenario in the development of arthritis in transgenic mice can be compared to that of RA in human. Both require the presentation of an arthritogenic epitope by HLA class II molecules to CD4 T cells, leading to the proliferation of autoreactive cells and the production of RF by B cells, subsequently leading to joint pathology. Further, studies using CD4-deficient and CD8-deficient mice suggested that the disease was mediated by CD4+ T cells while CD8+ T cells may be the regulatory cells as CD8-deficient mice transgenic for DQ8 develop high amounts of autoantibodies including RF and antinuclear antibodies (ANA) (Taneja et al., 2002). A similar phenomenon can be envisaged in RA where the production of autoantibodies such as RF and ANAs could be related to the functional status of CD8 T cells. On the other hand, mice expressing DQA1\*0103, DQB1\*0601 (DQ6) were resistant to develop CIA. The double transgenic mice expressing both DQ6 and DQ8 developed moderate CIA when compared with the severe arthritis observed in DQ8 transgenic mice (Bradley et al., 1998) much like RA patients bearing both susceptible and nonsusceptible HLA haplotypes. These observations contributed to the concept that polymorphism in DQ may be a major contributing factor in human RA.

Predisposition to RA has been associated with the expression of some subtypes of HLA-DR4 in most human studies ever since the first association of DW4 and RA shown by Stastny (1978). However, most of the studies in different ethnic groups have observed only two alleles, DRB1\*0401 and \*0404, which occur with an increased frequency in RA patients. Thus while DRB1\*0401, 0404 are associated with predisposition, DRB1\*0402 is associated with resistance or protection against RA. To determine the role of DR4 molecules in RA, DRB1\*0401 mice were generated in complete MHC knockout mice (AE – / –). DRB1\*0401.AE – / – mice develop arthritis that mimics human arthritis in sex-bias and autoantibodies production (Taneja et al., 2007a). AE – / – mice have the deletion of an 80 kb region of MHC class II such that none of the classical murine class II molecules are expressed. Human T cell is unique from mice in the expression of MHC class II molecules on their cell surface. Interestingly, similar to humans, T cells from AE – / – DR transgenic mice express HLA-DR molecules on their cell surface and can present peptide antigen. Thus the presentation of an antigen in the context of HLA by an activated T cell might also contribute toward severity. Interestingly, antigen presentation by B cells was shown to generate a sex-bias response, and treatment with B cell depleting antibody shows sex-biased response in humanized mice (Behrens et al., 2017).

To simulate human haplotypes, double transgenic mice expressing autoimmune-associated DQ and DR alleles were generated on the AE – / – background. DR4\|DQ8.AE – / – mice developed arthritis similar to DQ8 but also showed gender differences. Gender differences in CIA were not observed in DQ8 mice suggesting the modulation of DQ8-restricted disease by DR4 molecules. To understand the modulation by DR polymorphism, DRB1\*0402 mice were studied (Taneja et al., 2008) for their influence on CIA. DRB1\*0402 mice are not susceptible to arthritis, similar to humans. Mice expressing both susceptible and resistant DR4 subtypes, 0401/0402, developed arthritis with lower incidence than \*0401 mice (Taneja et al., 2003). Further, data in DR\*0401/DQ8 mice suggested that antigen-presenting cells present DR-restricted peptides differentially suggesting a role of hormones in influencing APCs (Behrens et al., 2010; Luckey et al., 2012). Based on the data in transgenic mice, it can be speculated that hormone-influenced PAD enzymes may lead to citrullination of antigens in females, thus enhancing the presentation of certain antigens. The experimental and human data led us to hypothesize that DQ polymorphism may be responsible for susceptibility, while DR may be involved in the modulation of disease. Thus both DQ and DR alleles as a haplotype influence the development of disease (Taneja et al., 1998). From the studies on DQ and DR transgenic mice, it can be extrapolated that gene complementation or interaction between DQ and DR molecules mediates susceptibility to RA in the human. Depending on the haplotypes carried by an individual, they could be susceptible to severe or mild disease. A homozygous haplotype for predisposing DQ and permissive DR will lead to severe disease. Also, heterozygous RA-susceptible haplotypes will result in very severe disease since there will be two predisposing DQ molecules. However, one predisposing and one protective haplotype should show less severity and low incidence.

## NONRHEUMATOID ARTHRITIS-ASSOCIATED HUMAN LEUKOCYTE ANTIGEN ALLELES CAN PREDISPOSE TO AUTOIMMUNITY

HLA-DQ6 alleles, DQB1\*0601 and \*0604, are not associated with susceptibility to develop arthritis. DQB1\*0601 occurs in linkage with DQA1\*0103 and DQB1\*0604 with DQA1\*0102. To understand if transheterodimers of two nonsusceptible HLA alleles may have a role in rendering susceptibility to develop arthritis, we generated mice expressing DQB1\*0601/ DQA1\*0103 (DQ6.1) and DQB1\*0604/DQA1\*0103 (DQ6.4). Immunization of transgenic

mice leads to the development of severe CIA in DQ6.4 but not DQ6.1 mice (Behrens et al., 2011). Further, data showed that DQ6.4 molecules could present CII-derived peptides similar to those presented by the CIA-susceptible DQ8 allele. These studies suggested that transheterodimer molecules between two DQB1 and DQA1 alleles may result in the presentation of unique antigens and susceptibility to develop arthritis. Molecular modeling of the CII peptides showed that DQB1\*0604/DQA1\*0103 shares the p4 pocket with the arthritis-susceptible DQB1\*0302 allele and further a critical role of p4 and p9 pockets is suggested with susceptibility to arthritis. In some conditions, DQA1\*0103 can form heterodimer with CD74 and be expressed on the cell surface and present antigen leading to the development of arthritis (David et al., 2016). This provides an explanation for the presence of nonsusceptible alleles in some RA patients and a mechanism by which they can predispose to develop arthritis.

### HUMAN LEUKOCYTE ANTIGEN-DR TRANSGENIC MICE WITH EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS AS AN ANIMAL MODEL OF MULTIPLE SCLEROSIS

Multiple sclerosis (MS), a chronic inflammatory disease of the central nervous system, shows strong linkage with the presence of HLA-DR2 haplotypes (DRB1\*1501, DRB5\*0101, DQA1\*0102, and DQB1\*0602) (DRB1\*1501, DRB5\*0101, DQA1\*0102, and DQB1\*0602) (Oksenberg et al., 1993). Besides DR2, MS has also been associated with HLA-DR3 and -DR4 haplotypes (Weinshenker et al., 1998; Coraddu et al., 2001). HLA DR3/DQ2 haplotypes have been shown to confer an increased risk for relapsing-remitting MS in individuals (Weinshenker et al., 1998). The lack of a complete association to a particular HLA allele suggests that MS is a heterogeneous disease at the molecular level. MS is hypothesized to be mediated by autoreactive T cells against a variety of myelin antigens including myelin basic protein (MBP), proteolipid protein (PLP), and myelin oligodendrocytic glycoprotein (MOG).

Experimental autoimmune encephalomyelitis (EAE) has been used as an animal model of MS where the immunization of susceptible strains of mice with autoantigens, such as PLP, MBP, or MOG, can lead to the development of inflammation and demyelination in CNS, similar to MS pathology observed in patients (Mangalam et al., 2004; Rich et al., 2004). Induction of EAE with recombinant myelin oligodendrocyte glycoprotein (rMOG) in DR2 mice (DRB1\*1501, DRB1\*1502, and DRB1\*1503) showed that all three strains developed EAE; however, the disease incidence and severity was higher in DRB1\*1501 transgenic mice. Almost all the T-cell epitopes identified in HLA transgenic mice using overlapping epitopes of MBP, PLP, and MOG are similar to those identified among T cells isolated from peripheral blood mononuclear cells of MS patients (Khare et al., 2003; Kawamura et al., 2000). The administration of PLP91-110 peptide-induced EAE in DR3 transgenic mice (Mangalam et al., 2009). Recently we have also observed that PLP178-197 peptide can induce EAE in HLA-DR4 (DRB1\*0401) transgenic mice, while HLA-DR4 (DRB1\*0402) transgenic mice were resistant to disease. The disease in transgenic mice was characterized by the paralysis of limbs with mild demyelination, while in humans demyelination is the major feature of MS. CD4+ T cells have been shown to infiltrate the CNS and are responsible for inflammation and demyelination in MS. It is speculated that class II molecules on T cells may present myelin antigen in CNS and exacerbate the disease. To replicate the human disease, DR3.AEo mice were utilized for EAE with PLP peptide (Mangalam et al., 2006). The DR3.AEo transgenic mice with EAE showed severe inflammation and demyelination in the meningeal, stratum, and brain-stem regions, a hallmark for human MS. HLA class II expression was detected in the CNS, especially on microglial cells. These experiments suggest that humanized HLA class II transgenic mice simulate human MS and are a good model to study the role of class II molecules in its pathogenesis.

### ROLE OF DQ MOLECULE IN PREDISPOSITION TO MULTIPLE SCLEROSIS

To simulate the human haplotype, we generated double transgenic mice expressing HLA-DR2 and DQ8 (DR2/DQ8). When immunized with rMOG, 90% of the mice-developed disease accompanied with severe inflammatory and demyelinating lesions in CNS as compared to DR2 single transgenic mice (Khare et al., 2005). Similarly, the expression of DQ8 on a disease susceptible DR3 background (DR3/DQ8 double transgenic mice) led to the development of severe EAE upon immunization with PLP91-110 peptide (Mangalam et al., 2009). The disease in DR3/DQ8 double transgenic mice was characterized by earlier disease onset, higher clinical score and increased inflammation, and demyelination in CNS compared to single DR3 transgenic mice. Since HLA-DQ8

mice were resistant to EAE, our data suggested that DQ8 allele synergizes with disease susceptible HLA-DR allele(s) for a more severe disease phenotype suggesting its pathogenic role in disease etiology. We further determined that the increased susceptibility in DQ8/DR3 mice was due to the increased production of the proinflammatory cytokines IL-17 and GM-CSF. Higher IL-17 levels might lead to the activation and recruitment of more inflammatory cells inside the CNS, while GM-CSF has been shown to increase antigen presentation, both in the periphery and CNS.

In contrast, HLA-DQB1\*0601, observed frequently in Japanese and Asian populations, is known to be protective in MS ([Amirzargar et al., 1998](#); [Marrosu et al., 2001](#)). DQB1\*0601 transgenic mice were resistant to EAE on immunization with MOG, MBP, or PLP antigens. The expression of HLA-DQB\*0601 allele in disease-susceptible HLA-DR2 or -DR3 transgenic mice led to a decrease in disease incidence and severity suggesting a protective role of the allele in disease pathogenesis. Immunization of DR2/DQB1\*0601 mice with rMOG led to lower disease incidence compared to DR2 single transgenic mice. Similar findings were also observed in DR3/DQ6 mice immunized with whole myelin or human PLP91-110 ([Das et al., 2000](#)). We have further characterized that the protective effect of DQ6 molecules is due to high levels of IFN $\gamma$  produced by DQ6 restricted T cells, which suppressed the proliferation of encephalitogenic DR3-restricted T cells by inducing apoptosis. Our study suggests that DQ6 modifies the PLP91-110 specific T-cell response in DR3 through antiinflammatory effects of IFN $\gamma$ .

From the EAE data generated using whole myelin (CNS extract), rMOG and PLP91-110, we have observed that the presence of (1) HLA-DR molecules is required for the development of disease; (2) HLA-DQ6 or DQ8 molecules alone are not sufficient for disease induction; (3) HLA-DQ8 on disease susceptible HLA-DR2 or HLA-DR3 transgenic mice increased the severity and incidence of disease; (4) DQ6 (DQB1\*0601) molecules suppress disease incidence and severity on disease susceptible HLA-DR2 or HLA-DR3 transgenic mice; (5) DQ6 or DQ8 on a disease-resistant background had no effect on disease induction as none of the HLA-DR2/DQ6, DR2/DQ8, or DR4/DQ8 double transgenic mice developed EAE on immunization with PLP91-110 peptide. These data would suggest that while the presence of certain DR gene(s) predisposes an individual to MS, polymorphism in DQ gene(s) might play a modulating role. This study also points out that MS is a heterogeneous disease and HLA association is specific for various autoantigens involved.

## ANIMAL MODEL OF CELIAC DISEASE

We have used transgenic mice that express HLA-DQ8 to evaluate the response to gliadin (done in collaboration with Dr. Joseph Murray and Dr. Eric Marietta; [Marietta et al., 2011](#)). Immunization of DQ8 mice with gluten led to a strong T-cell response and IgG antibodies against gluten, but no enteropathy was observed. In order to introduce an autoimmune component to our mouse model of CD, we backcrossed DQ8 transgenic mice to a NOD genetic background that was deficient in endogenous murine MHCII. This resulted in transgenic NOD mice that expressed human DQ8. With parenteral sensitization to gluten, these mice developed blistering upon the ears, reminiscent of dermatitis herpetiformis (DH), the skin manifestation that is found in 3%–5% of the patients with CD ([Marietta et al., 2004](#)). This model had all the elements of DH, including IgA deposits at the dermal–epidermal junction, infiltration of neutrophils into the dermis of the lesional tissue and, most importantly, the resolution of the disease with a gluten-free diet and/or dapsone treatment. However, unlike the majority of DH patients, these mice did not develop enteropathy with gluten sensitization.

Using DQ8 mice, it was shown that T-cell hybridomas generated to native peptides mounted a heteroclitic response against the deamidated peptide, suggesting a role of the class II molecule in amplifying the T-cell response against dietary gluten. Thus an aberrant innate immune response to gliadin could activate tTg that would result in deamidated forms of gliadin-derived peptides. This could result in an enhanced T-cell response to gliadin, causing damage and enteropathy. This heteroclitic response would also explain why most adult celiac patients have a strong T-cell response against the deamidated forms of the specific gliadin-derived peptide.

In transgenic mice that express both HLA-DQ2 and DR3 ([de Kauwe et al., 2009](#); [Du Pre et al., 2011](#)), sensitization to gliadin resulted in a strong T-cell response to gliadin, but no overt enteropathy. One group went further and generated a DQ2/DR3 mouse that expressed a gliadin-specific TCR that had been identified in the gliadin-sensitization studies ([de Kauwe et al., 2009](#)). These mice responded to deamidated gliadin peptide and generated the Th1 response present in CD patients but did not develop enteropathy, suggesting that a second insult to mucosa may be required for the development of enteropathy in humans. The absence of pathology in the presence of antigen-specific CD4 T cells may suggest that other systemic factors may be involved in disease

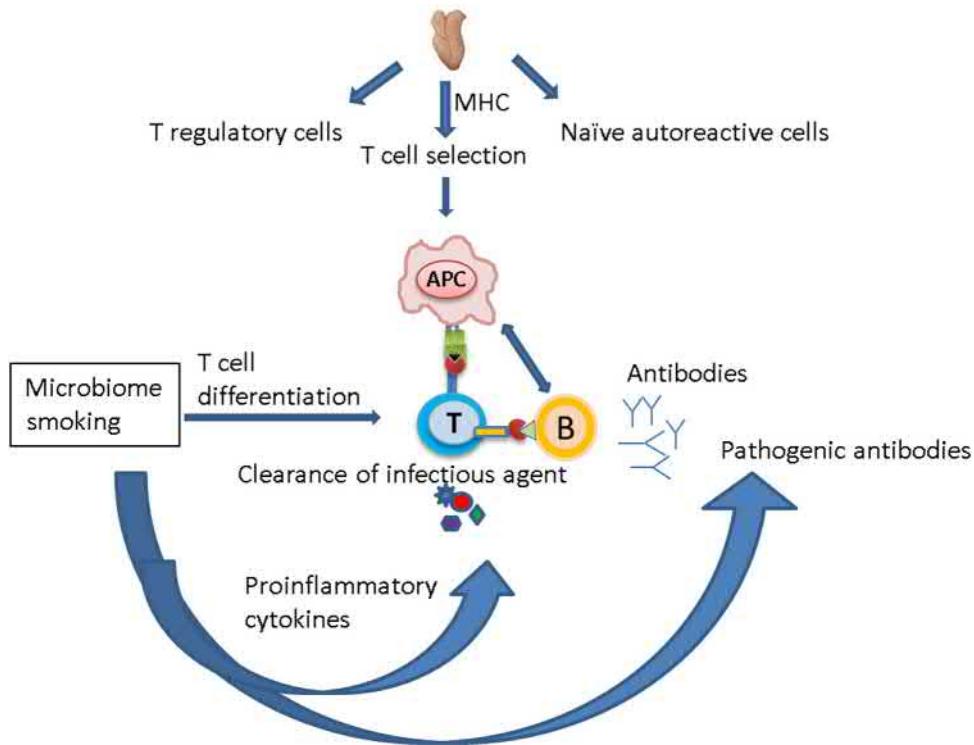

pathogenesis. The patients with CD have upregulated the expression of IL-15 in lamina propria and intestinal epithelium (Abadie and Jabri, 2014). Mice overexpressing IL-15 in the presence of antigen-reactive T cells did not lead to enteropathy suggesting other pathways are involved in breaking tolerance (Korneychuk et al., 2015).

## ANIMAL MODEL FOR TYPE 1 DIABETES

Type 1 diabetes show familial clustering and is linked with the presence of HLA-DQ8/DR4 and HLA-DQ2/DR3 haplotypes. Within the HLA-DQ8/DR4 haplotype, HLA-DQ8 is believed to be the predisposing class II molecule. Most knowledge about autoimmune diabetes comes from a special strain of NOD mice that develop spontaneous diabetes. Elegant genetic studies performed in these mice have mapped the development of disease to the presence of MHC class II molecule H2-A<sup>g7</sup>. Interestingly, the H2-A<sup>g7</sup> molecule shows strong structural and functional homology with human HLA-DQ8 molecules, thus strengthening the major pathogenic role of DQ8 in human T1D. Although HLA-DQ8 transgenic mice do not develop spontaneous diabetes, they lost tolerance to self-GAD65 antigen, leading to activation of autoreactive T cells in the periphery and pancreas. These transgenic mice show insulitis but do not progress to diabetes. As with DQ8 transgenic mice, the presence of a T1D predisposing MHC allele in certain individuals could result in the escape of autoreactive T cells against pancreatic antigens. However, the onset of disease might require a second hit in the pancreas. This second hit can come in the form of virus/bacterial infection, and/or the overproduction of a cytokine, the overexpression of an accessory molecule, or other genetically determined variations completing the causal pie and precipitation of disease in these individuals. To simulate such an insult in the pancreas, we generated HLA-DQ8 (disease susceptible) and HLA-DQ6 (disease resistant) transgenic mice expressing the costimulatory molecule CD80 (B7.1) in islet  $\beta$  cells under the rat insulin promoter (RIP) (Wen et al., 2000). HLA-DQ8/RIP/B7.1 mice developed spontaneous diabetes, while no disease was seen in DQ6/RIP/B7.1 transgenic mice. These studies further confirmed that while the HLA class II allele is the major predisposing gene for the development of most, if not all, autoimmune diseases, other insults or signals are required for precipitation of the disease. Further studies using double transgenic mice expressing DQ8 with HLA-DR3 or HLA-DR4 indicated that the HLA-DR molecule can modulate the diabetogenic effect of DQ8 (Rajagopalan et al., 2003), which in turn suggests that interaction between various MHC class II molecules in *cis* as well as *trans* plays an important role in predisposition, onset as well progression of the disease.

## HUMAN LEUKOCYTE ANTIGEN CLASS II MOLECULE REGULATE INFECTION THROUGH MODULATION OF CYTOKINE NETWORKS

The MHC has evolved over millions of years to fight infection. Mediators such as cytokines and chemokines produced following antigen presentation play an important role in the clearance of pathogens. The association of a particular HLA class II haplotype with disease seems to depend on geographical locations as well as the ethnic composition of the populations. Evolutionarily DQ is a stable molecule with less polymorphism than observed in DRB1 locus. The DQ8 molecule has not undergone many changes during evolution and occurs with only three known subtypes. This could be because DQ8 has the advantage of being able to bind and present multiple peptides. On the other hand, DR has many subtypes. For example, DRB1\*04 has at least 50 subtypes; however, not all the subtypes are associated with susceptibility to autoimmune diseases. We speculate that DR4 polymorphism occurred to counteract the predisposition to autoimmunity imposed by the DQ8 molecule. Thus multiple subtypes of DR4 lead to many possible DR4\DQ8 haplotypes. Only those with an advantage of presenting microbial antigens, clearing infections, and with the capacity to counter the autoimmune responses may eventually be selected. Therefore it's possible that HLA molecules were selected based on their ability to induce subsets of T cells for the production of a particular cytokine that is responsible for controlling one set of microorganisms. Interferon gamma (IFN $\gamma$ ) is one of the signature cytokines of Th1 type of T cells and controls intracellular pathogens. At the same time, IL-17, a signature cytokine of Th17 T cells, controls extracellular pathogens. Thus one set of class II genes might have evolved to produce IL-17 for controlling the spread of extracellular pathogen, while others produce Th1/Th2 to control other pathogens. Using our transgenic mice, we have observed that while transgenic mice expressing HLA-DQ8 induce more TH17 type of T cells, HLA-DQ6 transgenic mice induce more IFN $\gamma$ -producing CD4 T cells. This might result in a cytokine milieu that can regulate disease onset and progression (Mangalam et al., 2013; Luckey et al., 2014). A scenario

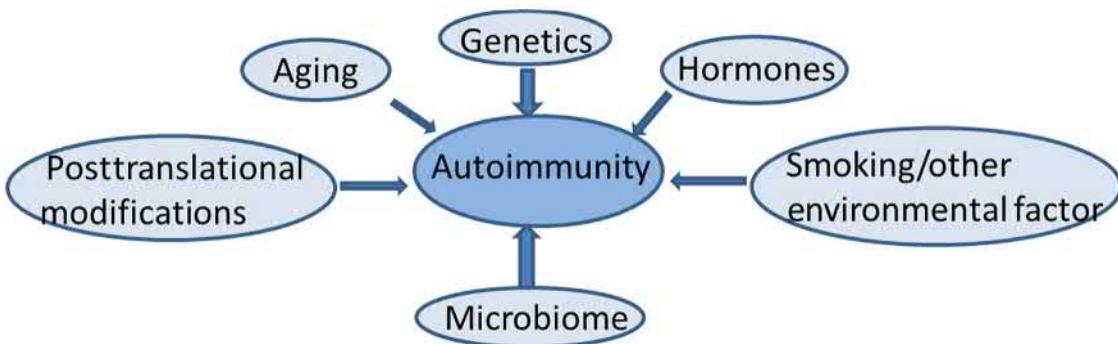

**FIGURE 26.2** HLA molecules select T-cell repertoire in the thymus by presenting peptides and also serving as donors of self-peptides. T cells are selected on the basis of their interaction with self-MHC molecules expressed in thymus. Thus T cells reactive with self-peptide binding with high affinity to MHC are negatively selected in the thymus while those with weak interactions may escape negative selection. Such a mechanism may explain the selection of an autoreactive T-cell repertoire. In the periphery, positively selected T cells can recognize nonself-antigens, produce cytokines and antibodies to clear infections. The autoreactive T cells that have escaped can recognize viral peptide that mimics self-antigen, or cryptic epitopes that are exposed during infection or posttranslational modification causing the activation of autoreactive T cells. These T cells can migrate to various organs, and depending on the host genotype and its interaction with the nongenetic factors, they can cause inflammation locally. The response can be exacerbated in the presence of self-peptides, that when presented by antigen-presenting cells in the tissue leading to the production of proinflammatory cytokines and autoantibodies ensuing an autoimmune response. Environmental factors such as microbiome can lead to differentiation of T cells into T follicular cells that with the help of B cells produce antibodies. Smoking can augment the modification of proteins and contribute to proinflammatory cytokine production, thus enhancing disease severity. *HLA*, Human leukocyte antigen; *MHC*, major histocompatibility complex.

where interaction between HLA molecules and environmental factors leads to the onset of an autoimmune response and disease can be envisaged (Fig. 26.2).

## HUMAN LEUKOCYTE ANTIGEN CLASS II MOLECULES REGULATE AUTOIMMUNITY BY ANTIGEN-SPECIFIC T REGULATORY CELLS

As suggested above, cytokines play a major role in driving an overall proinflammatory or antiinflammatory response based on the HLA polymorphism. Now there is evidence that HLA-mediated protection from autoimmune diseases may be associated with T regulatory cells specific to an antigen involved in the disease. The evidence for this comes from two elegant studies. Vimentin is considered an autoantigen in RA pathogenesis as ACPA+ antibodies have antivimentin antibodies. Using DRB1\*0401 tetramers coupled with citrullinated Vim-59-71 peptide, Scally et al. (2013) showed that while healthy individuals also carried CD4+ T cells specific to the peptide, the ratio of T regulatory to effector memory cells was higher in healthy controls as compared to RA patients. This data suggested that the disproportionate expansion of antigen-specific Treg and effector cells may be associated with RA. In another elegant study, using HLA-DR15 and DR1 transgenic mice, authors investigated a role of antigen-specific T cells in the pathogenesis of autoimmune Goodpasture disease (Ooi et al., 2017).

**FIGURE 26.3** Autoimmunity is multifactorial that involves both genetic and environmental factors. Among genetic factors, HLA class II alleles provide the strongest risk. Among environmental factors, microbiome and smoking are the prime risk factors. Host genotype determines an individual's core gut microbiome, and certain species may contract or expand depending on the exposure to various environmental factors, thus influencing the immune system locally in the gut as well as adaptive immune system. A role of hormones and age-associated changes in immune system may contribute to altered immune response in autoimmunity. Responses to posttranslational modified proteins, generated for efficient presentation, augment proinflammatory response and enhance autoreactivity. *HLA*, Human leukocyte antigen.

The presence of CD4+ T cells to an epitope derived from the  $\alpha 3$  chain of type IV collagen 135–145 is linked to Goodpasture disease. Using DR15 antigen-specific tetramers, authors showed that in DR15 mice, these cells exhibit a proinflammatory profile and cause kidney disease. On the other hand, DR1-antigen-specific tetramers + CD4 T cells express tolerogenic CD4+ FoxP3+ Treg cells. These studies suggest that the autoimmune-associated HLA molecules may predispose or protect based on what T cells are expanded and the cytokines produced by those T cells. The question what determines the expansion of pathogenic T cells may lie in the role of environmental factors as discussed above.

## CONCLUDING REMARKS

From various *in vivo* and *in vitro* studies, it has become clear that MHC and non-MHC genetic components are common elements for various autoimmune diseases, and in corresponding animal models (Fig. 26.3). Thus polymorphism in MHC is an advantage for human survival, but autoimmunity is the price that the population must pay for combating infection effectively and for survival. In evolutionary terms, only those HLA genes that can generate strong immune responses to infections are selected. The constant mutations observed might be leading to the generation of new subtypes of an allele to circumvent autoimmunity. Haplotypes and not a single class II allele function in the selection of the T-cell repertoire and susceptibility to disease.

The problem of science will consist precisely in this, to seek the unitary character of physiological and pathological phenomena in the midst of the infinite variety of their particular manifestations. *Bernard (1865)*.

All models are wrong but some are useful. *Box (1979)*.

## WHAT CAN ANIMAL MODELS TEACH US ABOUT ORGAN-SPECIFIC AUTOIMMUNITY?

Throughout recorded history, animals have claimed a principal place in our imagination and inspired a broad range of practices that substantially shaped the course of our collective pursuit to organize and control the natural world. Based on the notion that humans and other animal species apparently share certain anatomic and physiological characteristics, the heuristic use of animals to specifically address questions about human health and disease emerged at least 2500 years ago and the potential, limitations, and ethical implications of "animal

experimentation" have been discussed ever since (Ericsson et al., 2013; Franco, 2013). The related concept of "animal model" can therefore draw on a rich history of practical and discursive exploration but its actual formalization emerged only in the late 20th century and includes the proposed definition of "a living organism in which normative biology or behavior can be studied, or in which a spontaneous or induced pathological process can be investigated, and in which the phenomenon in one or more respects resembles the same phenomenon in humans or other species of animal" (CMBR, 1985; Hau, 2003; Held, 1980; Wessler, 1976). The contemporary concretization of these ideas further integrates the ethical core principles that build on Russell and Burch's original "3Rs" (replacement, reduction, and refinement) as a guide for animal studies and that continue to evolve to meet the concerns and challenges arising from an ongoing effort to balance the importance of empiric and value judgments (Tannenbaum, 2017). Since "the definitions of key concepts used in any scientific endeavor express the fundamental aims and priorities of that endeavor" (Tannenbaum and Bennett, 2015), it is within this larger context that animal models for organ-specific autoimmune diseases have to be considered (Cohen and Miller, 1994; Morel, 2004; Taneja and David, 2001; Wekerle et al., 2012; Williams, 2010; Yu et al., 2015). We submit that beyond the practical aspects of harnessing animal models for the study of specific autoimmune disorders, a historically and epistemologically informed perspective ultimately will precipitate the development of more productive research practices by allowing for more accurate diagnoses of current shortcomings and better prescriptions for needed course corrections. In what follows, we will first sketch out examples of scientific questions that are typically answered with the aid of animal models before embarking on a broad survey of their use and utility for the study of major organ-specific autoimmune diseases.

## Animal Models in Basic Science: Understanding the Complexity of Organ-Specific Autoimmunity

Arguably the most important and certainly most obvious path toward an improved and actionable understanding of organ-specific autoimmune diseases is the combination of clinical observation and intervention as well as experimentation with human blood and/or tissue samples. In as much as certain aspects of pathogenesis and pathology can be reproduced in animal models, such experimental strategies may complement and expand the scope of interrogation beyond the restrictions of human tissue access, availability, and ethical considerations; relevant observations and insights may then in turn inform and guide further human research endeavors. These "dialogical dynamics" of human and animal model research, including their possible pitfalls, are readily illustrated by the history of type 1 diabetes (T1D) research over the past half-century. The conception of T1D as an autoimmune disease in the mid-1970s emerged in the wake of seminal discoveries made primarily through investigations of the human disease (inflammatory infiltrates affecting the pancreatic islets, islet cell antibodies, HLA associations) and provided the impetus for the subsequent development of suitable animal models (Gale, 2001). However, the relative ease and success with which the animal models supported, refined, and enriched the autoimmune hypothesis over the ensuing three decades also detracted from the further pursuit of the logically, practically, and ethically more challenging interrogation of the human pancreas. Only more recent assessments have emphasized the inherent limitations of *in vivo* T1D models, their potential to promote a biased or even distorted understanding of the disease process, and the importance to realign preclinical investigations according to relevant pathogenetic parameters of the human disease (Roep, 2007; von Herrath and Nepom, 2009). As a consequence, interest in the detailed histopathology of the pre/diabetic human pancreas has been rekindled (Morgan et al., 2014; Richardson et al., 2014), and its pursuit greatly facilitated by the creation of initiatives such as the Network for Pancreatic Organ Donors with Diabetes (nPOD), a T1D tissue repository that collects, processes, and distributes pancreatic tissues to accredited T1D research teams (Campbell-Thompson et al., 2012; Kaddis et al., 2015). The direct study of the diseased organ can now provide an important referent and corrective for future studies of accessible human tissues such as peripheral blood, and for the more effective and adjusted use of T1D animal models. Disease-specific and technological constraints further define the potential scope of experimental exploration; here the fact that biopsy of the human pancreas is difficult, risky, raises ethical concerns, and, given the regional and lobular distribution of the pathological processes as revealed in recent nPOD studies, may not necessarily capture representative biological material (Atkinson, 2014; Gianani et al., 2010; Krogvold et al., 2014).

Even when human tissue samples are readily accessible, interpretation of experimental results can be difficult due to the lack of tissue or organism context. Let's take as an example here intestinal diseases such as Crohn's disease (CD), where biopsies are relatively easily obtained. Even under the best possible culturing conditions, how can an isolated slice of intestinal epithelium faithfully reproduce the milieu of the T cells it harbors? Stress responses, disrupted interactions with microbiota, altered gravitational, and osmotic conditions are only a few of

the confounding factors. That is not to say that one cannot obtain valuable data from these *ex vivo* systems. But some type of validation within the context of a living organism is typically required to corroborate the physiological validity of such findings. This applies particularly to results obtained using human-derived cell lines, which represent often aberrantly functioning clones from a single cell, from a single organ, and from a single individual, thus missing even the slightest organismal context.

Animal models have helped us to understand the complexity of autoimmune disease processes by partially replicating these conditions within an organismal context. This is an important notion, as it acknowledges that no animal model should ever be studied in isolation. Chemically destroying the intestinal barrier, for example, will reproduce certain mechanisms associated with cellular stress, altered microbial sensing, and tissue repair as observed in inflammatory bowel diseases (IBDs) (Chassaing et al., 2014). It will not, however, provide information the primary role of regulatory T cells (Tregs) in maintaining immune homeostasis in the gut, for which a T-cell transfer model would be more suitable (Eri et al., 2012). In other words, our understanding of human disease has historically been built on the combined datasets emerging from work on cell lines, primary cells, tissues and organ cultures, and all available animal models. Neither a single human explant study nor a particular animal model should be relied upon to generate a complete picture because each has its specific limitations.

In the immunogenetic arena, animal models have provided particularly useful insights. Genome-wide association study (GWAS) technology has revealed a tremendous degree of detail on the array of genes associated with human autoimmune diseases. Gene-function relationships are extremely difficult to study in humans and genetically modified animals have historically filled that void. The role of the IL-10 pathway in IBD (Kuhn et al., 1993), interferon signaling in multiple sclerosis (MS) (Chu et al., 2000), and insulin autoreactivity in T1D (Nakayama et al., 2005) are examples where transgenic animals have elucidated what are now believed to be the key aspects of the immunopathology. Moreover, broad concepts that apply to multiple forms of autoimmunity have been discovered or characterized in mice, with AIRE-mediated thymic T-cell selection (Anderson et al., 2002) and Foxp3-regulated natural Treg development and function (Hori et al., 2003) being prime examples. Overall, the comparison between mouse models and humans deficient in respective genes greatly contributes to our understanding of autoimmunity, even if complete phenotypic homology between knockout mice and the respective human genetic deficiency is often lacking.

Finally, despite intensive research over the last few years, there are some crucial elements in organ-specific autoimmunity that we are yet to fully comprehend. One major problem is that for many organ-specific autoimmune diseases, we still do not know the targets of the initial autoimmune response, although in others such as in pemphigus vulgaris (Lin et al., 1997), myasthenia gravis (Fambrough et al., 1973), and autoimmune gastritis (Karlsson et al., 1988), the driving autoantigen has been defined. This is a research question which needs to originate from or at least be confirmed by human studies, not animal models. The same applies to studies on inciting environmental factors, where epidemiological studies have much more relevance and power. Ideally, animal models should then be designed based on that knowledge. We believe that human polygenic autoimmune diseases are likely triggered by a wide variety of environmental factors in individual patients, making it unlikely that we will ever be able to define a single or a small set of environmental risk factors. We should therefore rather focus on common downstream disease pathways, for which animal models are excellent tools.

## Animal Models in Drug Development: Picking the Winners

During the course of commercial drug development, animal models are primarily used during the early discovery phase to support drug targets for further progression into the pipeline. The important decision to select drug targets for progression toward further analog design and screening is rarely ever based on the outcome of a single animal model. Typically, the criteria for progression involve genetic association, target protein, or mRNA association in human disease tissue, *in vitro* and *ex vivo* human cell or tissue experiments demonstrating beneficial responses, and, in addition to all of this, successful treatment with a research lead molecule in multiple animal models.

There are some general preferences in the drug industry when it comes to the use of animal models. Firstly, experimental disease should be reliably induced or occur spontaneously within a predictable time period and should exhibit a reproducible disease phenotype. A popular animal model for rheumatoid arthritis (RA) for instance is the collagen-induced arthritis (CIA) model in DBA/1 mice (Brand et al., 2007), because it fulfills these criteria and can thus be used in a relatively high-throughput *in vivo* screening approach. A variant of the model, induced with autologous collagen, may well mimic the remitting–relapsing course of RA better, but it takes much longer to induce, shows more variability, and has therefore never really enjoyed widespread use (Malfait et al., 2001).

Secondly, models with an established track record of translatability are favored. Returning to the CIA example, we have long known that standard-of-care biological therapies such as anti-TNF agents reproducibly alter the model's disease course (Williams et al., 1992). So, even though the acute nature of the model may not faithfully reproduce human disease, many drugs that are efficacious in humans can serve as positive controls for experimental compounds. On the contrary, many have argued that the nonobese diabetic (NOD) model for diabetes has proven unreliable in predicting clinical translatability, although we would argue that perhaps the model has historically not been used correctly. One example in the T1D arena is CTLA-4-targeted therapy, which is able to prevent diabetes in the NOD mouse when given early but is incapable of reversing clinical disease (Lenschow et al., 1995). In a subsequent clinical trial, 2-year continued administration in recently diagnosed patients was only effective in the initial months of treatment, which to some extent serves to confirm what was predicted by the animal data (Orban et al., 2011). Thus the choice of drug and trial design does not always seem to be rationally based upon animal research and is often more governed by the availability of certain drugs.

Thirdly, a robust understanding of the model's disease mechanisms is required to enable proper usage. Sticking with the CIA example, one could argue that after decades of use, there is substantial information available on every imaginable gene, cell, or protein that drives the disease process (Luross and Williams, 2001). We know that the eventual effector mechanisms are multifaceted and to some extent redundant. Asking the original question of whether TNF plays a primordial role in this model makes sense and the result of those experiments supported the medical hypothesis that spurred the development of anti-TNF biologicals for RA. Likewise, it would be suitable to study agents affecting the IL-6 pathway (Alonzi et al., 1998), currently a major class of drug target in RA. It would, however, not make sense in our opinion to treat animals that transgenically overexpress TNF with a TNF inhibitor because that result would not be very informative based on the fact that the mechanism is known to be primarily driven by TNF. That would be stacking the deck in favor of the therapy under observation.

When all these criteria are fulfilled and the experimental approach is planned, we cannot stress enough the need for properly powered study designs and sufficient numbers of experimental repetitions. Not a single animal model we know of doesn't show at least some degree of heterogeneity, be it in disease penetrance, progression rate, or severity. Even relatively subtle environmental changes can cause alterations in for instance the colony's microbiome, leading to variations in disease development. Nevertheless, rather than trying to control all possible variables in order to achieve reproducible drug effects, one should expect a sufficiently potent drug to confer mildly variable levels of protection regardless of environment, animal vendor, injection volume, etc. We have evaluated preclinical intervention strategies developed by others that are reproducible only if all of the aforementioned parameters are precisely controlled. When the ultimate aim is to take robust treatment strategies to an outbred human population, with vastly differing environmental conditions and notoriously heterogeneous disease courses, treatment efficacy contingent on tightly controlled conditions constitutes a considerable limitation (Harris, 2017).

An example of a theoretically attractive niche where animal models still have to deliver on predictive potential is the area of antigen-specific therapies (Coppieters et al., 2012b). This treatment approach holds significant promise since it specifically targets only immune cell subsets responsible for disease pathogenesis rather than inducing generalized immunosuppression with its associated complications. From a translational angle, it is still unclear whether tolerizing the "driver" T-cell clones would be sufficient to reverse an ongoing autoimmune process and has therapeutic value. Some reports suggest a striking oligoclonality, which in turn indicates that deletional immunotherapy using one or a few autoantigenic determinants might be feasible (Hafler et al., 1988; Kent et al., 2005). Animal models also suggest that T-cell receptor (TCR) avidity plays a pivotal role, as it was shown that low-avidity clonotypes can act protectively (Han et al., 2005). Numerous other reports, however, suggest that low-affinity clones might in fact be the driving force. For example, in the slow-onset variant of the RIP-LCMV model (mice susceptible to T1D after lymphocytic choriomeningitis virus infection due to transgenic expression of LCMV proteins under control of the rat insulin promoter), low-affinity T cells are responsible for disease induction (von Herrath et al., 1994). In human T1D, similar conclusions were drawn from studies using a preproinsulin-specific human CD8 T-cell clone that is capable of inducing beta cell death (Skowera et al., 2008). Remarkably, the TCR of this clone was of extraordinarily low affinity, redefining the understanding of what constitutes a functionally relevant TCR–pMHC interaction (Bulek et al., 2012).

Within that framework of knowledge, animal models have been used to evaluate antigen-specific therapies that have now completed early clinical trials, including proinsulin plasmid (Roep et al., 2013), peptide therapies (Alhadj Ali et al., 2017), and oral insulin (Bonifacio et al., 2015; Greenbaum, 2017) for T1D. The jury is still out on the former two approaches with only safety data being available, while the book can probably be closed on the latter. In fact, we recently attempted to elicit antigen-specific tolerance using oral insulin of various sources, formulations, and doses but failed to generate support for robust efficacy (Pham et al., 2016).

Finally, one interface between discovery research and clinical development that may benefit from animal model research is the field of biomarker discovery. Well-characterized animal models are suitable tools to pose questions that often cannot be asked in humans, such as whether peripheral blood cell populations reflect the events at the target organ, change in response to therapy, or correlate with therapeutic benefit. One could then take such mode-of-action-related biomarkers into Phase 1 trials to assess whether they can be reliably measured and then correlate levels to efficacy in Phase 2 proof-of-concept trials. Again, rather than offering ultimate proof, animal models should be seen as part of the hypothesis generation, which ultimately would be tested in the clinic.

### Summary of Advantages and Disadvantages of Animal Models

As illustrated in [Box 27.1](#) and as outlined earlier, there are several areas of investigation, where we have learned much from animal models of organ-specific autoimmunity. The first is the investigation of immune responses at locations that are inaccessible in humans. Moreover, in these diseases, much of what we know has often been derived from peripheral blood samples but it is unclear how this correlates to immune status at the target organ. We, for instance, were able to pioneer the *in vivo* visualization of immune responses at cellular resolution in the mouse pancreas during the development of autoimmune diabetes ([Coppieters et al., 2012a](#)); such information can not be gathered in the human target organ with any of the technologies currently available.

It is difficult to establish the proof of concept in humans. Many techniques that are frequently used to unequivocally identify cellular subsets that are important in the etiology or progression of autoimmunity are impossible to implement in a clinical setting. Examples include adoptive transfer experiments, knockout technologies, bone marrow chimeras, and many more. Accordingly, the continued and refined use of animal models remains at present indispensable to provide initial preclinical support for novel drugs and to define suitable dose ranges and regimens for immunotherapies.

How far reaching should the conclusions that we draw from observations in a given animal model be? The prevailing approach in scientific communication is still that a discovery in one of the animal models thought to faithfully represent the human disease is sufficient for acceptance for publication. If the same result is found in a subsequent submission, it is typically considered “confirmatory;” if a different result is discovered, the “secondary” model is frequently labeled as not-as-good or even flawed, for which various reasons are cited. This, we believe, can be treacherous and may hamper the translation of research performed in animal models, because our pathogenetic insight into human diseases is often still rather limited due to ethical constraints. For example, only about 10% of patients with T1D exhibit the same clinical features as the NOD diabetic mouse, which is characterized by a polyglandular autoimmune syndrome affecting thyroid, salivary glands, and testes ([Atkinson and Leiter, 1999](#); [Roep et al., 2004](#)). However, there are also striking similarities between NOD and human diabetes, for example, the occurrence of autoantibodies that precedes the development of clinical disease in NOD mice and humans ([Pietropaolo and Eisenbarth, 2001](#)).

#### BOX 27.1

### WHAT CAN ANIMAL MODELS TEACH US THAT WE CANNOT LEARN OTHERWISE?

- *In vivo* immune kinetics at *sites that are difficult to access in humans.*
- *Proof of concept* using techniques that cannot be used in humans, such as adoptive transfers, genetic knockouts, bone marrow chimeras, etc.
- *Preclinical drug validation*, large-scale assessment of *dose range, toxicity, and immunization sites* in drug and vaccine development.
- A single model is unlikely to cover all aspects of human pathology; concepts should therefore ideally be confirmed in multiple models.
- Genetic knockout models do not mimic the subtle and complex genetic imbalances that are thought to underlie human diseases.
- Environmental factors are usually not known and thus cannot be mimicked.

Reasons to be *cautious with animal data:*

We can now be certain that one single genetic defect or polymorphism will not be the cause for most human autoimmune disorders. We have learned from the multitude of GWAS that the far more common scenario is a substantial degree of polygenic complexity. This is likely to involve many protective and predisposing genes that act in concert, leading to disease manifestation in a fraction of their bearers. In addition to major histocompatibility complex (MHC) class II molecules that are found in association with several organ-specific autoimmune diseases such as MS and T1D, many less frequent polymorphisms in immune-related genes contribute to the expression of autoimmune disease (Bluestone et al., 2010). Immunogenetic studies in genetically identical mice can therefore not be expected to fully mimic the diverse array of polymorphisms that lead to disease in genetically distinct human subjects. Thus, seeking direct relevance to the human disorder becomes very important, and the assumption that there is a necessity to identify genetic defects in animal models in order to obtain the best pathways to cure human disease may not be correct. Indeed, in today's medicine, there is little evidence that the optimal treatment for a given disease is always the elimination of its cause. However, immunogenetics in animal models might still help the adoption of novel predictive strategies and subclassifications for autoimmune diseases, which may in the future allow for more individualized treatments.

Finally, most of these genetic associations are weak enough to allow for the possibility that environmental factors in addition to genetic determinants precipitate penetrance of disease. These factors, however, are poorly defined in most organ-specific autoimmune diseases. In the NOD mouse, for example, there appears to be a role for the gastrointestinal microbiome (Wen et al., 2008), although under normal specific pathogen-free conditions, diabetes develops without the need for an external stimulus. In human T1D, the strongest evidence for a potential trigger points toward enteroviral infection (Yeung et al., 2011). While viral infection can also accelerate disease in the NOD model under certain conditions, it is normally not required for onset. It is thus obvious that the NOD model does not faithfully integrate the environmental factors that seem to characterize the human disease. Similar discordances are present in models for MS, where neuronal antigens are often injected in adjuvant to induce demyelinating disease. Such nonphysiological conditions should always be kept in mind when interpreting results from animal models.

## A SURVEY OF ANIMAL MODELS FOR ORGAN-SPECIFIC AUTOIMMUNE DISEASES

Parsing animal models for organ-specific autoimmune diseases is a taxonomic exercise that readily evokes the "ambiguities, redundancies, and deficiencies" so brilliantly illustrated by Borges in his "*Celestial Emporium of Benevolent Knowledge*", an apocryphal classification of the animals that distinguishes, amongst others, "*those that belong to the emperor*", "*those that are included in this classification*", "*those that have just broken the flower vase*", and "*those that, at a distance, resemble flies*" Borges (1942). So, while the basic distinction between "spontaneous" and "induced" autoimmune disease models appears sensible (Hau, 2003), the oft-used addition of "genetically engineered animals" as a third category generates a logical conundrum since genetic manipulation may of course be employed to refine existing or create new models for both spontaneous or induced autoimmune disease. Additional subdivisions such as those made according to inducing agents can be equally confounding [proteins/peptides and adjuvant, pathogens, specific immune effectors (antibodies or T cells), chemicals, etc.], some "proof-of-principle" demonstrations may exude a whiff of circular logic [e.g., combining tissue-specific expression of "neo-autoantigens" with TCR-transgenic (TCRtg) T cells recognizing that very antigen], and certain interventions may stretch the limits of what can be considered autoimmunity (e.g., toxin-induced destruction of selected target tissues); all of this poses a challenge to constructive classification, yet it also constitutes a celebration of the manifold and at times wondrous combinatorial possibilities afforded by experimental autoimmunology. Since the topic of our survey therefore proves somewhat resistant to a convincing organization of its constituents, namely, the relevant animal models available for study of organ-specific autoimmune diseases, we have aimed to avoid an otherwise arbitrary selection of models for further discussion by grounding our choices in a ranking of human autoimmune diseases according to their overall prevalence (Hayter and Cook, 2012). Building and expanding on just a few earlier reports, Hayter and Cook identified 81 human autoimmune diseases that together affect an estimated ~4.5% of the population; 23 autoimmune diseases can be considered as "non-rare" (i.e., present at a frequency of >1/10,000) and of these, 17 are classified as organ specific (Table 27.1). In terms of prevalence, these 17 organ-specific diseases represent ~75% of all autoimmune disorders, and we provide here a brief overview of the corresponding animal models developed to emulate and study these conditions a clear majority of which (~80%) involves endocrine or digestive systems. For a more detailed discussion of the various diseases and their in vivo models, the reader is referred to respective review articles cited later as well as the disease-focused chapters in this book.

**TABLE 27.1** The Most Common Organ-Specific Autoimmune Diseases in Humans

Organ system	Organ-specific autoimmune disorder	Prevalence	
		(per 10 <sup>5</sup> )	Ratio F:M
Endocrine system	Hashimoto's thyroiditis (HT)	791.7	19:1
Digestive system	Celiac disease	750.0	1.3:1
Endocrine system	Graves' disease (GD)	629.0	7.3:1
Endocrine system	Type 1 diabetes (T1D)	480.0	0.8:1
Integumentary system	Vitiligo	400.2	1.1:1
Digestive system	Pernicious anemia/autoimmune gastritis	150.9	2.0:1
Integumentary system	Alopecia areata (AA)	150.0	1.0:1
Hematopoietic system	Immune thrombocytopenic purpura (ITP)	72.0	2.3:1
Nervous system	Multiple sclerosis (MS)	58.3	1.8:1
Nervous system	Narcolepsy	30.6	0.6:1
Cardiovascular system	Giant cell arteritis (GCA)/temporal arteritis	30.0	5.7:1
Digestive system	Ulcerative colitis (UC)	30.0	1.9:1
Digestive system	Crohn's disease (CD)	25.0	0.7:1
Digestive system	Autoimmune hepatitis (AIH) types 1 and 2	19.9	3.6:1
Digestive system	Primary biliary cirrhosis (PBC)	14.6	8.1:1
Endocrine system	Addison's disease (AD)	14.0	1.7:1
Integumentary system	dermatitis herpetiformis (DH)	11.2	0.6:1

Modified from Hayter, S.M., Cook, M.C., 2012. Updated assessment of the prevalence, spectrum and case definition of autoimmune disease. *Autoimmun. Rev.* 11, 754–765.

## Hashimoto's Thyroiditis and Graves' Disease

Thyroid-specific autoimmunity covers the spectrum from hypo- [Hashimoto's thyroiditis (HT)] to hyperthyroidism [Graves' disease (GD)] and preferentially targets thyroglobulin, thyroid peroxidase, and the thyroid-stimulating hormone receptor (TSHR). Antibodies and T cells specific for these autoantigens are detected not only in HT and GD patients but also healthy individuals reinforcing the concept that autoimmunity in fact represents a continuum stretching from the physiological to the pathological (Coppieters et al., 2013). Of historical interest is a series of studies conducted by Rose and Witebsky in the mid-1950s that explored the consequences of immunizing rabbits with leporine thyroid extracts in adjuvant and that noted the generation of autoantibodies and mononuclear thyroid infiltrations (Rose and Witebsky, 1956; Witebsky et al., 1957); this observation was complemented by the parallel demonstration of Roitt et al. (1956) that sera from HT patients contain thyroglobulin-specific autoantibodies. The work of Rose and Witebsky not only paved the way for the development of “experimental autoimmune thyroiditis (EAT)” to model the most common of organ-specific autoimmune diseases but in fact changed the course of autoimmune research *at large* by finally, if reluctantly, rejecting a persistent misreading of P. Ehrlich's half-century old “horror autotoxicus” (Silverstein, 2009). EAT is readily induced in genetically susceptible mice by immunization with thyroglobulin (and more recently also with thyroid peroxidase), following neonatal thymectomy in certain mouse and rat strains, after transfer of specific T cells but not antibodies, and through various other modulations of T-cell immunity. In addition, spontaneous thyroiditis occurs in several species including obese strain chickens, biobreeding (BB) rats, and NOD mice lacking the chemokine receptor CCR7 or expressing the H-2A<sup>k</sup> allele (the latter mice are diabetes-resistant, spontaneous disease is exacerbated by dietary iodine and reproduces hallmarks of HT such as high titers of TG antibody and cellular infiltration of the thyroid). Altogether, these models have contributed to the identification of genetic, cellular, molecular, and environmental pathogenesis determinants, have established HT as a paradigm for other T-cell-mediated organ-specific autoimmune diseases, and have provided fundamental insights into peripheral tolerance mechanisms by

precipitating the second wave of regulatory T-cell research (Kong et al., 2009; Ludgate, 2008; Nagayama and Abiru, 2011; Stassi and De Maria, 2002). For historical, conceptual, and practical reasons, the strategies to model HT therefore occupy a role unlike any other in the field of autoimmunity research. In contrast, a truly satisfactory GD model has not yet been established. An autoimmune condition apparently unique to humans, GD is caused by agonistic TSHR-specific antibodies that mimic the action of TSH and drive uncontrolled thyroid hormone production. No spontaneous GD model exists, and traditional protein/adjuvant approaches to TSHR immunization have failed to promote hyperthyroidism. Over the past 20 years, several GD models have been developed that are all based on immunization against and, *in vivo* expression of, the TSHR; they can be broadly divided into injection of TSHR-expressing cells and genetic immunization with TSHR-DNA plasmids or recombinant adenoviral vectors. Overall, the A-subunit of TSHR is more efficient in inducing disease than the holoreceptor, and more recent methodological refinements employing repetitive adenoviral vaccinations or the *in vivo* electroporation of TSHR expression plasmids have succeeded in reproducing some aspects of Graves' orbitopathy (McLachlan et al., 2005; Moshkelgoshia et al., 2015; Nagayama et al., 2015; Wiesweg et al., 2013).

## Type 1 Diabetes

In a notably broad array of animal models, hyperglycemia or T1D-like disease develops either spontaneously or in the wake of chemical, surgical, infectious, and/or genetic manipulations (Chatenoud, 2008; King and Austin, 2017; King, 2012; Van Belle et al., 2009). Streptozotocin (STZ) and alloxan are toxic glucose analogs (Lenzen, 2008) routinely used to model end-stage disease in rodents for the purpose of testing drugs (e.g., new insulin formulations) and interventions (e.g., islet transplantation) that specifically aim to lower blood glucose. An important and perhaps underused alternative to chemical T1D induction is the Akita mouse that exhibits hypoinsulinemia and pronounced hyperglycemia as a consequence of an insulin 2 gene mutation, overload with misfolded proteins and resultant ER stress. Hyperglycemia may also be induced in pigs and nonhuman primates through tailored STZ treatment or pancreatectomy but all of the preceding approaches obviously are of limited value for the elucidation of genuine autoimmune processes. Certain viral infections (coxsackie B virus, encephalomyocarditis virus, and Kilham rat virus) may promote direct and/or immune-mediated beta cell destruction, and transgenic expression of model antigens in beta cells [ovalbumin, influenza hemagglutinin, or LCMV glycoprotein (LCMV-GP)] renders them susceptible to attack by TCR<sup>T</sup> T cells specific for the same antigens. Of these models, the LCMV-GP and related mouse strains are particularly useful since T1D can also be induced following LCMV infection and efficient beta cell destruction by the endogenous virus-specific T-cell response (Ohashi et al., 1991; Oldstone et al., 1991). Collectively, the transgenic models offer a substantial degree of experimental freedom that greatly facilitates the visualization, quantification, characterization, and manipulation of antigen-specific, diabetogenic T-cell immunity and, in particular, allows for a thorough interrogation of pathogenic mechanisms and potential therapeutic interventions. However, the models do not feature the gradually accumulating, diversified, and endogenous beta cell antigen-specific and mostly low-affinity T-cell populations present in T1D patients; they do not capture aspects of genetic susceptibility other than the engineered components; and, in the absence of TCR<sup>T</sup> T cells, they do not develop spontaneous or even peptide/protein immunization-induced disease. The latter observations support the general conclusion about the not inconsiderable challenges to break peripheral tolerance and bolster the importance of spontaneous T1D models. The four major models in this category are the NOD mouse and three rat strains (BB, Komeda diabetes-prone, and LEW.1AR1-iddm rats) (King and Austin, 2017; Lenzen, 2017; Whalen et al., 2001); other spontaneous T1D models such as canine autoimmune diabetes may offer distinct advantages in terms of pathophysiological similarities with the human disease but are otherwise not widely employed (O'Kell et al., 2017). The NOD mouse was discovered in Japan in 1974, introduced to the public in 1980, and by 1987 had become a fully established T1D model (Tochino, 1987). Since then, some 11,000 articles have been published (corresponding to an average of one publication per day over the past 30 years) making the NOD mouse the most widely studied autoimmune disease model. In these mice, a slow and seemingly stochastic progression from initial insulitis to beta cell destruction culminates in frank hyperglycemia by 30 weeks in ~80% of females and ~30% of males; T1D development is affected by various husbandry practices, "cleanliness" of the facility, viral infections, and intestinal microbiota (King and Sarvetnick, 2011; Paun et al., 2017; von Herrath et al., 2011) and therefore overall disease incidence may vary substantially in different mouse colonies. Immunopathogenetically, a complex interplay of T and B cells, dendritic cells, macrophages, and NK cells initiates and perpetuates spontaneous T1D in NOD mice, and various approaches can accelerate disease onset for practical purposes (cyclophosphamide injection, diabetogenic T-cell transfer, islet transplantation to

overtly diabetic recipients). Because of its remarkable breadth and depth, the cumulative delineation of genetic, pathologic, and immunologic factors in NOD diabetes as well as the development of multiple effective prophylactic and therapeutic interventions (Chaparro and Dilorenzo, 2010; Shoda et al., 2005) constitutes a fundamental and fascinating contribution to T1D research and beyond. The seeming failure to translate these insights into treatment modalities for human T1D, however, has caused an early backlash and of late an abundance of discussions that attempt to reassess the potential and limitations of NOD research from a translational perspective (Driver et al., 2011, 2012; Graham and Schuurman, 2015; Pearson et al., 2016; Reed and Herold, 2015; Roep et al., 2004; von Herrath and Nepom, 2009). The arguments are overall nuanced; the utility of NOD (and other preclinical T1D) models has to be ascertained in an appropriate, detailed, and highly context-specific manner; and among the promising recommendations is an increased investment in humanized mouse models (Serreze et al., 2016). Lastly, it should be noted that the profound immune dysregulation in NOD mice (Anderson and Bluestone, 2005) is not restricted to promotion of beta cell destruction and can affect multiple other organ systems such that wild-type, congenic, transgenic, and/or immunodeficient NOD mice may be harnessed for the study of other major organ-specific autoimmune diseases [HT, Addison's disease (AD), celiac disease, autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), dermatitis herpetiformis (DH), and MS] as well as autoimmune cholangitis, sialadenitis, orchitis, neuritis, and other conditions.

### Addison's Disease

Throughout the second half of the 20th century, various attempts to model AD employed the immunization of guinea pigs, rabbits, rats, or mice with adrenal extracts and adjuvant. Collectively, "experimental autoimmune adrenalitis" emulates the aspects of the human disease (lymphocytic infiltration of adrenal glands, autoantibodies) and emphasizes the dominance of cell-mediated autoimmune processes (adoptive transfer of cells but not serum from immunized rodents causes adrenalitis in recipients) but remains of limited value due to the different histopathological presentation of adrenal lesions, their transient nature, and, with only two exceptions, a lack of adrenocortical insufficiency; similar considerations apply to the "spontaneous" lymphocytic infiltrations observed in NOD mice in the absence of clinical disease (Betterle et al., 2008; Bratland and Husebye, 2011). In contrast, both cats and dogs can develop spontaneous symptomatic AD (accompanied by adrenal infiltrations but usually not autoantibodies) and the identification of orthologous genetic susceptibility loci in canine and human AD suggests a common underlying autoimmune etiology (Mitchell and Pearce, 2012). In an interesting twist to animal experimentation, however, human AD studies appear to have been useful for research in dogs but not vice versa (Mitchell and Pearce, 2012), and a genetically well-defined, robust AD model remains to be developed.

### Celiac Disease

Defined as an autoimmune enteropathy induced by dietary gluten in genetically predisposed individuals, "spontaneous" celiac disease is also observed in Irish Setters, Rhesus macaques, and horses (Marietta and Murray, 2012). However, since the utility of these animals as research models is restricted by unclear or nonexistent disease associations with MHC-II genes (the main risk factor in humans) as well as practical and ethical considerations, considerable effort has been invested in the development of suitable murine models (Costes et al., 2015; Korneychuk et al., 2015; Verdu et al., 2015). Collectively, however, studies conducted with wild-type, immunodeficient, and especially humanized mice expressing HLA-DQ2.5 or -DQ8 haplotypes and challenged with gluten containing diet or gliadin have been hampered by the robust tolerance to food antigens in rodents. Accordingly, experimental systems have gained in complexity and emphasized the cooperation of multiple potentially pathogenic pathways such as specific CD4<sup>+</sup> T-cell immunity, the cytokine IL-15, intestinal microbiota and barrier function, and activation of transglutaminase 2 (a target of celiac disease-specific IgA autoantibodies) to break tolerance. Thus, despite some proof-of-principle demonstrations, the successful modeling of celiac disease in mice remains an outstanding challenge (Korneychuk et al., 2015).

### Pernicious Anemia

Pernicious anemia, the end-stage of autoimmune gastritis, presents an unusual case in the spectrum of autoimmune disorders: it is one of the most common and previously fatal autoimmune diseases, yet a highly effective

treatment (vitamin B12 replacement) based in part on pioneering canine studies (Whipple et al., 1920) became available before a detailed understanding of the pathogenic mechanisms could be developed. From the 1980s onward, murine models of experimental autoimmune gastritis contributed to the generation of pertinent insights by exploring spontaneous and lymphopenia-induced disease courses, immunization with gastric H<sup>+</sup>/K<sup>+</sup> ATPase, the use of infectious agents, and transgenic approaches (TCRtg T cells or GM-CSF expression by parietal cells). Notably, and in apparent contrast to many other autoimmune diseases, these models are considered to be particularly reliable and robust since they share key features with the human disease including H<sup>+</sup>/K<sup>+</sup> ATPase as the major autoantigen targeted by both antibodies and T cells (Field et al., 2005; Toh et al., 2012). Perhaps as an unintended consequence of this unusually favorable constellation of therapeutic efficacy in the human disease, access to excellent in vivo models and an overall compelling grasp of major pathogenetic mechanisms, the current literature on pernicious anemia animal models is limited to but a few review articles and book chapters (van Driel et al., 2014). Nevertheless, we emphasize that the precise nature of disease initiating events remains little understood and that vitamin B12 therapy does not tackle the underlying cause of the disease which is associated with an increased risk for gastric cancer; further research and an exploration of additional treatment strategies are therefore warranted.

### Ulcerative Colitis and Crohn's Disease

An impressive spectrum of IBD models established and/or refined over the past two decades has elucidated fundamental principles of human IBD pathogenesis including the unique tissue-specific constraints that drive intestinal inflammation through a complex interplay of microbiota, disrupted epithelial barriers, and dysregulated immune responses (in particular polarized T helper and innate immunity) (Jamwal and Kumar, 2017). In a recent authoritative review, Kiesler et al. (2015) have organized IBD models into five major groups comprising dextran sulfate sodium colitis, TNBS (trinitrobenzene sulfonic acid) colitis, oxazolone colitis, adoptive cell transfer-induced colitis, and IL-10-deficient mice. Informed by the notion that no single model captures the complexities of human IBD, relevant insights can nevertheless be generated as composite constructs that draw on the strength of individual models to illuminate particular aspects of specific diseases. Thus, instead of emphasizing the lack or shortcomings of mouse models for ulcerative colitis (UC) or CD, this model- rather than disease-centered conception advocates for a deliberately distributed approach to disease study that builds on the specific contribution of multiple models to progressively reconstruct human IBD entities (Kiesler et al., 2015). Obviously, the particular extent to which individual models prove useful in this context can vary considerably. For example, oxazolone colitis is considered a useful "UC model" on the basis of morphological and immunopathogenetic aspects shared with the human disease; at the same time, IL-10-deficient mice may highlight other aspects of UC development since polymorphisms at the IL-10 locus confer increased disease risk in humans. IL-10 polymorphisms or IL-10R mutations are also associated with an enhanced CD risk or a familial form of early onset CD, respectively, demonstrating the utility of IL-10-deficient mice in CD research. Adoptive transfer colitis and especially TNBS colitis models further reproduce important features of CD but an integrated "CD model" has not yet been established. Lastly, we note that the experimental modeling of IBD pathogenesis goes well beyond the major (and minor) mouse models mentioned here and ranges from invertebrates (nematodes, insects, fish) to other rodents (rats, guinea pigs) and related species (rabbits) as well as pigs, ruminants, dogs, and nonhuman primates (Jiminez et al., 2015).

### Autoimmune Hepatitis

Attempts to establish animal models of AIH, beyond a few scattered earlier reports, slowly gained traction from the 1960s onward with an almost exclusive focus on immunization with liver antigens in adjuvant (Lohse and Meyer zum Büschenthal, 1994). Since the early 1990s, more than two dozen murine AIH models were introduced and include protocols for immunization with surrogate antigens; transgenic antigen expression, use of TCRtg T cells, or a combination thereof; certain systemic or conditional immunodeficiencies; dendritic cell immunization; viral infection; and challenge with AIH type-2 antigens (CYP2D6: 2D6 isoform of the large cytochrome P450 enzyme family; FTCD: formiminotransferase cyclodeaminase). These models have been reviewed in great detail (Christen and Hintermann, 2015, 2016; Czaja, 2010; Hardtke-Wolenski et al., 2012; Yuksel et al., 2014) and collectively support the sobering conclusion that truly satisfactory and reliable mouse models reflecting the clinical and histopathological features of human AIH have not yet been developed. In the majority of models, an

acute breakdown of tolerance to liver antigens is readily achieved but cannot be maintained due to the inherent tolerogenic capacity of the liver and the relative efficacy of immunoregulatory mechanisms. Immunization with adenoviral vectors expressing CYP2D6 or FTCD shows promise based on its capacity to promote the development of chronic hepatitis and fibrosis, and these models can conceivably be improved through a concurrent inhibition of peripheral tolerance pathways. However, these experimental strategies are restricted to the modeling of type-2 AIH and mouse models specific for the ~sixfold more frequent type-1 AIH have not yet been established (though the targeting of PD-1, Tim-3, and/or IL-4R pathways is being considered).

## Primary Biliary Cirrhosis

Apart from reports on an age-associated development of PBC-like liver lesions in C57BL/6 mice some 25 years ago, PBC appeared somewhat resistant to the study in suitable small animal models. However, over the past 15 years, about a dozen murine PBC models have been reported that feature both spontaneous and induced development of disease (Concepcion and Medina, 2015; Katsumi et al., 2015; Leung et al., 2012; Pollheimer and Fickert, 2015; Wang et al., 2014). The former models employ congenic mice including spontaneously occurring mutations (scurfy, MRL/lpr) and genetic modification such as IL-2Ra deficiency or T-cell-specific suppression of TGF $\beta$  signaling while the latter approach includes xenobiotic immunizations and bacterial infections. Several recent and comprehensive reviews offer a consensus assessment that the complex nature of PBC pathogenesis and pathology cannot be captured in a single animal model but may now be studied in complementary models that adequately recapitulate specific aspects of the disease (Concepcion and Medina, 2015; Katsumi et al., 2015; Leung et al., 2012; Pollheimer and Fickert, 2015; Wang et al., 2014).

## Vitiligo

Spontaneous vitiligo develops in horses carrying the dominant Gray allele (Arabians, Andalusians, and Lipizzaners), Sinclair miniature swine, certain dog breeds, water buffalo, and Smyth line chicken (Erf, 2010; Essien and Harris, 2014). Among these, the Smyth line chicken constitutes the most important vitiligo model since it recapitulates many aspects of the human condition and permits an integrated evaluation of genetic determinants, melanocyte defects, and autoimmune responses throughout all stages of the disease (Erf, 2010). In the absence of a spontaneous mouse model (the “vitiligo mouse” [mi<sup>vit</sup>/mi<sup>vit</sup>] does not reflect mechanisms operative in the human disease since disease develops independent of a functional immune system, and the underlying point mutation in the *Mitf* gene does not correspond to any mutation in human vitiligo), the induction of vitiligo in mice has been achieved through chemical sensitization, immunization with melanocyte antigens, and, perhaps most prominently, TCRtg CD4 $^{+}$  and CD8 $^{+}$  T-cell populations recognizing melanocyte or model antigens (Essien and Harris, 2014). As with other autoimmune disorders, the complexities of the human disease cannot be reproduced by a single animal model and necessitate a composite approach that takes into account specific strengths and weaknesses of individual models.

## Alopecia Areata

Similar to humans, adult onset alopecia areata (AA) can be observed in dogs, horses, cattle, and nonhuman primates but these animals typically do not serve as experimental disease models (Sundberg et al., 2015). The first reported animal model for AA was the “Dundee experimental balding rat,” and although it is no longer in use, it was instrumental in demonstrating that AA is a T-cell-mediated autoimmune disorder. Currently, the most prominent models are inbred C3H/HeJ mice that develop spontaneous or induced AA-like hair loss, and the xenotransplantation of healthy human scalp onto SCID mice followed by intracutaneous injection of IL-2-activated human PBMC; the latter model is noteworthy for the fact that it effectively phenocopies a major autoimmune disease using previously healthy primary human tissue (Gilhar et al., 2016). Among other insights, the C3H/HeJ model confirmed a central role for IFN $\gamma$  in AA pathogenesis and provided the proof-of-principle that Janus kinase inhibitors are suitable agents for AA management (Gilhar et al., 2016). Of potentially farther reaching importance is the notion that the considerable progress in preclinical AA research may establish AA as a “model disease” that offers both conceptual and practical tools for the study of less accessible organ-specific autoimmune diseases that share certain pathogenic determinants such as T1D and MS.

## Dermatitis Herpetiformis

DH is an autoantibody-mediated autoimmune blistering disease caused by gluten consumption and may be considered a skin manifestation of celiac disease. Accordingly, the challenges pertaining to the establishment of a robust celiac disease model also apply to DH. To date, the first and only DH model that captures some of the genetic and clinical features of the human disease is a transgenic NOD mouse expressing HLA-DQ8 instead of murine MHC-II, and similar treatment responses in humans and HLA-DQ8 transgenic NOD mice further underscore their experimental utility for exploration of pathogenic mechanisms and novel therapeutic modalities (Marietta and Murray, 2012; Marietta et al., 2012; Pollmann and Eming, 2017). While it is not unreasonable to predict a refinement and diversification of DH models in the future, we also note that no new models have been reported since the original introduction of the HLA-DQ8 NOD mouse a dozen years ago.

## Multiple Sclerosis

With no other animal species developing a spontaneous demyelinating disease of sufficient similarity, MS appears to be an autoimmune disorder unique to humans (Ransohoff, 2012). This, however, has not hampered the creation of multiple animal models that are typically grouped into the three main categories of experimental autoimmune encephalomyelitis (EAE), virus-induced chronic demyelinating disease, and toxin-induced demyelination. Collectively, these models have established and illuminated various pathogenetic, clinical, and therapeutic correlates of the decidedly heterogeneous human disease, and numerous review articles have discussed in exquisite detail their roles in past, present, and potentially future investigations, their principal prospects and apparent limitations, and their translational relevance or lack thereof (Baker and Amor, 2015; Denic et al., 2011; Kipp et al., 2017; Mix et al., 2010; Procaccini et al., 2015; Stimmer et al., 2018). Perhaps more so than anything else, historical contingency has turned EAE into one of the most prominent autoimmune disease models with some 10,000 articles on the topic currently featured in the PubMed database. The earliest evidence that encephalomyelitis could be triggered by challenging the immune system with “self-proteins” came from side effects associated with the use of Pasteur’s rabies vaccine at the end of the 19th century (Mackay, 2010). The vaccine, made from the dried spinal cord of rabies-infected rabbits, in some cases led to ascending paralysis. This postvaccination encephalomyelitis was shown in the late 1920s to also occur in rabbits immunized with extracts of normal human spinal cord or sheep brain; paralysis in challenged monkeys was shown to correlate with defined histological lesions and demyelination in the 1930s; and more formal demonstrations that EAE could be provoked in animals via a short course of injections of normal brain combined with Freund’s adjuvant were provided in the 1940s. In time, EAE research converged from nonhuman primates and larger rodents toward mice and to some extent relinquished neuropathological and -behavioral complexity in favor of greater experimental flexibility and control, economic feasibility, and important ethical considerations that limit the use of higher species in animal research. Altogether, EAE research has proved fruitful for the identification of immunological and genetic determinants of disease pathogenesis as well as the study of histopathological features but decidedly less so for an evaluation of new treatment modalities. Among the other classes of MS animal models, infection with Theiler’s murine encephalomyelitis virus constitutes a well-defined experimental system that has contributed important discoveries about the initiation and perpetuation of autoimmune processes, demyelination, and even behavioral alterations. Similarly, the mouse hepatitis virus system provides a controlled framework for a comprehensive analysis of specific immune responses at the interface of pathogen control and targeted immunopathology. Lastly, toxin-induced models, the most popular of which are feeding of the copper chelator cuprizone and the microinjection of lysophosphatidyl choline, are particularly useful for the study of remyelination and therefore have important translational potential (although they do not address the autoimmune nature of MS) (Baker and Amor, 2015; Denic et al., 2011; Kipp et al., 2017; Mix et al., 2010; Procaccini et al., 2015; Ransohoff, 2012; Stimmer et al., 2018). Beyond the applied specifics of EAE research in particular and MS models in general, two aspects are worth emphasizing: (1) basic experimental strategies originally established for EAE studies have come to serve, arguably for better and worse, as a general template for the development of many other organ-specific “experimental autoimmune” models and (2) the long history and extraordinarily rich record of EAE experimentation offer an abundance of detailed and diversified insights that can and should inform important discussions about the utility, constraints, pitfalls, and future directions of animal studies in autoimmune disease research. It is certainly not a coincidence that the apparent limitations of animal research have been most readily identified and critically assessed in the very fields that benefitted from a profusion of published *in vivo* studies (i.e., MS and T1D research); the resultant recommendations, namely, a careful selection of particular animal

models to address specific and only partial aspects of the human disease, may appear as a more modest goal but in fact emphasize the fundamentally dialogical nature of animal experimentation, that is, the necessity to better define human pathophysiology so as to better tailor the corresponding animal studies.

## Narcolepsy

Narcolepsy type 1 (NT1) arises from the presumed autoimmune-mediated destruction of hypocretin/orexin-producing neurons in the hypothalamus (NT2, despite many clinical similarities, is a poorly defined heterogeneous disorder of unknown origin). However, the evidence supporting an autoimmune pathogenesis for NT1 is at best indirect (autoreactive antibodies and T cells detected only in some cases in blood but not hypothalamus) and circumstantial (association with certain HLA haplotypes, likely role of environmental triggers) (Kornum et al., 2017). Narcolepsy has been observed in several animal species (cat, horse, sheep, and cattle), and familial canine forms of the disease, established in the 1970s as a model system, were instrumental for the identification of orexin 2 receptor mutations as an underlying gene defect in 1999. At the same time, a narcolepsy phenotype was described in hypocretin-deficient mice, and since then, multiple genetically engineered strains have been generated including a model for inducible ablation of hypocretin neurons (Chen et al., 2009; Sakurai, 2015; Sinton, 2010; Toth and Bhargava, 2013). Among the attempts to create a mouse model that better mimics the potential autoimmune pathogenesis of NT1, a most recent approach demonstrated that mice expressing a “neo-self-antigen” specifically in hypocretin neurons developed NT1-like symptoms after transfer of CD8<sup>+</sup> but not CD4<sup>+</sup> effector T cells specific for that antigen (Bernard-Valnet et al., 2016). However, despite the experimental utility of the NT1 models generated to date, their contributions to an elucidation of autoimmune processes operative in the human disease have been limited (Kornum et al., 2017).

## Immune Thrombocytopenic Purpura

Primary chronic immune thrombocytopenic purpura (ITP), resulting from the autoantibody-mediated targeting and destruction of platelets, is not limited to humans and has been reported for various domesticated animals such as dogs, cats, pigs, and horses; similarly, a remarkably broad range of animals (mice, rats, guinea pigs, rabbits, marmosets, swine, sheep, cattle, and horses) has served as recipients of heterologous anti-platelet serum in the so-called passive ITP model (Semple, 2010). However, out of practical, economic, and ethical considerations, ITP research has moved over the past 20 years toward mice as the primary model (Neschadim and Branch, 2015). In addition to the popular passive transfer model nowadays mostly employing monoclonal anti-platelet antibodies, “secondary ITP” models encompass various experimental scenarios wherein ITP emerges as a consequence of an underlying disease (e.g., “spontaneous” ITP in the [NZWxBXSB]F1 lupus mouse), drug therapy, infection or immunization, and “platelet-induced” ITP models make use of platelet GP-deficient mice and/or adoptive transfer of sensitized T cells. The development of a convincing humanized ITP mouse model, however, has apparently not yet been achieved (Neschadim and Branch, 2015; Semple, 2010). Overall, the available ITP models have served quite well in reproducing critical features of the human disease and therefore will continue to inform investigations into pathogenic determinants and novel treatment options.

## Giant Cell Arteritis

The estimated prevalence of giant cell arteritis (GCA), also known as temporal arteritis, seems to be on par with that of UC or CD; yet in contrast to the considerable investment into the development of animal models for IBD, *in vivo* studies of GCA appear to be limited to a single experimental strategy introduced some 20 years ago. Originally conceived by Weyand et al. (Brack et al., 1997a,b), temporal artery-SCID mouse chimeras (NOD-SCID mice subcutaneously engrafted with temporal artery specimens obtained from GCA patients) have been used in about a dozen studies investigating aspects of disease pathogenesis and/or therapeutic modalities (Weyand and Goronzy, 2013). An explanation for the lack of other GCA models certainly has to consider disease-specific constraints and challenges in developing suitable rodent models but contributing factors are probably the advanced age of the patient population and the overall excellent response to high dose corticosteroid treatment (Frohman et al., 2016).

## CONCLUSIONS

Building largely on the established concepts and hypotheses but facilitated and accelerated by remarkable technological advances, many new, refined, and improved animal models for organ-specific autoimmune diseases have been introduced in the early 21st century. Altogether, they have considerably contributed to our understanding of fundamental immunological processes in health and autoimmune disease yet the degree to which they have precipitated therapeutic progress is less clear. The reasons for this shortcoming are undoubtedly manifold, but we contend that it is above all a relative “lack of diversity” that has compromised the reproducibility, robustness, and relevance of preclinical animal studies. (1) Reproducibility: several recent publications reexamining successful strategies for T1D prevention and/or reversion in the NOD model have failed to replicate previously published results (Gill et al., 2016; Grant et al., 2013; Pham et al., 2016) and thus are symptoms for the more pervasive “reproducibility crisis” afflicting animal studies in diabetes research (Ackermann et al., 2018; van der Meulen et al., 2018) and beyond (Drucker, 2016). Confronting these challenges require nothing short of a recalibration of our research culture (Drucker, 2016; Flier, 2017) that in particular will have to incentivize independent verification of potentially significant observations by implementation of applicable experimental protocols under deliberately varied conditions (other research teams, facilities, locations, etc.). (2) Robustness: specific inbred and genetically defined mouse strains evaluated under strictly controlled environmental conditions not only offer unique research opportunities but also impose considerable constraints that limit any generalization of experimental findings to outbred populations; the deliberate diversification and extension of investigations to other strains as well as “wild” (outbred) and “dirty” (subjected to natural environmental exposures including pathogens) mice may lend much needed robustness to consequential conclusions (Abolins et al., 2017; Masopust et al., 2017; Sellers et al., 2012; Tao and Reese, 2017). (3) Relevance: while it is generally agreed upon that no single autoimmune disease model captures all relevant aspects of the human disorder, principal limitations observed in particular for murine models need to be considered more carefully (Davis, 2008; Mestas and Hughes, 2004; Zschaler et al., 2014); the translational potential of animal studies therefore increases with the degree to which experimental findings are supported by a mosaic of carefully chosen, complementary, and diversified model systems. Lastly, we need to consider the possibility that animal models may at times hamper rather than promote progress. For example, in their excellent 2007 review of mouse models for psoriasis, Gudjonsson et al. (2007) issue the lament that “lack of a suitable animal model has greatly hindered research into the pathogenesis of psoriasis”); Guttman-Yassky and Krueger (2007) on the other hand argue in a contemporaneous article that animal models may sometimes “hinder the overall translational enterprise” that, in the case of psoriasis, has brought about “rapid advances in pathogenic understanding and development of new therapeutics”. The notion that animal models can distort our perspective onto the human disease is also echoed by most recent histopathological findings in human T1D that challenge some of the central tenets about T1D pathogenesis as established in rodent models (Battaglia and Atkinson, 2015). The potential dangers of narrowing our investigative scope along the dictates of the “murine-industrial complex” are further elaborated and vividly illustrated in a journalistic essay aptly entitled “The Mouse Trap” (Engber, 2011). The specific utility, value, and importance of animal research arise only in a larger context of biomedical knowledge formation that draws on extraordinarily wide-ranging ideas, disciplines, tools, and practices and that integrates the specific contributions of animal models in an essentially cumulative and dialectical (or perhaps better dialogical) fashion (Carbone, 2012). The study of T1D and MS animal models in particular has generated an impressive wealth of data, information, and knowledge that also has illuminated the very limitations of this type of research endeavor (Wekerle et al., 2012). Moving forward from this point can neither mean “business as usual” nor a radical break with the past but perhaps a strategic “retreat from the seductions of model organisms to something more diverse—a throwback, perhaps, to the slower, more comparative style of the 19th century, when theories were constructed from the differences among the many, rather than the similarities of the few” (Engber, 2011).

## INTRODUCTION

There are more than 300 distinct primary immunodeficiencies, the majority being defined by single-gene defects (Picard et al., 2015). With an increased identification of primary immunodeficiencies through genomic sequencing, it is clear that many primary immunodeficiencies are characterized not only by susceptibility to infection but also by dysregulation of the immune response manifesting as autoimmunity. With improved prevention of infectious complications, even well-characterized “classic” primary immunodeficiencies such as T and B-cell deficiencies are recognized to have immune dysregulation. The clinical findings together with delineation of the genetic basis for many of these “experiments of nature” have led to an expanded understanding of various pathways involved in immune homeostasis and the maintenance of self-tolerance. In this chapter the major primary immunodeficiency disorders associated with immune dysregulation and autoimmunity are presented (Table 28.1), paying particular attention to the mechanisms by which defects in different arms of the immune system cause autoimmunity. Immunodeficiencies presented here are classified based on the primary immunologic defect in each disorder, for the most part using classifications proposed by the Primary Immunodeficiency Expert Committee of the International Union of Immunological Societies (Picard et al., 2015 and [www.iuisonline.org](http://www.iuisonline.org)), with a focus on primary immunodeficiencies with infectious susceptibility and/or

**TABLE 28.1** Autoimmune Clinical Manifestations by Organ System of Select Primary Immunodeficiency Syndromes<sup>a</sup>

<sup>a</sup>Primary immunodeficiency syndromes are classified based on their major immunologic defect, however there is significant overlap in the mechanisms of each, and most syndromes are not strictly limited to one type of cellular defect.

AI, Autoimmune; HIGM, hyper-IgM; WAS, Wiskott–Aldrich syndrome; XLA, x-linked agammaglobulinemia; CVID, common variable immunodeficiency; APECED, autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia; ALPS, autoimmune lymphoproliferative syndrome; IPEX, immunodysregulation, polyendocrinopathy, enteropathy, x-linked; LRBA, lipopolysaccharide-responsive beige-like anchor; LATAIE, LRBA deficiency with autoantibodies; CHAI, CTLA4 haploinsufficiency with autoimmune infiltration; LOF, loss-of-function; GOF, gain-of-function; CGD, chronic granulomatous disease; LAD, leukocyte adhesion deficiency; SCID, severe combined immunodeficiency; PNP, purine nucleoside phosphorylase; RAG, recombinase-activating genes; AIRE, autoimmune regulator; CIDS, combined immune deficiencies; CD40L, CD40 ligand; STK4, serine-threonine protein kinase; ICOS, inducible T-cell costimulator; APDS, activated phosphoinositide-3-kinase δ syndrome; STIM, stromal interaction molecule; BTK, Bruton's tyrosine kinase; FOXP3, forkhead box P3 protein; FASL, FAS ligand; STAT, signal transducer and activator of transcription. Other includes vasculitis, uveitis, hepatitis, systemic lupus erythematosus, and others. +++, a key clinical feature seen in most patients; ++, a major feature (>30%); ++, observed in <30% of the patients; +, <5%; -, not a feature of disease.

dysregulated T lymphocytes. In addition to the primary immunodeficiencies presented here, there are a variety of other monogenic disorders of the immune response whose sole and/or major clinical manifestations are autoimmune or autoinflammatory, including primary autoinflammatory disorders such as the periodic fever syndromes, early-onset inflammatory bowel disease (e.g., IL-10 pathway defects), early complement disorders associated primarily with autoimmunity risk and not infection (i.e., C1q, C1r/C1s, C4, or C2), and interferonopathies such as TREX1-associated disease, which are reviewed in detail in this text and elsewhere.

## IMMUNODEFICIENCIES AFFECTING CELLULAR AND HUMORAL IMMUNITY

This group of immunodeficiencies includes diseases with significant T-cell dysfunction, due to either defects in T-cell differentiation or function. There has been an increasing appreciation for the association of T-cell developmental defects producing a combination of immune deficiency and dysregulation. In addition to intrinsic defects in T-cell function, impaired T-cell cross talk and interactions with other components of the immune system, particularly B cell or humoral immunity, lead to more global immune defects contributing to autoimmunity and immune dysregulation.

### Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a group of genetic defects characterized by severe defects in T-cell numbers and immunity. Patients with typical SCID have severe deficiency of naïve T cells with varied effects on B cells and natural killer (NK) cells depending on the genetic defect. The resulting immune deficiency is of such severity that without hematopoietic cell transplantation (HCT) early in life, patients have a high likelihood of developing failure to thrive and recurrent opportunistic infections that result in death within the first 2 years of life. In the United States, the initiation of newborn screening for SCID has dramatically changed the way that this disease is detected and treated, and infants are typically identified within the first 2 weeks of life and treated with HCT within the first few months of life ([Dorsey et al., 2017](#)).

Patients with SCID not detected in the newborn period typically present with severe and recurrent respiratory and gastrointestinal (GI) infection before 6 months of age. Despite the characteristic lack of T-cell immunity, autoimmunity and immune dysregulation can also be a clinical features of SCID. The immune dysregulation in SCID patients typically occurs due to hypomorphic mutations of genetic defects causing SCID associated with residual, but dysregulated, T-cell function such as Omenn syndrome (OS) ([Somech et al., 2009; Cassani et al., 2010](#)). Autoimmunity and immune dysregulation can also be seen with complete loss-of-function (LOF) of certain SCID-associated genes as described in adenosine deaminase (ADA), purine nucleoside phosphorylase (PNP), and zeta chain-associated protein kinase 70 (ZAP70) genes.

OS is a description for patients with different genetic forms of SCID presenting with opportunistic infections and generalized erythroderma, alopecia, failure to thrive, autoimmunity, particularly hepatitis and enteritis resembling graft-versus-host disease (GVHD). Additional findings include hepatosplenomegaly, lymphadenopathy, increased serum IgE, lymphocytosis, and eosinophilia suggesting an involvement of a Th2 polarized immune response. The age of onset is usually in the first weeks of life. OS is classically caused by hypomorphic mutations in the recombinase-activating genes 1 and 2 (*RAG1* and *RAG2*) ([Marrella et al., 2011](#)) associated with classic T-/B-/NK + SCID. *RAG1* and *RAG2* proteins are the key enzymes in the V(D)J recombination process, important for the assembly and diversity of T- and B-cell antigen receptors. The phenotypes of patients with RAG deficiencies depend principally on the residual quantity of V(D)J activity ([Niehues et al., 2010](#)). Patients with OS have residual V(D)J recombination and, unlike classical SCID, have significant numbers of circulating T cells due to clonal expansions of T cells with restricted T-cell receptor (TCR) repertoire. The circulating cells are highly activated based on CD45RO and HLA-DR expression, and they are primarily autoreactive and prove to be incapable of providing appropriate T-cell responses to microbial pathogens. The genetic defects associated with OS also include mutations in other SCID-associated genes encoding other proteins including Artemis, DNA ligase IV, common-gamma chain, IL-7 receptor alpha chain, ADA, ZAP70, and the ribonuclease mitochondrial RNA processing complex ([Villa et al., 2008](#)). The association of *RAG1/2* and other SCID genotypes with an altered clinical phenotype sets the stage for investigations that have uncovered further expansion of the clinical phenotypes linked to hypomorphic or leaky SCID. The range of findings appears to be linked to the level of protein function with less severe phenotypes in the aspect of infectious susceptibility associated with mutations that result in residual protein activity. Syndromic disorders with T-cell defects such as DiGeorge syndrome (DGS) and coloboma of the eye, heart defects, atresia of the choanae, retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness (CHARGE) syndrome may also be associated with Omenn-like manifestations ([Pirovano et al., 2003; Gennery et al., 2008](#)).

Autoimmunity has evolved as a major common feature of patients with OS including autoimmune cytopenias, granulomas, alopecia, vitiligo, myasthenia gravis, vasculitis, and psoriasis ([Notarangelo et al., 2016](#)). It has also been shown that patients with hypomorphic *RAG* mutations can present with delayed-onset combined

immunodeficiency with granulomas and autoimmunity similar to clinical features of common variable immunodeficiency (CVID) (Avila et al., 2010; Abolhassani et al., 2014). These patients may produce a wide range of autoantibodies including neutralizing antibodies specific for interferon-alpha and interferon- $\omega$  (Walter et al., 2015).

The combination of autoimmunity and immune deficiency associated with defective T-cell development may be explained by abnormalities in the thymic stroma found in experimental models of "leaky" SCID (Rucci et al., 2011). The predominant finding in these models is a reduction in the pool of medullary thymic epithelial cells (mTECs) and reduction in the level of self-antigen expression in the thymic medulla, which appears to diminish the effectiveness of negative selection of self-reactive T cells during thymopoiesis. There also appears to be a contribution of defective B-cell tolerance associated with RAG gene mutations (Walter et al., 2010; Lee et al., 2016b). In addition, findings in these models also identify a marked reduction in thymic-derived regulatory T cells (Tregs), an observation that is also likely to be contributing to the development of autoimmunity (Cassani et al., 2010). In summary, impaired negative thymic selection, B-cell tolerance, Tregs development, and/or homeostatic proliferation may largely account for the development of autoimmunity in patients with OS.

ZAP70 is a tyrosine kinase that is involved in TCR signaling. The complete lack of this enzyme results in combined immunodeficiency characterized by the selective absence of CD8 $^{+}$  T cells with recurrent infections in the first few months of life. However, there have been case reports of patients with hypomorphic ZAP70 defects, potentially both LOF and gain-of-function (GOF), associated with early-onset autoimmunity including inflammatory bowel disease, eczematous skin lesions, immune thrombocytopenia purpura (ITP), bullous pemphigoid, and autoimmune hypothyroidism (Chan et al., 2016; Liu et al., 2017). ZAP70 deficiency is associated with reduced numbers of autoimmune regulator-positive (AIRE $^{+}$ ) mTECs, thymic dendritic cells, and thymic-derived natural Tregs, which could explain the predisposition to autoimmunity in these patients (Poliani et al., 2013).

ADA and PNP are the key enzymes in the purine salvage pathway. The deficiency of either of these enzymes results in an accumulation of substrates that are toxic to lymphocytes. Both ADA and PNP are expressed ubiquitously in all cells. Hence, the lack of either of these enzymes leads to systemic manifestations in addition to immune dysfunction. Hereditary deficiency of ADA is the second most common cause of SCID in North America. This type of autosomal-recessive SCID is characterized by progressive depletion to nearly the absence of T, B, and NK cells. Patients frequently have nonimmune defects including skeletal alteration, neurological abnormalities, hepatic, and renal diseases. It has been shown that alterations in the adenosine metabolism affect Treg functions (Sauer et al., 2012). Autoimmune manifestations have been observed in milder forms of this disease including autoimmune hemolytic anemia (AIHA), immune thrombocytopenia (ITP), neutropenia (Grunebaum et al., 2013), type I diabetes (Notarangelo et al., 1992), and autoimmune thyroiditis causing acquired hypothyroidism (Nagpala et al., 2007). PNP deficiency is less common than ADA. The deficiency of PNP leads to progressive decline of T-cell number and function but tends to spare B and NK cells (Grunebaum et al., 2013). Infectious and neurological manifestations including developmental delay, hypotonia, and spasticity are predominant symptoms. Approximately one-third of the patients develop autoimmune manifestations including hemolytic anemia and immune thrombocytopenia (Markert, 1991), and these can be presenting symptoms (Rich et al., 1979). The basis of autoimmunity in patients with this enzymatic defect is not known but must be linked in some fashion to the toxic metabolite's impact on T-cell (and possibly B-cell) function.

*SCID with maternal engraftment.* A subset of SCID patients may have an engraftment by transplacentally acquired maternal T and B cells (Okano et al., 2017). If these maternal cells are functional, patients may have a delayed clinical presentation of SCID (Al-Muhsen, 2010). Immune dysregulation from the oligoclonal expansion of these maternal cells can lead to cutaneous GVHD of skin presenting as diffuse scaly erythematous morbilliform rashes and even erythroderma similar to OS (Muller et al., 2001). Liver involvement and cytopenia have also been described in these patients (Palmer et al., 2007).

## Combined Immune Deficiencies

Combined immune deficiencies (CIDs) include primary immunodeficiencies with T-cell defects that are generally less severe than those seen in SCID, sometimes presenting later in childhood, and not universally requiring HCT.

*Immunodeficiency with hyper-IgM (HIGM) syndrome* is a heterogeneous group of disorders caused by defects in genes that critically involved in immunoglobulin class switch recombination or somatic hypermutation

(Jesus et al., 2008). X-linked forms of HIGM are caused by defects in the CD40 ligand (CD40L) and autosomal-recessive defects in CD40. The serological hallmark of these disorders is a normal to increased serum level of IgM in the face of decreased levels of IgG, IgA, and IgE. Other monogenic primary immunodeficiencies manifesting with a HIGM phenotype include missense variants in the gene encoding nuclear factor- $\kappa$ B (NF- $\kappa$ B) essential modulator (NEMO) which leads to defects in multiple immune cell types (see the “Combined Immunodeficiencies with syndromic features” section) (Qamar and Fuleihan, 2014), and disease caused by defects in enzymes involved in generation or repair of DNA breaks during immunoglobulin isotype switching including activation-induced cytidine deaminase (AID) and uracil-DNA glycosylase (UNG) (presented in the “Predominantly antibody deficiencies” section), as well as postmeiotic segregation 2 (Qamar and Fuleihan, 2014).

X-linked CD40L deficiency is the most common cause of HIGM syndrome (70%) and manifests clinically before the age of 2 years with recurrent pyogenic infections as well as with an increased risk of infections with certain viruses, fungi, and parasites, most notably *Pneumocystis jiroveci* and *Cryptosporidium* species (Notarangelo et al., 2006; Jesus et al., 2008). CD40L is expressed by T lymphocytes, and much of the infectious susceptibility in this disorder is thought to be due to impaired T-cell function. In addition, a substantial number of patients develop autoimmune disorders (Jesus et al., 2008). In particular, autoimmune neutropenia occurs in up to 50% of the patients. AIHA and ITP have been estimated to occur in 2%–10% of the patients (Hirbod-Mobarakah et al., 2014). Other autoimmune manifestations in CD40L-deficient patients include seronegative arthritis, hypoparathyroidism, hypothyroidism, nephritis, autoimmune retinopathy, inflammatory bowel disease, and cutaneous sarcoid-like granulomas (Jesus et al., 2008; Levy et al., 1997). A less common form of HIGM associated with an autosomal-recessive *CD40* deficiency presents clinically similar to *CD40L* deficiency.

A review of the function of CD40L, a member of the TNF superfamily, provides a context for understanding these seemingly unrelated clinical phenotypes (Hirbod-Mobarakah et al., 2014). It is expressed transiently on activated T-helper cells and interacts with its counter-receptor, CD40, on B cells, dendritic cells, and macrophages. The engagement on B cells is a critical proximal step in the isotype switch of naïve B cells following their encounter with T-dependent antigens. This cognate interaction initiates the activation of a family of TNF receptor-associated factors, which leads to the activation of nuclear translocation of NF- $\kappa$ B and the expression of the genes *AID* and *UNG* triggering isotype class switch. In the absence of CD40L, patients have low serum IgA and IgG levels, normal-to-elevated levels of IgM, and show impaired IgG antibody responses to T-dependent antigens together with a marked reduction of circulating isotype-switched memory B cells. CD40L/CD40 interaction promotes germinal center of lymph nodes, and lymph nodes of affected patients show primary lymphoid follicles that are devoid of germinal centers. The engagement of CD40 molecules expressed is required for the upregulation of CD80/CD86 on B cells, macrophages, and dendritic cells. The interaction of these costimulatory molecules with CD28 on the collaborating T cells leads to full T-cell activation and promotes the survival of these antigen-presenting cells. Thus it is not surprising that X-linked CD40L-deficient patients experience opportunistic infections and develop malignancies in tissues infected by the prototypical organisms. Defects in peripheral B-cell tolerance contribute to immune dysregulation of CD40L-deficient patients (Herve et al., 2007). Their mature naïve B cells express a high proportion of autoreactive antibodies. It has also been shown that the lack of CD40L results in a defect of Tregs both quantitatively and qualitatively (Herve et al., 2007; Tang et al., 2014). Finally, serum levels of B cell-activating factor of the tumor necrosis factor family (BAFF), a molecule that promotes the B-cell survival, are increased in X-linked CD40L deficiency, offering another factor that might contribute to the expression of B-cell autoimmunity (Herve et al., 2007).

*Major histocompatibility complex (MHC) class I deficiency* is associated with a defect in the surface expression of class I MHC proteins (often referred to as the bare lymphocyte syndrome) that present with low numbers of CD8<sup>+</sup> T cells and recurrent infections. The underlying defect in this disorder is associated with mutations in genes for specific proteins, including transporter-associated with antigen processing (TAP) 1, TAP2, and TAPBP, required for the transport of antigenic peptides to the endoplasmic reticulum necessary to assemble the MHC protein peptide complex that is normally expressed on the cell surface. MHC class I deficiency is a very rare disorder clinically characterized by recurrent respiratory tract infections, bronchiectasis, and necrotizing granulomatous skin lesions typically involving extremities and the midface that required a differentiation from granulomatosis with polyangiitis (Zimmer and Ollert, 2015; Villa-Forte et al., 2008). Nonerosive polyarthritides and leukocytoclastic vasculitis have also been reported in TAP-deficient patients (Gadola et al., 2000).

*Serine-threonine protein kinase (STK4 or MST1) deficiency* is an autosomal-recessive CID that was first described in 2012 in two consanguineous kindreds, presenting with recurrent bacterial and viral infections and autoimmunity (Nehme et al., 2012). The disease is caused by homozygous mutations in the STK4 gene, coding for protein MST1. The STK4-deficiency patients have T- and B-cell lymphopenia and reduced in vitro T-cell proliferation.

Dermatitis, autoimmune neutropenia, AIHA, and hypergammaglobulinemia associated with increased titers of autoantibodies have been described as clinical features of this novel primary immunodeficiency disease (Abdollahpour et al., 2012).

*Inducible T-cell costimulatory (ICOS)* deficiency is associated with defects in activated T cells and clinically resembles CVID-like disease (Grimbacher et al., 2003). ICOS is a costimulatory molecule upregulated on activated T cells and plays a role in T-cell help for late B-cell differentiation, class-switching, and memory B-cell generation. ICOS also has a distinct role in the generation and maintenance of germinal centers in lymphatic tissue, and ICOS deficiency leads to severe reduction of memory B cells and impaired switched antibody responses (Warnatz et al., 2006). ICOS deficiency in patients typically manifests with recurrent bacterial infections of respiratory tracts (onset from childhood to adults) and GI involvement including giardiasis, inflammatory bowel disease salmonellosis, and nodular lymphoid hyperplasia (Warnatz et al., 2006). These patients were reported to have total B-cell lymphopenia, severe reduction of switched memory B cells, hypogammaglobulinemia, and impaired antibody responses to vaccines. Importantly, the majority of 15 patients in multicenter studies developed autoimmunity (73%, 11/15) including enteropathy (9), psoriasis (4), arthritis (3), and interstitial pneumonitis (1) (Schepp et al., 2017). Patient also can develop thrombocytopenia from splenomegaly. The precise mechanism of autoimmunity is unclear. However, it has been shown that plasmacytoid dendritic cells prime IL-10-producing Tregs via ICOS-L.

*Activated phosphoinositide-3-kinase δ syndrome (APDS)* is a combined T- and B-cell immunodeficiency resulting from heterozygous GOF mutations in *PIK3CD* encoding the p110 $\delta$  catalytic subunit or *PIK3R1* encoding the p85 $\alpha$  regulatory subunit of class IA phosphoinositide-3-kinase (class IA PI3K) (Angulo et al., 2013; Lucas et al., 2014, 2016). Class IA PI3Ks are heterodimeric proteins that function as signaling complexes, with the p110 $\delta$  subunit restricted to immune cells. p110 $\delta$  is downstream of multiple receptors in the immune system, including T and B-cell receptors, as well as a variety of cytokine receptors. The signaling cascade downstream of class IA PI3K leads to the activation of AKT and mTOR (mammalian target of rapamycin).

The clinical phenotype of APDS is heterogeneous and characterized by recurrent bacterial infections, severe/persistent herpes virus infections, lymphoproliferation, and autoimmunity. Immunologic findings described in APDS include progressive T- and B-cell lymphopenia, decreased numbers of naïve T cells, expansion of terminally differentiated senescent effector CD8 $^{+}$  T cells, relatively increased numbers of transitional B cells, and hypogammaglobulinemia (Elgizouli et al., 2016). Autoimmune manifestations found in 34% of the p110 $\delta$  GOF (also known as APDS1) patients in an international cohort included cytopenias, glomerulonephritis, exocrine pancreatic insufficiency, thyroiditis, seronegative arthritis, sclerosing cholangitis, systemic lupus erythematosus, and enteropathy with lymphoid nodular hyperplasia (Coulter et al., 2017). For patients with APDS2 from GOF of p85 $\alpha$ , 17% had autoimmune complications including cytopenias, insulin-dependent diabetes, chronic arthritis, autoimmune hepatitis, and eczema (Elkaim et al., 2016). Given the pathology of APDS is in part caused by increased mTOR signaling, the treatment of patients with mTOR inhibitors has been described with some success (Lucas et al., 2014). An open-label clinical trial of a selective PI3Kδ inhibitor in six patients with APDS resulted in improvement of lymphoproliferation in all patients, suggesting this might be an effective targeted therapy for this disease.

## Combined Immunodeficiencies With Syndromic Features

*DGS* results from defective third and fourth pharyngeal pouch development during embryogenesis, which in the majority of cases is associated with a deletion at chromosome 22q11.2. Heterozygous LOF mutations in *TBX1* can cause a similar clinical phenotype. As a result of the developmental abnormality, patients with DGS typically have a combination of conotruncal cardiac anomalies, hypocalcemia due to hypoparathyroidism, dysmorphic facial features (e.g., low set ears, shortened philtrum, high arched, or cleft palate), and T-cell immunodeficiency from thymic hypoplasia. In addition, patients with DGS have an increased incidence of autoimmunity including ITP, AIHA, autoimmune neutropenia, and organ-specific autoimmunity particularly juvenile idiopathic arthritis (JIA) and autoimmune thyroid diseases (Zembla et al., 2010; Gennery, 2012; Sullivan et al., 1997). Based on a cohort study of 130 pediatric patients, 8.5% of the partial DGS had autoimmune diseases with autoimmune cytopenias and hypothyroidism were the most common manifestations (Tison et al., 2011). From an immunologic perspective, a small minority of DGS patients (1%–2%) have thymic aplasia that results in marked T-cell lymphopenia with increased susceptibility to opportunistic infections, and among this patient group, chromosomal microdeletions are only found in about 50% of the patients. This group is referred to as complete DGS, and

among these patients is a subgroup that carries a diagnosis of complete atypical DGS with a clinical phenotype that is virtually indistinguishable from OS (Markert et al., 2004). Due to the severity of the infectious complications associated with complete (including atypical) DGS, the thymic transplantation is indicated to reconstitute T-cell function. However, due to the autoreactive T cells present in the complete atypical DGS presentation, aggressive immunosuppression is required to control the autoreactive cells prior to initiating the thymus transplantation. Alternatively, fully matched donor T-cell transplant has also been suggested as therapeutic option and in this case, reconstitution is presumably derived from long-lived donor T cells since there is no thymus present for new T-cell development (Gennery et al., 2010). Long-term follow-up studies of complete DGS (including atypical complete DGS) patients post successful thymic transplantation have demonstrated an increased incidence of autoimmune thyroid disease as well as autoimmune cytopenias (Markert et al., 2007). It has been shown that the decreased Tregs and homeostatic dysregulation of CD4<sup>+</sup> T cells may contribute to autoimmunity in DGS (Sullivan et al., 2002; Ferrando-Martinez et al., 2014). However, the mechanism is likely more complex beyond Tregs and could be similar to the pathophysiology of immune dysregulation in OS.

*Wiskott–Aldrich syndrome* (WAS) is an X-linked primary immunodeficiency that variously presents with thrombocytopenia involving small platelets, eczema, recurrent infections, and high incidence of autoimmunity and malignancies (Notarangelo et al., 2008; Thrasher and Burns, 2010). Affected patients are particularly susceptible to infections with encapsulated bacteria and herpes viruses. This disorder is caused by mutations within the gene encoding the WAS protein (WASP), a critical factor in actin polymerization and skeletal remodeling initiated by cellular activation. In particular, the above-described clinical phenotype is caused by mutations that lead to abrogation of WASP expression. By contrast, missense mutations in exon 1–3 of WASP gene resulting in some WASP expression generally lead to a milder clinical phenotype characterized by X-linked thrombocytopenia (XLT) (Notarangelo et al., 2002).

As WASP is ubiquitously expressed in all nonerythroid hematopoietic cells, it is not surprising that affected individuals present with a number of immunological abnormalities. These include progressive T-cell lymphopenia, impaired in vitro T-cell proliferation and IL-2 production following TCR cross-linking, low serum IgM levels often associated with elevated serum IgA and IgE levels, impaired IgG antibody responses to both T-dependent and T-independent antigens, impaired migratory responses of monocytes, dendritic cells, T and B cells and neutrophils to chemokines, and impaired NK-cell cytolytic activity.

As is true for many immunodeficiency disorders, the clinical phenotype of WAS does not show consistent fidelity with the genotype. This was demonstrated in a report of monozygotic twins, associated with WAS including autoimmune disease in one twin and a milder XLT phenotype in the other (Buchbinder et al., 2011). Interestingly, CpG methylation, diminished WASP gene transcripts, diminished WASP expression, and more impaired cellular function were detected in the more symptomatic twin. These findings are consistent with the previously reported effects of epigenetic changes on the clinical expression of genetically based autoimmune and primary immunodeficiency disorders.

Autoimmune disease affects as many as 70% of the WAS patients with clinical presentation in rank order including AIHA, ITP, vasculitis, renal disease, Henoch–Schönlein-like purpura, arthritis, and inflammatory bowel disease (Notarangelo et al., 2008; Thrasher and Burns, 2010; Walter et al., 2016; Sullivan et al., 1994). Autoimmunity most commonly occurs in patients with WAS but occasionally is also present in patients with XLT. Early explanations for the pathogenesis of autoimmunity referred to possible contributions of recurrent exposure to microbes and chronic inflammation as well as reduced IL-2 production and impaired clearance of apoptotic cells/bodies and debris due to the defective migration of phagocytic cells. Further studies have shown impaired functions of Tregs (Marangoni et al., 2007) and regulatory B cells (Bregs) (Bouma et al., 2014), dysregulated plasmacytoid dendritic cells, and diminished NK-cell cytotoxicity in WASP-deficient mice and/or humans that may collectively contribute to immune dysregulation in WAS (Crestani et al., 2015). WASP-dependent intrinsic B defects in the setting of normal T-cell function may also account to the pathology of systemic autoimmunity in WAS (Becker-Herman et al., 2011). This may contribute to the findings that posthematopoietic stem cell-transplantation autoimmunity is particularly problematic in patients who remain mixed chimeras for B cells suggesting that the WASP-negative B cells may be mediating autoimmunity in this situation.

*NEMO syndrome* is caused by defects in NF-κB activation due to hypomorphic mutations in the *IKBKG* gene encoding NEMO on the X-chromosome. Males with NEMO syndrome have ectodermal dysplasia associated with immunodeficiency and susceptibility to recurrent pyogenic, mycobacterial, and serious viral infections (Orange et al., 2004), sometimes with a HIGM-like phenotype (Qamar and Fuleihan, 2014). HIGM and hyper-IgA were reported in 15% and 27% of the patients in hypomorphic NEMO mutation database (Hanson et al., 2008). These patients also develop a range of inflammatory and autoimmune conditions (25%) including inflammatory colitis,

AIHA, and chronic arthritis. This association suggests that in addition to defective host defense, there is also some degree of immune dysregulation in this disorder.

*Schimke immune-osseous dysplasia (SIOD)* is an autosomal-recessive disease characterized by spondyloepiphyseal dysplasia, focal segmental glomerulosclerosis, renal failure, and T-cell deficiency caused by biallelic mutations in SMARCLA1 (SWI/SNF-related matrix-associated actin-dependent regulator of chromatin, subfamily-a-like-1) gene. Based on the report of 41 patients with SIOD, 9 had autoimmune manifestations including ITP, AIHA, enteropathy, and pericarditis (Zieg et al., 2011).

*Immunodeficiency associated with  $\text{Ca}^{2+}$  release-activated  $\text{Ca}^{2+}$  (CRAC) channelopathy* due to LOF mutations in genes encoding ORAI1 and stromal interaction molecule (STIM1) proteins have been identified as etiologies of severe T-cell immunodeficiencies (Picard et al., 2009; McCarl et al., 2009). ORAI1 is a pore-forming subunit of the CRAC channel that is activated by STIM1 that is localized in endoplasmic reticulum where it senses the concentration of stored  $\text{Ca}^{2+}$  (Feske et al., 2010). As store-operated calcium influx via CRAC channels is a requirement for lymphocyte activation, ORAI1 and STIM1-deficient patients were found to have severe defects in T-cell function leading to recurrent and severe infection similar to SCID patients. Their clinical phenotypes are similar and characterized by SCID-like disease, autoimmunity, muscular hypotonia, and ectodermal dysplasia (Lacruz and Feske, 2015). Interestingly, these patients have normal number of lymphocyte subsets including T, B, and NK cells; however, they have a loss of naïve and increase in memory CD4 $^{+}$  and CD8 $^{+}$  T cells with impaired lymphocyte proliferative responses to mitogen and skin delayed-type hypersensitivity reactions.

Autoimmune manifestations of LOF mutations of STIM1 include lymphoproliferation, AIHA, neutropenia, thrombocytopenia, and colitis (Lacruz and Feske, 2015). These autoimmunities are less common in ORAI1 due to unclear etiology. One presumed mechanism of autoimmunity in STIM1-deficient patients is a reduction in Treg cells based on observations in one patient as well as a murine model with T cell-specific deletion of STIM1 and STIM2 demonstrating reduced numbers and diminished function of Treg cells (Picard et al., 2009).

## PREDOMINANTLY ANTIBODY DEFICIENCIES

*X-linked agammaglobulinemia (XLA)* was the first primary antibody deficiency identified and is caused by mutations in Bruton's tyrosine kinase (BTK) gene necessary for B-cell differentiation and signaling (Tsukada et al., 1993). In BTK-deficient patients, the B lymphocyte lineage is arrested at the pro- to pre-B-cell stage of differentiation resulting in a marked deficiency of circulating B cells and panhypogammaglobulinemia but intact T-cell function. Affected individuals usually present clinically by 5–6 months of age with recurrent sinopulmonary infections involving encapsulated bacteria following the loss of maternally transferred IgG antibodies. Up to 15% of the XLA patients develop autoimmune disease including chronic arthritis, inflammatory bowel disease, alopecia, AIHA, glomerulonephritis, and type 1 diabetes (Winkelstein et al., 2006; Howard et al., 2006; Barmettler et al., 2017).

The mechanism of autoimmunity in XLA remains uncertain. BTK has been shown to play a crucial role in setting the threshold of B-cell activation and negative selection of autoreactive T cells in mice (Kil et al., 2012), and the selective inhibition of BTK prevents murine lupus and antibody-mediated glomerulonephritis in mice (Rankin et al., 2013). The absence of B cells and immunoglobulins in these patients suggests that immunoglobulin-independent, BTK-dependent processes may be involved in the pathogenesis of autoimmune disorders. Bregs, described in mice and humans, appear to contribute to suppression of the development and expression of inflammatory reactions, particularly those mediated by T cells suggesting an important role in immune homeostasis and prevention of autoimmune and inflammatory diseases (Klinker and Lundy, 2012). The absence of Bregs in XLA could also contribute to the risk of developing autoimmunity.

*HIGM syndrome due to B-cell defects.* Deficiency of AID and UNG are autosomal recessive forms of HIGM that present with an infectious phenotype consisting of recurrent sinopulmonary infections with encapsulated bacteria but without opportunistic infections (Jesus et al., 2008). AID-deficient patients typically present with enlarged tonsils and lymph nodes presumably related to expansion of the B cells attempting to undergo class switch as evidenced by massive germinal center expansion. Autoimmune manifestations are found in 25% of the AID-deficient patients (Jesus et al., 2008) including diabetes mellitus (DM), polyarthritis, hepatitis, AIHA, ITP, Crohn's disease, and chronic uveitis (Quartier et al., 2004). Patients with UNG deficiency clinically resemble those with AID deficiency.

*CVID* is a group of heterogeneous disorders with a common feature of hypogammaglobulinemia and failure to mount adequate antibody response to pathogens and vaccination (Bonilla et al., 2016). Patients with CVID

have low serum IgG and frequently low IgA and/or IgM due to a failure of terminal B-cell differentiation, due to either intrinsic B-cell defects and/or impairment of helper T-cell function. The onset of the varied clinical manifestations of CVID can occur at any age. Based on the worldwide study in 2212 patients with CVID, one-third of the patients had an onset of symptoms before the age of 10 years (Gathmann et al., 2014). While there is no sex preference in adults, in pediatric patients, the male-to-female ratio was 2:1 (Gathmann et al., 2014). Clinical phenotypes of CVID include recurrent pneumonia (32%), autoimmunity (29%), splenomegaly (26%), bronchiectasis (23%), granuloma (9%), enteropathy (9%), and others (<5%). The onset of autoimmune manifestations was before the diagnosis of CVID in 50% of the patients. They also found that autoimmune manifestations were independently associated with the presence of splenomegaly and granulomas. Due to the nature of data collection, the study did not specify the type of autoimmunity in their cohort. In a cohort study of 473 CVID patients in the United States, hematologic and organ-specific autoimmune diseases were found in 29% of the patients. These manifestations include ITP (14%), AIHA (7%), Evans syndrome (4%), inflammatory bowel disease (4%), rheumatoid arthritis (3%), and other less common conditions (<2%) including alopecia, DM, pernicious anemia, uveitis, multiple sclerosis, neutropenia, primary biliary cirrhosis, systemic lupus erythematosus, autoimmune thyroid disease, vasculitis, psoriasis, and vitiligo (Chapel et al., 2012).

The pathophysiology of autoimmunity in CVID is unclear. The immunologic phenomena found to be associated with autoimmunity in CVID includes the reduction of switched memory B cells and expansion of CD21 low B cells, reduction of naïve and Tregs, dysregulated cytokine responses with increased levels of a proliferation-inducing ligand (APRIL) and BAFF, upregulated interferon signature expression, and increased circulating inflammatory innate lymphoid cells (Maglione, 2016). The heterogeneity of these studies is in part due to complex genetic origins of CVID that are not entirely understood.

Monogenic causes of CVID have been found in only 2%–10% of the patients, but these patients have provided an insight into mechanisms of immune dysregulation leading to antibody deficiency (Bogaert et al., 2016; Bonilla et al., 2016). Genetic discovery has led to a better appreciation of the heterogeneity of this complex disease. For example, some patients, previously classified as “CVID” or “CVID-like,” have monogenic disorders of T-cell function such as defects in ICOS or PI3K-pathway genes (see the “Combined immune deficiencies” section) or T-cell tolerance due to altered Treg function, including disease associated with CTLA4 and lipopolysaccharide-responsive beige-like anchor (LRBA) (see the “Disorders of regulatory T cells” section). Here, we highlight the current knowledge and clinical phenotypes of two genetic pathways associated with a primary antibody deficiency and CVID-like disease and autoimmunity, transmembrane activator and calcium modular and cyclophilin ligand interactor (TACI), and Ikaros.

TACI is encoded by TNFRSF13B gene. It is one of the receptors of BAFF and APRIL. TACI is a regulator in immune responses. Biallelic and monoallelic LOF variants in TACI have been associated with some degrees of antibody deficiency with variable penetrance and clinical outcomes (Bogaert et al., 2016). In certain cohorts, 7%–10% of the CVID patients carry allelic mutation in this gene. However, the family members and approximately 2% of the healthy control subjects who lacked immune abnormalities shared the same heterozygous mutations (Martinez-Gallo et al., 2013). This finding may suggest that other factors, potentially genetic or epigenetic modifiers and/or environmental triggers, interact to promote the CVID clinical phenotype. The incidence of autoimmunity is high in CVID patients with heterozygous mutation of TACI, and they have increased levels of circulating T follicular helper cells and antinuclear antibodies. Interestingly, patients with homozygous TACI deficiency have less severe disease compared to patients with heterozygous TACI deficiency, and they do not have increased predisposition for autoimmunity (Maglione, 2016).

Ikaros deficiency is caused by heterozygous germline-dominant LOF mutations of IKZF1 gene encoding Ikaros, a transcription factor that plays a critical role in hematopoiesis and B-cell differentiation. The disease is characterized by progressive loss of B cells with a lack of plasma cells and decreased serum immunoglobulins with a CVID-like phenotype (Kuehn et al., 2016; Hoshino et al., 2017). In the largest cohort of 29 patients, most had recurrent infections, one patient had ITP, two had B-cell acute lymphocytic leukemia, and some were asymptomatic despite mildly low IgG (Kuehn et al., 2016). Of nine patients described in a subsequent cohort, three presented with recurrent sinopulmonary infection and three had no significant infections but had autoimmune manifestations including one with SLE and Evans syndrome (Hoshino et al., 2017). Other manifestations described in this cohort were ITP and IgA vasculitis.

Selective IgA deficiency (sIgAD) is the most common primary immune deficiency affecting humans. The diagnosis of sIgAD is defined by a lack of serum IgA of <7 mg/dL with normal serum IgM and IgG levels in an individual older than 4 years, and exclusion of other causes of immunodeficiency (Bonilla et al., 2015). The prevalence of sIgAD varies across studied ethnic populations with a high of 1:143 on the Arabian Peninsula to a

low of 1:18:500 in Japan. In the United States the range is 1:223–1:1000 in community studies. There is considerable variability in clinical presentation with the majority of patients reported as being asymptomatic. The most common clinical manifestation occurring in the roughly 10%–15% symptomatic patients is recurrent sinopulmonary infections caused by encapsulated bacteria (Geha et al., 2007). IgA-deficient patients are also considered to have an increased frequency of allergic disorders, and this is particularly true in younger patients (4–32 years of age) where a prevalence of 84% was reported in one study.

The prevalence of autoimmune disorders in sIgAD patients varies from 7% to 36% with more than 40% of the patients having abnormal serum antibodies to cells or tissues (Jacob et al., 2008; Edwards et al., 2004; Abolhassani et al., 2015). Autoimmune manifestations described in these patients include ITP, JIA, thyroiditis, vitiligo, inflammatory bowel diseases, myasthenia gravis, Henoch–Schönlein purpura, type 1 DM, and SLE. The role of positive serum autoantibodies in sIgAD patients is unclear since it is commonly found in the absence of clinical manifestations of autoimmune diseases. First-degree relatives of IgA-deficient patients display an increased frequency of autoimmune disorders. In addition, patients are at risk for the development of GI complications including gluten-sensitive celiac disease, lactose intolerance, nodular lymphoid hyperplasia, giardiasis, malabsorption, chronic active hepatitis, and ulcerative colitis.

The pathogenesis of sIgAD remains obscure in that patients have immature B cells that express surface IgA as well as IgM and IgD but fail to differentiate into IgA secreting plasma cells (Conley and Cooper, 1981). While some investigators have provided evidence of an intrinsic B-cell defect, others have found reduced number of Tregs and decreased or impaired helper T-cell activation in sIgAD patients (Yazdani et al., 2017; Soheili et al., 2013). Similarly, the basis of the association of this PID and autoimmunity has yet to be elucidated, although several hypotheses have been proposed, including altered mucosal immunity.

No single genetic defect has been reported in sIgAD patients, although a small number of TACI deficient patients have been found with sIgAD (Castigli et al., 2005). Indeed, the same TACI mutation has been found in IgA-deficient patients and patients with CVID. Some patients with sIgAD progress to developing full-blown CVID, adding support to the contention that both disorders fall along a continuum of the same overarching PID (Aghamohammadi et al., 2008). Further support for this argument is the observation that both IgA deficiency and CVID are associated with the same common extended MHC haplotype, HLA A1, B8, DR3, and DQ2 (Mohammadi et al., 2010).

## DISORDERS OF IMMUNE DYSREGULATION: T-CELL TOLERANCE

T-cell tolerance is essential for maintenance of a pool of effectors capable of recognizing pathogens and tumor cells but not host. There are multiple mechanisms by which the immune system maintains T-cell tolerance, and monogenic disorders disrupting these pathways highlight the importance of the pathways discussed here.

### Monogenic Defects Affecting T-Cell Selection and Homeostasis

*Autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED)*, also referred to as autoimmune polyendocrinopathy syndrome type 1, is a human disorder caused by a deficiency in the AIRE protein. AIRE is a transcriptional regulator that is critical for ectopic expression of tissue-specific antigens by mTECs in the thymus and T cell-negative selection (Proekt et al., 2017). As classically defined, APECED presents with a triad of findings including hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis (CMC) with ectodermal dysplasia. As advances in genetic sequencing have allowed for the identification of additional patients based on a genetic diagnosis, it has become clear that there are many additional autoimmune features, some of which may be as prominent as those traditionally described. A recent cohort of 35 patients, primarily from the United States, demonstrated additional major features including urticarial, autoimmune hepatitis, gastritis, intestinal dysfunction, pneumonitis, and Sjögren-like disease (Ferre et al., 2016). Additional less common autoimmune features described in APECED patients include gonadal failure, hypothyroidism, type 1 diabetes, celiac disease, B12 deficiency, and others.

APECED was initially described as an autosomal-recessive disorder caused by LOF in the AIRE protein. However, more recently autosomal-dominant AIRE-associated disease has been described associated with dominant-negative variants in the protein (Oftedal et al., 2015). There is a higher incidence of APECED in certain populations including Iranian Jews (1:9000), Sardinians (1:14,000), and Finns (1:25,000) with lower prevalence in

Slovenia (1:43,000), Norway (1:80,000), and Poland (1:129,000) (Kisand and Peterson, 2011). In these settings, there tend to be predominantly specific AIRE mutations. Importantly, the same mutation in different patients can present with varied clinical phenotypes, pointing out that additional factors impacting the clinical presentation.

AIRE-induced expression of tissue-specific antigens by mTECs is critical in the negative selection of antigen-specific autoreactive T cells within the thymic medulla. AIRE also appears to play a role in Treg-cell development and studies in APECED patients have identified a decrease in forkhead box P3 protein (FOXP3) expression together with diminished in vitro suppressive capacity of circulating Treg cells (Laakso et al., 2010). It is clear that in APECED patients, many of the autoimmune disorders are accompanied by the production of autoantibodies that in some cases may be linked to disease and in others simply serve as biomarkers of disease. The explanation for CMC in this disorder was linked to the development of high affinity, neutralizing autoantibodies to IL-17A and IL-22 (Puel et al., 2010). This finding was noted in all APECED patients evaluated but was not detected in any other conditions tested. This finding fits well with prior descriptions of autoantibodies to another cytokine ( $\alpha$ -interferon) found in the majority of these patients. The finding of the neutralizing anticytokine antibody establishes a new paradigm with an autoantibody inhibiting the activity of a critical cytokine resulting in the development of a specific host defense defect. This type of autoimmune process (i.e., anticytokine autoantibody) has also been linked to susceptibility to nontuberculous mycobacterial infections associated with high titer, neutralizing autoantibodies to gamma interferon.

*Autoimmune lymphoproliferative syndrome (ALPS)* is a lymphoproliferative disorder characterized by an increased percentage of peripheral blood alpha–beta TCR double-negative T cells and abnormal lymphocyte apoptosis (Oliveira et al., 2010). The underlying defect in the majority of ALPS patients is an abnormality in the extrinsic apoptotic pathway linked to defective signaling via the FAS receptor (Lenardo et al., 2010). Clinically, ALPS patients have a high incidence of autoimmune cytopenias and a substantially increased risk for the development of non-Hodgkin and Hodgkin lymphoma. The typical course of disease in ALPS patients begins during childhood with the development of nonmalignant lymphadenopathy and splenomegaly. In many of the patients, the lymphoid accumulation is followed by the development of autoimmunity that is almost exclusively immune-mediated cytopenias, most commonly AIHA and ITP. Some ALPS patients also develop neutropenia and dermatologic findings that can include an urticarial rash. Rare autoimmune findings reported in ALPS include glomerulonephritis, Guillain–Barré syndrome, autoimmune hepatitis, and polyneuropathy. A very significant problem in the most common genetic form of ALPS associated with defects in the FAS gene is an increased risk for the development of Hodgkin and non-Hodgkin lymphoma.

The homotrimeric FAS receptor is a member of the TNF receptor superfamily and plays a critical role in lymphocyte homeostasis as well as in immune-mediated cytotoxicity following receptor engagement by FAS ligand (FASL). Among patients diagnosed with ALPS, 65%–70% have a heterozygous defect in the *FAS* gene that acts as a dominant negative mutation in most patients (i.e., autosomal dominant). These patients are now categorized as ALPS-FAS with the majority having a heterozygous germline mutation. However, a significant percentage of ALPS-FAS patients have a heterozygous somatic mutation affecting FAS (categorized as ALPS-sFAS) that can be detected by performing sequencing of circulating alpha–beta double-negative T cells. There are additional, rare, and genetic causes of ALPS including mutations in the genes encoding FASL (categorized as ALPS-FASLG) and caspase-10 (categorized as ALPS-CASP). In addition, there remain ~20% of the patients with an ALPS clinical phenotype who do not have a defined genetic defect (categorized as ALPS-U). In all ALPS cases with genetically defined mutations, there is a defect in the death inducing signal mediated by FAS. This can be analyzed in vitro, and the degree of the apoptotic defect varies based on the site of the FAS mutation with those affecting exons coding for the intracellular part of the protein generally conferring more severe disease with higher disease penetrance. Additional biomarkers have been identified that are linked with both germline and somatic FAS mutations including elevation in soluble FASL, IL-10, and vitamin B12. Combining an elevation in one of these biomarkers with increased alpha–beta double-negative T cells yields a greater than 95% likelihood of a FAS mutation (either germline or somatic).

The defect in the FAS-dependent extrinsic apoptotic pathway presumably interferes with peripheral tolerance and the normal control of specific autoreactive T cells (and possibly autoreactive B cells). Clearly, based on varied penetrance observed in extended family pedigrees, the FAS gene defect requires additional (currently unidentified) factors for the development of clinical disease. This situation is analogous to the murine model of autoimmunity associated with a FAS defect, the *lpr* mouse, where strain variations can significantly impact the degree of autoimmunity. The range of autoimmunity in ALPS is quite limited and suggests that the FAS-mediated

pathway of tolerance has a more restricted role in controlling self-reactivity, and the increased risk of lymphoma in ALPS patients suggests that FAS also serves as a tumor suppressor pathway.

## Disorders of Regulatory T Cells

*Immunodysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome* is a severe disorder of immune function due to loss of Treg differentiation. Patients with IPEX syndrome usually present during infancy with severe enteropathy, insulin-dependent type I DM, and dermatitis (Ochs et al., 2007; Verbsky and Chatila, 2013). The GI disease produces intractable diarrhea and malabsorption causing failure to thrive. The histopathology of the enteropathy includes villous atrophy and lymphocytic infiltration of the mucosa.

The type I DM in IPEX syndrome can be present as early as birth and is often difficult to control with typical insulin regimens. Dermatitis is a generalized eczematous-like rash. Additional autoimmune features include cytopenias, thyroid disease, renal disease, and hepatitis. Immunologic laboratory findings include eosinophilia and hypergammaglobulinemia including elevation of serum IgE, as well as the presence of a variety of autoantibodies (Tsuda et al., 2010). Early recognition of this syndrome is crucial as mortality is extremely high without therapy, which initially consists of aggressive immunosuppression to control the autoreactivity and hematopoietic stem-cell transplantation to provide curative immune reconstitution and a source of Tregs (Rao et al., 2007).

The underlying genetic basis for IPEX is an X-linked recessive defect in the gene encoding FOXP3, a member of the forkhead/winged helix family of transcription factors located at Xp11.23. There have been a wide range of mutations found including single base substitutions, deletions, and splicing mutations. Defective FOXP3 expression leads to a defect in Treg production, and this is reflected by the virtual absence of circulating CD4<sup>+</sup>/CD25<sup>+</sup>/FOXP3<sup>+</sup> T cells in these patients. Additional patients with hypomorphic variants of FOXP3 deficiency have been described, and these patients may express normal, or even increased, levels of protein that is dysfunctional. Such patients frequently present later in life with milder symptoms but may also present during the neonatal period. Therefore the presence of FOXP3<sup>+</sup> T cells in the periphery does not exclude IPEX syndrome, and patients suspected of having this disorder should have genetic testing.

The actual mechanism(s) mediating the immunosuppressive activity of Tregs in humans is not fully understood, although it appears to involve both inhibition by cell–cell contact and the secretion of immunomodulatory cytokines including transforming growth factor-β and IL-10. The consistently targeted organs in the IPEX syndrome suggest that Treg function is particularly important in developing and maintaining self-tolerance in the GI tract, (selected) endocrine organs, blood cells, and skin. However, owing to the severity of this syndrome, it is unclear if autoimmunity to other target organs could arise over time in this patient population.

*IPEX-like syndromes* caused by genetic defects in other genes important for Treg differentiation highlight the importance of these cells for maintenance of T-cell tolerance (Verbsky and Chatila, 2013). The first involves an autosomal-recessive defect in the gene encoding the CD25 protein, a component of the high-affinity IL-2 receptor heterotrimer (IL-2 receptor alpha chain). In this disorder, patients not only have an autoimmune phenotype that resembles IPEX but also develop a SCID-like picture with early onset of opportunistic infections (Caudy et al., 2007). Findings in the murine model of CD25 deficiency suggest that Treg development is normal but the survival, maintenance, and competitive fitness of these cells are defective due to the absence of IL-2 signaling associated with the defective IL-2 receptor.

Another overlap syndrome is an autosomal-recessive disorder due to LOF mutations in the gene encoding signal transducer and activator of transcription (STAT) 5B (STAT5B), which is a transcription factor necessary for IL-2 signaling. In this disorder, patients also have an IPEX-like clinical picture together with a marked immune deficiency, growth hormone–resistant dwarfism, and other clinical features found in IPEX syndrome including eczema and endocrinopathy with less prominent enteropathy (Bernasconi et al., 2006; Hwa et al., 2007; Kanai et al., 2012). Patients with STAT5B deficiency have prominent lung disease with lymphoid interstitial pneumonitis, and the mechanism of this is uncertain. The growth defect in STAT5B deficiency is due to impaired growth hormone signaling, which also uses this transcription factor. Studies in these very rare patients have demonstrated decreased numbers of circulating Tregs that expressed diminished levels of FOXP3 and were functionally ineffective when tested in vitro.

*LRBA protein deficiency with autoantibodies (LATAIE)* is caused by LOF autosomal-recessive LOF mutations in the LRBA gene and manifests clinically with hypogammaglobulinemia, autoimmune cytopenias, splenomegaly, and lymphadenopathy. LATAIE disease shows LRBA-deficient patients frequently present with organ-specific autoimmunity including severe inflammatory bowel disease, thyroiditis, and arthritis (Kostel Bal et al., 2017;

Levy et al., 2016; Lopez-Herrera et al., 2012; Alangari et al., 2012; Alkhairy et al., 2016). The immune dysregulation in LRBA deficiency is thought to be due to increased turnover of CTLA4 protein and impaired trafficking and cell-surface expression CTLA4 (Lo et al., 2015). CTLA4 is expressed by Tregs and activated T cells and is a key inhibitory checkpoint protein that inhibits T-cell activation. Immunologic abnormalities in this disease include defects in class-switched B cells and increased T-cell apoptosis similar to ALPS (Alkhairy et al., 2016). Symptoms of immune dysregulation in these patients are responsive to abatacept therapy (soluble CTLA4/IgG1 fusion protein), offering proof of concept for the ability to translate molecular targets into personalized therapies for patients with primary immunodeficiency (Lo et al., 2015). Chloroquine increased the ability of CTLA4 to traffic to the cell surface of T cell in vitro, and partially restore protein expression on Tregs and activated T cells, suggesting this is another potential therapeutic option (Lo et al., 2015).

*CTLA4 haploinsufficiency with autoimmune infiltration (CHAI)* is an autosomal-dominant immune dysregulation syndrome due to heterozygous LOF mutations in the gene encoding CTLA4 (Schubert et al., 2014; Kuehn et al., 2014). CHAI is a monogenic disease with incomplete penetrance. In mice, deficiency of CTLA4 results in a lethal autoimmune phenotype. In humans, CHAI patients have some clinical features resembling ALPS, but with other autoimmune manifestations, similar to LATAIE patients. The majority of CHAI patients present with symptoms of immune dysregulation including diarrhea/enteropathy (78%), hypogammaglobulinemia (76%), granulomatous lymphocytic interstitial lung disease (66%), respiratory infections (57%), organ infiltration (50%), and splenomegaly (50%) (Schubert et al., 2014). Other autoimmune manifestations include ITP, AIHA, psoriasis and other skin disease, autoimmune thyroiditis, and autoimmune arthritis. Lab findings in CHAI are normal-to-low IgG and/or IgM, normal IgA, decreased or normal antibody response to polysaccharide vaccines, increased double-negative T cells, and decreased FOXP3/CD25 expression on Tregs with decreased Treg suppression activity. As both CHAI and LATAIE are diseases caused by CTLA4 checkpoint deficiency, their manifestations are quite similar. However, CHAI is present in older children or young adults, while LATAIE frequently has an onset in preschool children. Abatacept and sirolimus, a rapamycin inhibitor, have been used for the treatment of autoimmunity and systemic inflammation in CHAI patients with some improvement of their symptoms (Lee et al., 2016a).

## GAIN-OF-FUNCTION DISORDERS OF CYTOKINE SIGNALING

The development, homeostasis, and function of immune cells are critically dependent on cytokine signaling. Defective cytokine signaling has been well recognized to lead to impaired immunity, such as SCID associated with common-gamma chain deficiency. More recently, GOF variants in cytokine signaling have been discovered as a cause of primary immunodeficiency and autoimmunity. Most cytokine signals are mediated through the janus kinase (JAK)/STAT pathway (O'Shea et al., 2013). Following binding of cytokines to their receptors, phosphorylation of JAKs leads to the recruitment and activation of STAT molecules which then form homo- or heterodimers and translocate to the nucleus to induce transcriptional changes. Genetic variants causing a GOF in these pathways have been discovered in genes encoding STAT and JAK proteins.

*STAT1 GOF* due to heterozygous mutations in the *STAT1* gene was originally described in association with susceptibility to mycobacterial infection due to defective Th17-mediated immunity (Liu et al., 2011; van de Veerdonk et al., 2011). Functional assays demonstrated hyperphosphorylation of STAT1 with cytokine activation of primary immune cells. Identification of additional patients and careful analysis of the clinical phenotype have revealed a wide spectrum of disease, including prominent autoimmunity. A recent analysis of 274 patients from 167 kindreds demonstrates a wide variety of other associated clinical symptoms including recurrent infections caused by bacteria, mycobacteria, and viruses, autoimmunity (37%), increased risk of aneurysms (6%), and tumors (6%), and asthma/eczema (20%) (Toubiana et al., 2016). Autoimmune thyroid disease was seen in 22% of the patients, and other autoimmune features include endocrinopathies (4%), skin disease (10%), GI disease (4%), autoimmune hepatitis (2%), and autoimmune cytopenias (4%).

T cells from STAT1 GOF patients have increased expression of PD-L1 on their naïve T cells which may inhibit Th17 lineage commitment (Romberg et al., 2013). In addition, STAT1 GOF increases B-cell apoptosis, which may contribute to progressive loss of B cells and susceptibility to infection. Autoimmunity is unlikely to be associated with a defect in Th17 differentiation, since other patients with monogenic defects in IL-17A/F do not have autoimmunity. In addition, it has been reported that STAT1 GOF does not alter Tregs, although disease similar to IPEX has been reported in patients (Uzel et al., 2013), thus the mechanism of autoimmunity with STAT1 GOF is uncertain.

Patients with STAT1 GOF are treated with antimicrobial prophylaxis and specific therapy for their autoimmune manifestations. An international cohort of 15 patients who received HCT was recently reported (Leiding et al., 2017). Retrospective analysis of these patients treated with a variety of conditioning regimens demonstrated 40% survival, with poor event-free survival and frequent graft failure, suggesting that HCT has significant risk in this population. Targeted therapy with the JAK inhibitor ruxolitinib has been reported to be well tolerated and leads to the improvement of clinical symptoms including autoimmunity in a small number of patients (Weinacht et al., 2017; Higgins et al., 2015), suggesting that this targeted approach may be more successful.

STAT3 GOF syndrome is caused by heterozygous genetic variants in the gene encoding STAT3 (Vogel et al., 2015; Milner et al., 2015; Flanagan et al., 2014; Haapaniemi et al., 2015). Patients with STAT3 GOF present at a young age, typically less than 4 years, with poly-autoimmunity. Majority of the patients exhibit lymphoproliferation with hepatosplenomegaly and/or lymphadenopathy, autoimmune cytopenias, and many patients have been described to have GI tract disease including enteropathy and celiac-like disease. Additional autoimmune manifestations that have been described include skin disease (atopic dermatitis and scleroderma), autoimmune hepatitis, neonatal-onset type I DM, lymphocytic interstitial lung disease, and arthritis. Most patients have hypogammaglobulinemia, and some demonstrated susceptibility to a variety of infections, including viral upper respiratory tract infections, sepsis, candidiasis, herpes zoster, osteomyelitis, mycobacterial disease, and others, although the contribution of immunosuppressive therapy versus intrinsic risk of infection with STAT3 GOF is unclear. Other features of STAT3 GOF include postnatal short stature and an increased risk of malignancy with reports of associated Hodgkin lymphoma and large granular lymphocytic leukemia (Milner et al., 2015; Haapaniemi et al., 2015).

STAT3 is an important transcriptional regulator of the balance between Tregs and Th17 cells, with inhibitory effects on peripheral Treg differentiation and stimulation of Th17 immunity. Patients with STAT3 GOF have a decreased percentage of Tregs, and there is evidence that these cells from patients have decreased suppressive capacity, likely due to observed decreased level of the IL-2 high-affinity CD25 receptor on Tregs. Defects in T cell IL-17 production have been reported; however, other patients have normal production of IL-17 by CD4<sup>+</sup> T cells after stimulation (Haapaniemi et al., 2015; Milner et al., 2015). These studies have been limited to peripheral blood samples, and it is unknown whether tissue-resident immune cells (T cells and innate lymphoid cells) have an altered IL-17 phenotype. Additional immunologic abnormalities assessed in small numbers of patients include defects in B-cell maturation and dendritic cell subsets (Haapaniemi et al., 2015). Interestingly, patients with STAT3 GOF do not exhibit constitutive phosphorylation of STAT3 in primary immune cells, and the majority of GOF defects in STAT3 do not cause hyperphosphorylation of the protein but result in increased transcriptional activity of the activated protein and in some cases delayed dephosphorylation of STAT3. Targeting the initial activation of STAT3 using therapy with an anti-IL-6R biologic therapy or JAK inhibitors has been reported to lead to improvement of autoimmunity in some patients. HCT of patients with STAT3 GOF has also been reported with varying success.

JAK1 GOF was recently described in a single family who presented with liver cysts, atopic dermatitis, eosinophilia with infiltration of the GI tract, hepatosplenomegaly, thyroiditis, and failure to thrive (Del Bel et al., 2017). JAK1 is downstream of multiple cytokine receptors, including those utilizing the common gamma chain (e.g., IL-2, -7, -9, -15, and -21) the gp130 receptor family (including IL-6 family members), type I interferons, and IL-10. Immune cells from affected patients had increased phosphorylation of STAT1 and STAT3 after cytokine activation. The immunologic defects in this disease are unknown, and the discovery of additional patients will be important to uncover the immunologic and clinical phenotype of this new disorder. Treatment with a JAK inhibitor was reported to be effective with clinical resolution of dermatitis and hepatosplenomegaly (Del Bel et al., 2017).

## INNATE IMMUNE DEFECTS

While the majority of primary immunodeficiencies associated with autoimmunity are those leading to disruption of adaptive T and B lymphocytes, there is also an increased risk of autoimmune disease with some defects of innate immunity. Complement deficiencies, predominantly those without a high risk of infection, including C1q, C1r, C1s, C2, and C4, predispose to autoimmunity, particularly systemic lupus erythematosus, and are discussed in a separate chapter in this text.

Chronic granulomatous disease (CGD) includes a group of genetic defects affecting the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system in neutrophils (and other cells) that results in recurrent bacterial and fungal infections. NADPH oxidase is the enzyme complex that produces superoxide and other reactive

oxygen species upon neutrophil ingestion of microbes required for killing a variety of bacteria and fungi. This disorder is also characterized by dysregulated inflammation resulting in an inflammatory process that typically affects the GI and genitourinary tracts often producing strictures (Rosenzweig, 2008; Kang et al., 2011). In addition, these patients can develop inflammatory bowel disease that resembles Crohn's disease. Up to 80% of the CGD patients have some inflammatory GI manifestations, with up to 30% having IBD-like illness, and in some instances, this is the initial clinical presentation for CGD (Uzzan et al., 2016). The histology of the GI lesions in CGD differs from Crohn's disease with the development of well-defined granulomata that are surrounded by dense lymphocytic infiltrates. CGD patients may also develop chorioretinal lesions that appear as asymptomatic "punch-out" retinal scars localized along retinal vessels.

The mechanism underlying the increased inflammatory responses is unknown and has been observed more commonly in CGD patients with defects in the membrane bound components of NADPH oxidase (gp91phox, p22phox) that are generally associated with a greater degree of compromised NADPH oxidase function. This suggests that the oxidase pathway is not only involved in host protection but also in controlling inflammation. However, the actual explanation for the inflammatory responses is more complicated since X-linked carriers of CGD, who show mosaicism in their neutrophils, are at increased risk for discoid lupus, oral ulcers, and other evidence of immune dysregulation, whereas the majority of carriers do not have an increased risk for infections.

## CONCLUSION

Although at one time a perplexing paradox, coexistent autoimmunity and primary immunodeficiency now stand as two sides of the coin of immunologic dysregulation. In most of the disorders affecting cellular and humoral immunity, including combined immunodeficiencies, autoimmunity occurs primarily as a consequence of the impairment of one of the more critical checkpoints in the development/maintenance of immune cells leading to defects in tolerance. Immunodeficiencies manifest primarily by antibody deficiencies, including CVID and HIGM syndrome, highlight the importance of proper differentiation of B cells in the pathogenesis of autoimmunity. The prominent autoimmunity in monogenic disorders of immune dysregulation, including the key checkpoints in T-cell tolerance such as APECED, ALPS, and disorders of Tregs, reveals the importance of proper T-cell selection and control of aberrant T-cell activation. GOF disorders in cytokine signaling lead to autoimmunity through skewing of immune responses that are typically tightly regulated by the cytokine milieu and signaling patterns. Finally, defects in neutrophil oxidase (CGD) associated with autoimmunity highlight the potential for chronic infection and uncontrolled inflammation to lead to autoimmune complications. Importantly, all of the immunodeficiency disorders highlighted here can be quite heterogeneous with regard to their clinical phenotype and whether or not they are complicated by autoimmunity. This suggests that additional genetic, epigenetic, and environmental factors yet to be elucidated likely contribute to the clinical phenotype of these primary immunodeficiencies.

In addition to instructing our understanding of how autoimmunity develops, patients with primary immunodeficiency and autoimmunity present a clinical dilemma for clinicians attempting to balance therapies that will alleviate autoimmune symptoms while not rendering affected individuals more susceptible to infection. With the identification of molecular defects underlying many primary immunodeficiencies, it is now possible to provide targeted therapies, as highlighted above for patients with APDS, LRBA, CTLA4, STAT1/3 GOF, and JAK1 GOF-associated disease. Over the past decade, there has also been increasing use of early transplantation (HCT) in patients with primary immunodeficiency and immune dysregulation, offering the potential for a definitive "cure" for both immunodeficiency and autoimmunity in these patients, with the caveat that this procedure has significant risks and varying success in different disorders. Thus a better understanding of the molecular and cellular mechanisms of autoimmunity in primary immunodeficiencies has the potential to lead to enhanced therapeutic options for these patients.

## INTRODUCTION

Animal models have greatly facilitated the study of systemic autoimmune diseases, notably systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), and helped to develop rational new treatments. In addition, autoimmunity-prone mice have served as important tools in the study of genes involved in the expression of autoimmunity and related disease. Genes that facilitate or inhibit disease have been identified and these have in turn facilitated the study on immunogenetics and immunopathogenesis of human systemic autoimmune diseases. The etiology of both SLE (Tsokos, 2011) and RA (McInnes and Schett, 2011) is heterogeneous and complicated, but animal models bring a consistent understanding of disease pathogenesis. Mouse models of systemic autoimmune disease can be grouped into three types: spontaneous, gene manipulation-derived, and induced.

## SPONTANEOUS MODELS OF SYSTEMIC AUTOIMMUNITY

### Overview of Spontaneous Autoimmune Disease Models and Autoimmune-Susceptibility Loci

Commonly studied spontaneous models of lupus include the MRL-Fas<sup>lpr/lpr</sup> (MRL/*lpr*) [New Zealand Black (NZB) x New Zealand White (NZW)] F1, and BXSB mice. These murine models develop SLE spontaneously and their study has generated significant information on the role of hormones (Roubinian et al., 1978; Fernandes and Talal, 1986; Dhaher et al., 2000; Svenson et al., 2008) and the contribution of aberrant immune regulation (Handwerger et al., 1994) in the expression of the disease. They have been used to identify loci that contribute to the genetic pool required for the development of disease (Drake et al., 1995; Reilly and Gilkeson, 2002; Kono and Theofilopoulos, 2006). Forward genetic screening by gene complementation studies has shed light on the epistatic interactions of genes (Wakeland et al., 1997; Morel and Wakeland, 1998). Candidate genes have been identified including those of the CD2/SLAM family in the Sle1b locus (Wandstrat et al., 2004), the interferon (IFN)-inducible genes (Rozzo et al., 2001) for the NZB-derived Nba2 locus, and the complement receptor gene Cr2 for the NZW-derived Sle1c locus (Boackle et al., 2001). Numerous genes susceptible to lupus were identified and well characterized (Kono and Theofilopoulos, 2011). Identification of disease candidate genes by quantitative trait loci (QTLs) mapping strategy has been prompted to proceed analysis of mice deficient of targeted genes (reverse genetics). For example, it has been shown that the introduction of an IFN- $\alpha/\beta$  receptor null gene into NZB mouse results in decreased production of antierythrocytic antibodies (Santiago-Raber et al., 2003). Because IFN- $\alpha$  has been found to be increased in patients with SLE and to promote dendritic cell maturation (Blanco et al., 2001), a case has been made for the construction of biologics to limit the action of type I IFNs in systemic autoimmunity. Moreover, identification of contributing genes and loci in animal models has guided the search for orthologs in humans with systemic autoimmune diseases (Tsao et al., 1997, 2002; Gaffney et al., 1998, 2000; Harley et al., 1998; Moser et al., 1999).

### New Zealand Mixed Mice

The NZB (H-2<sup>d</sup>) mouse develops anemia due to an antierythrocyte antibody. Hybrids with NZW (H-2<sup>z</sup>) (NZBxNZW) F1 mice, develop systemic autoimmune disease with a high titer of anti-DNA antibodies and severe glomerulonephritis (GN) that becomes apparent at 5–6 months of age. The decreased average lifespan of these mice is 8 months for females and 13 months for males (Vyse et al., 1998; Ibnoou-Zekri et al., 1999). Among New Zealand Mixed (NZM) mice generated by (NZBxNZW) F1 and NZW backcross and sib mating, the NZM2328 and NZM2410 strains were found to develop lupus-like disease. Importantly, three lupus susceptibility loci, *Sle1–3*, were identified by the lupus linkage analysis of NZM2410 mice (Morel et al., 1994). From the findings in mice, variations in many genes in these loci have been directly associated with human SLE. *Sle1b* corresponds to polymorphisms in four signaling lymphocytic activation molecule family (SLAMF) member genes (Wandstrat et al., 2004), including Ly108, which was directly implicated in the regulation of B-cell tolerance (Kumar et al., 2006). Variants of SLAMF3 (Ly9) and SLAMF4 (CD244) have been associated with human SLE and RA (Cunningham Graham et al., 2008; Suzuki et al., 2008).

### MRL/lpr and gld Mice

The MRL mouse strain was derived from several inbred lines that included LG/J (75%), AKR/J (12.6%), C3H/Dehi (12.1%), and C57BL/6 (0.3%). MRL/MpJ-Fas<sup>lpr</sup>/J (MRL/*lpr*) mice, bearing two doses of mutation in the Fas gene, develop accelerated autoimmune disease characterized by severe lymphadenopathy due to the accumulation of CD3<sup>+</sup>CD4<sup>-</sup>CD8<sup>-</sup>B220<sup>+</sup> (double-negative) T cells. Disease onset with severe dermatitis and/or lymphadenopathy is seen from 10 to 12 weeks and death occurs at around 25 weeks. The disease is severe in female and the average lifespan for female MRL/*lpr* mice is 17 weeks. Mice display high concentrations of immunoglobulins including elevated levels of autoantibodies such as antinuclear antibodies (ANA), anti-ssDNA, anti-dsDNA, anti-Sm, and rheumatoid factors (Andrews et al., 1978). B and T cells from these mice have a defect in apoptosis due to the lack of functional Fas receptor (Reap et al., 1995). A mutation of Fas ligand (FasL) gene leads to generalized lymphoproliferative disease (gld) similar to that caused by the *lpr* mutation (Takahashi et al., 1994). In humans, defective Fas signaling can lead to the development of autoimmune lymphoproliferative syndrome which shares many manifestations with SLE (see Chapter 22: Autoimmune Diseases: The Role for Vaccines). Further study of the intense lymphoproliferation has enabled

the identification of genes whose products are central to the expression of systemic disease. For example, while deletion of the cyclin-dependent kinase inhibitor p21 does not lead to autoimmunity (Lawson et al., 2002, 2004), transfer of the *p21* null gene into the MRL *lpr/lpr* mouse results in a reduced autoimmune disease by allowing T-cell death and decreasing the accumulation of G0/G1 arrested T cells (Lawson et al., 2004). Expression of the *lpr* mutation in nonautoimmune strains such as C3H/HeJ and C57BL/6 leads to the development of lymphoproliferation and autoantibody production but limited GN in female mice. C3H/HeJ<sup>Fas/gld</sup>/J (gld) mice, the point mutation of cognate receptor for Fas, FasL in C3H/HeJ background, also develop autoimmunity with lymphocyte expansion similar to that of MRL/lpr mice. However, they have a longer lifespan than MRL/lpr mice due to reduced renal pathology (Roths et al., 1984).

## BXSB Mice

Male only C57BL/6J × SB/Le sa bg/sa bg (BXSB) mice develop severe GN and autoantibodies. The genetic locus responsible for the expression of the disease is located in the Y chromosome and is known as *Yaa* (Y chromosome–accelerated autoimmunity) (Izui et al., 1995). *Yaa* was first identified from a cross between a C57BL/6 female and an SB/Le male that produced the BXSB hybrid line. BXSB mice develop SLE at much higher incidence and with earlier onset in males compared to females, whereas mice from the reciprocal cross (SB/LE female and B6 male) do not show the same acceleration of disease in males. The disease is heavily dependent on the presence of the H-2b allele, because its replacement with the H-2d allele results in prolonged survival. Of interest, the (BXSBxNZW) F1 mouse develops thrombocytopenia and coronary artery disease accompanied by the presence of antiphospholipid antibodies (Kono and Theofilopoulos, 2006). Toll-like receptor 7 (TLR7), a single-stranded RNA-binding innate immune receptor, was identified as a gene responsible for the Y chromosome–linked autoimmune accelerator, as duplication of the *Tlr7* gene in *Yaa*<sup>+</sup> mice was shown to be associated with the induction of autoreactive B cells (Pisitkun et al., 2006). Moreover, deletion of the endogenous copy of *Tlr7* from X chromosome abrogates *Yaa*-induced monocytosis, lymphoid activation, splenomegaly, and GN, with decreased mortality (Deane et al., 2007; Santiago-Raber et al., 2008). Consistently, a human allele of the *Tlr7* gene was recently reported to be associated with increased risk for SLE development in males (Shen et al., 2010).

## Palmerston North Mice

Palmerston North (PN) mice develop spontaneous autoimmunity manifested by the production of autoantibodies against ssDNA, dsDNA, caldiolipin, and other phospholipids (Handwerger et al., 1999). PN mice exhibit vasculitis and GN from the age of 6 month and die at 11–12 months. Male mice also develop autoimmune diseases but they occur later and less severe than those in female mice (Walker et al., 1978; Luzina et al., 1999).

## Ank/ank Mice

Mice homozygous for the *ank* mutation. *Ank/ank* mice develop early-onset joint ankylosis in the spine and peripheral joints resembling human spondyloarthritis (Krug et al., 1989). The *Ank* gene encodes a transmembrane protein expressed in joints that controls pyrophosphate levels and may be irrelevant to autoimmunity.

## K/BxN Mice

K/BxN T-cell receptor mice, the F1 generation mice from the crossing of a T cell receptor (TCR) transgenic KRN mice on C57BL/6 background with the autoimmune-prone nonobese diabetic strain (Monach et al., 2004; Kouskoff et al., 1996), develop spontaneously an autoimmune disease with most (although not all) of the clinical, histological, and immunological features of RA in humans. The murine disease is critically dependent on both T and B cells and is joint specific, but it is initiated and perpetuated by T- and B-cell autoreactivity to a ubiquitously expressed antigen, glucose-6-phosphate isomerase (GPI). Transfer of serum (or purified anti-GPI immunoglobulins) from arthritic K/BxN mice into healthy animals regularly provokes arthritis within a few days, even when recipients are devoid of lymphocytes (Ji et al., 2001; Christensen et al., 2016). Complement components, Fc receptors, and mast cells are important for the expression of the disease. The relevance of the K/BxN model to human RA is supported by one report showing that serum from almost two-thirds of patients with RA contains anti-GPI antibodies, which are absent from serum from normal individuals or of patients with Lyme arthritis or

Sjogren's syndrome (Matsumoto et al., 2003). However, not all investigators agree. The K/BxN model has been particularly useful in illustrating the role of immune-inflammatory components in the development of arthritis and notably the characterization of the role of mast cells (Lee et al., 2002); yet, this model offers little evidence that autoantibodies are involved in the pathogenesis of RA.

### SKG Mice

SKG mice develop spontaneously T cell-mediated arthritis due to a mutation of the gene encoding a Src homology 2 (SH2) domain of  $\zeta$ -associated protein of 70 kDa (ZAP-70), a key signal transduction molecule in T cells. The disturbance in the thymic T-cell selection from the absence of ZAP-70 results in the generation of arthritogenic T cells. Besides synovitis, SKG mice develop extraarticular lesions, including pneumonitis and vasculitis. Serologically, they develop high levels of rheumatoid factor (Marshall et al.) and autoantibodies specific for type II collagen (CII) (Sakaguchi et al., 2003). A molecule termed synoviolin/Hrd1 was found to play a key role in the development of synovitis. This represents an E3 ubiquitin ligase, which, by promoting the growth of synoviocytes, facilitates the development of arthritis. Mice lacking synoviolin are resistant to arthritis (Amano et al., 2003).

Mice that develop spontaneous autoimmunity have helped our understanding of hormonal and immunoregulatory influences in autoimmunity, but obvious restraints limit the direct transfer of this information to human disease. Human disease develops in individuals with a permissive genetic background in conjunction with environmental and stressful factors, possibly acting over a long period. However, these murine models allow us to analyze disease mechanisms and are very useful to test potential therapies. Moreover, analysis of gene-manipulated mice in these genetic backgrounds enables investigators to identify a number of molecules involved in the development of disease pathogenesis (Table 29.1). A number of cytokine/cytokine receptor signals are reported to be important for the pathogenesis of SLE, including IFN- $\gamma$ /IFN- $\gamma$ R (Balomenos et al., 1998; Haas et al., 1997), IL-6 (Cash et al., 2010), IFN $\alpha$ R (Santiago-Raber et al., 2003), IL-21/IL-21R (Bubier et al., 2009; Herber et al., 2007), and IL-23R (Kytaris et al., 2010; Zhang et al., 2009). Intracellular signaling molecules such as phosphoinositide 3-kinase gamma (Barber et al., 2005), mammalian target of rapamycin (Lui et al., 2008), spleen tyrosine kinase (Syk) (Deng et al., 2010; Bahjat et al., 2008), and calmodulin-dependent kinase IV (Ichinose et al., 2011) were also identified to be involved in the development of lupus. These molecules could represent therapeutic targets for the treatment of human SLE.

## GENETICALLY MANIPULATED MODELS OF SYSTEMIC AUTOIMMUNITY

Loss of tolerance is a fundamental immunological abnormality in SLE. Numerous studies of mice with genetic manipulation such as gene deletions and transgenes that develop autoantibodies and other features of SLE on nonautoimmune genetic backgrounds have provided great insights into mechanisms that govern tolerance and autoimmunity and suggested novel rational treatments (Fig. 29.1 and Table 29.1).

### Lymphocyte Activation Molecules

Human SLE T cells are known to express less TCR- $\zeta$  chain (Liossis et al., 1998) and to use alternative signaling through the FcR- $\gamma$  chain (Enyedy et al., 2001). Mice that lack TCR- $\zeta$  chain develop autoimmune manifestation and display disturbed positive and negative thymic selection (Yamazaki et al., 1997), and the phenotype can be rescued successfully by introducing the FcR- $\gamma$  chain (Shores and Love, 1997). The pathophysiology for the murine and human phenotypes may well differ and, although in mice lack of the  $\zeta$  chain may lead to autoimmunity by altering early thymic events that limit the export of autoimmune T cells, in humans the rewiring of TCR with the newly upregulated FcR- $\gamma$  chain will lead to increased TCR-mediated signaling processes (Tsokos et al., 2003).

The B7-CD28/CTLA-4 costimulatory pathway is pivotal for T-cell activation. Signaling through this pathway is complex due to the presence of at least two B7 family members, CD80 (B7-1) and CD86 (B7-2), and two counter receptors CD28 and CD152 (CTLA-4). CTLA-4-deficient mice rapidly develop lymphoproliferative disease with multiorgan lymphocyte proliferation and tissue destruction, with particularly severe myocarditis and pancreatitis, and die by 3–4 weeks of age (Waterhouse et al., 1995; Tivol et al., 1995). CTLA-4-Ig limits effectively murine

**FIGURE 29.1** Pathogenesis of systemic autoimmunity and molecules involved in the development of autoimmune disease, compiled from studies on mice and humans with SLE. Similar to organ-specific autoimmunity, systemic autoimmunity is a function of a deleterious combination of genetic and environmental factors that lead in concert to the loss of self-tolerance. T cells display numerous aberrations in the form of impaired cytokine productions, defective immunoregulatory function, and increased ability to provide help to B cells to produce autoantibodies. In systemic autoimmunity, autoantigens are frequently directed against nuclear antigens, with which they form immune complexes. Defective clearance of such immune complexes is the result of defective expression of Fc and complement receptors, and increased levels of nuclear materials may propagate the autoimmune responses. A number of cytokines including IFN $\alpha$ , IL-6, IL-21, IL-17, BAFF, and their receptors play critical roles for the development of lupus. *IFN*, Interferon; *IL*, interleukin; *MHC*, major histocompatibility complex; *SLE*, systemic lupus erythematosus.

lupus (Finck et al., 1994) and the use of CTLA-4-Ig biologics (Abatacept) has helped patients with RA (Kremer et al., 2003) and psoriatic arthritis (Abrams et al., 2000). Abatacept is now one of the biological agents for the treatment of RA. Phase II/III trial is undergoing for psoriatic arthritis, although clinical trials for SLE have failed to achieve their primary outcome (Pimentel-Quiroz et al., 2016).

Programmed death-1 (PD-1) is a member of the CD28 family of receptors and its intracytoplasmic domain defines an immunoreceptor tyrosine-based inhibition motif (ITIM); engagement of PD-1 with its ligands PD-L1 and PD-L2 delivers a negative signal. Mice lacking the PD-1 gene develop either autoantibody-mediated cardiomyopathy in BALB/c (Okazaki et al., 2003) or GN on a C57BL/6 background (Nishimura et al., 2001). PD-1 polymorphism has been identified among SLE patients (Prokunina et al., 2002) and/or RA patients (Lin et al., 2004). PD-L1-deficient mice show accelerated autoimmune inflammation in MRL/MpJ and MRL/lpr mice (Lucas et al., 2008).

Src homology 2-containing phosphatase 1 (SHP1) is one of the best-characterized protein tyrosine phosphatases (PTPase). SHP inhibits cell activation through its recruitment by negative regulatory molecules containing ITIM. The homozygous loss of SHP1 (*Ptpn6*<sup>me-v/me-v</sup>) in mice leads to the “moth-eaten” phenotype characterized by spotty hair loss and abnormalities in the immune system that lead to systemic autoimmunity and skin inflammation (Kozlowski et al., 1993; Tsui et al., 1993; Bignon and Siminovitch, 1994). T lymphocytes from these mice are hyperresponsive to TCR stimulation (Pani et al., 1996). Since neutrophils from SHP1-deficient

moth-eaten mice demonstrate increased oxidant production, surface expression of CD18, and adhesion to protein-coated plastic, the autoimmune phenotype in these mice may not directly reflect lymphocyte aberrations (Kruger et al., 2000). Moth-eaten *Rag1*<sup>-/-</sup> mice lack B and T cells but still develop severe systemic inflammatory disease (Yu et al., 1996). Furthermore, only B cell–specific deletion of SHP1 leads to systemic autoimmune disease (Pao et al., 2007).

Mice with beta1,6 N-acetylglucosaminyltransferase V (Mgat5) deficiency display decreased N-glycosylation of T-cell membrane proteins, which prevents galectin binding and thereby disrupts the galectin-glycoprotein lattice leading to increased clustering of the TCR (Demetriou et al., 2001). Increased TCR clustering in Mgat5-deficient mice results in autoimmunity, which implicate a phenotype compatible with human SLE, involving lowered T-cell activation thresholds and increased TCR signaling. In the case of T cells of human SLE, increased association of the TCR- $\zeta$  chain with lipid rafts, as well as membrane clustering, is claimed to lead to decreased tolerance and abnormal signaling (Nambiar et al., 2002; Krishnan et al., 2004). Thus defects in the expression and function of glycosylation processes may predispose to autoimmunity and, along the same lines, glycosylation of the transcription factor Elf-1, which enables the 80-kDa form to transform to the DNA-binding 98-kDa form, is defective in human SLE T cells (Juang et al., 2002).

Other lines of evidence suggest T cells from lupus-prone mice that are transgenic for a specific receptor have decreased antigen-initiated T-cell stimulation thresholds (Vratsanos et al., 2001; Bouzahzah et al., 2003). A similar concept of an “overexcitable” antigen-initiated proximal lymphocyte signaling phenotype has been proposed for human SLE (Tsokos et al., 2003). For example, protein tyrosine phosphatase nonreceptor 22 (PTPN22) is involved in negative regulation of T-cell signaling through the encoded lymphocyte-specific PTPase LYP (see Chapter 5: Immunological Tolerance—T Cells). Single nucleotide polymorphism (SNP) of PTPN22 at position 1858 was reported to be associated with autoimmune diseases such as type I diabetes, SLE, and RA. The mice orthologous proline, glutamic acid, serine and threonine (PEST) domain phosphatase (PEP) mutant (R619W) protein knock-in mice exhibit systemic autoimmunity with the elevation of autoantibody due to hyperactivation of T cells (Dai et al., 2013). Furthermore, only B cell–specific insertion of mutant protein is enough for the induction of autoimmune diseases.

A state of B-lymphocyte hyperactivity resembling SLE is seen in mice lacking the Src-family kinase Lyn. Lyn is an essential inhibitory component on B-cell receptor (BCR) signaling. Negative regulation of the BCR is a complex quantitative trait in which Lyn, the coreceptor CD22, and the tyrosine phosphatase SHP1 are each limiting elements (Cornall et al., 1998). When immunoreceptor tyrosine-based motif (ITIM) is phosphorylated by Lyn, ITIM recruits and activates SHP1 and SHIP-1 (SH2 domain-containing inositol-5-phosphatase). Lyn-deficient mice display decreased numbers of mature peripheral B cells, greatly elevated serum IgM and IgA (Bignon and Siminovitch), and production of autoantibodies that cause autoimmune GN reminiscent of SLE (Chan et al., 1997). Paradoxically, sustained activation of Lyn in vivo using a targeted gain-of-function mutation (*Lyn*<sup>up/up</sup> mice) led to the development of autoantibodies and lethal autoimmune GN. Interestingly, B cells from *Lyn*<sup>up/up</sup> mice show a heightened calcium flux in response to BCR stimulation (Hibbs et al., 2002). These data in humans and mice suggest that mechanisms that lead to sustained BCR signaling may override control mechanisms and lead to autoimmunity. SHIP-1 deficiency in C57BL6 background exhibits severe autoimmune disease characterized by a greater number of activated B cells, plasmacytosis, and intense GN (Maxwell et al., 2011).

Antigen presented in the context of immune complexes engages not only the BCR but also the Fc $\gamma$ RIIb, which exert an immunosuppressive effect through the phosphorylation of ITIM. Introduction of the Fc $\gamma$ RIIb null phenotype into the C57BL/6 background caused production of autoantibodies and GN (Bolland and Ravetch, 2000) and Fc $\gamma$ RIIb deficiency exacerbates autoimmunity in B6/lpr mice (Yajima et al., 2003). Yet the same null phenotype on the BALB/c background did not result in autoimmunity. In humans, polymorphisms of the Fc receptors have been associated with systemic autoimmunity and particularly with SLE and granulomatous polyangiitis (Kimberly et al., 1995).

## Ubiquitination-Related Enzymes

The ubiquitination system is an essential regulator for cellular processes such as differentiation, cell cycle, and DNA repair. Disruption of ubiquitination system could induce aberrant immune responses. The ubiquitin editing enzyme A20 [tumor necrosis factor  $\alpha$  (TNF $\alpha$ )-induced protein, Tnfp3], a cytoplasmic zinc-finger protein, restricts and terminates inflammatory responses through modulation of the ubiquitination status

of a central component in NF $\kappa$ B, IRF3, and apoptosis signaling components (Vereecke et al., 2011). In humans, polymorphisms in genomic A20 locus are associated with several autoimmune diseases including SLE, RA, and psoriasis. A20-deficient mice die prematurely from a severe wasting disease with multiorgan inflammation (Lee et al., 2000). Mice with dendritic cell-specific deletion of A20 develop lupus-like features with elevated anti-dsDNA, antiphospholipid syndrome, GN, and lymphosplenomegaly (Kool et al., 2011).

The Cbl-b (casitas B-lineage lymphoma-b) and Cbl adaptor proteins are E3 ubiquitin ligases that inhibit receptor and nonreceptor tyrosine kinases by promoting ubiquitination (Bachmaier et al., 2000). Loss of Cbl-b rescues reduced calcium mobilization of anergic T cells, which was attributed to Cbl-b-mediated regulation of PLC $\gamma$ -1 phosphorylation. Loss of Cbl-b in mice results in impaired induction of T-cell tolerance both in vitro and in vivo and shows exacerbated autoimmunity (Jeon et al., 2004). Moreover, B cell-specific deficiency of Cbl/Cbl-b in mice leads to impaired BCR downmodulation and anergy to self-antigen, and development of spontaneous lupus-like disease with anti-dsDNA, ANA, massive leukocytic infiltrates in multiple organs, and immune complex GN (Kitaura et al., 2007).

Roquin (Rc3h1), a RING-type ubiquitin ligase family member, was identified as a negative regulator of follicular helper T (Tfh) cell development. This molecule is identified by a novel forward genetic strategy: male C57BL/6 mice were treated with ethylnitrosourea (ENU), a mutagenic agent, and bred the variant genome sequences to homozygosity and progeny were screened for autoimmunity. M199R mutation within the roquin (ROQ) domain of Roquin was generated by ENU mutagenesis that resulted in ANA, anti-dsDNA, GN, necrotizing hepatitis, anemia, and immune thrombocytopenia (Vinuesa et al., 2005). This mouse displays increased germinal center formation and expansion of memory/effector CD4 $^{+}$  T cells, particularly Tfh cells. Tfh cells have been established as a T-helper cell subset specialized for providing help to B cells in germinal centers (GCs) (King et al., 2008). Overpresentation of Tfh cells is associated with the development of systemic autoimmunity (Linterman et al., 2009) and the expansion of circulating Tfh-like cells was also detected in human SLE and associated with severe disease (Simpson et al., 2010).

## Cytokines and Their Receptors

Mice that are deficient in IL-2 and IL-2a have disrupted immunological homeostasis that eventually leads to fatal autoimmune manifestations (Nelson, 2002). Specifically, these mice develop autoimmune hemolytic anemia and colitis with lymphoproliferation, expansion of effector/memory phenotype T cells, polyclonal hypergammaglobulinemia, and autoantibodies. IL-2RB – / – mice likewise develop anemia, splenomegaly, and lymphadenopathy, but not colitis. In humans, IL-2 deficiency is clinically manifested as severe combined immunodeficiency, whereas a patient lacking IL-2a was declared immunocompromised, and several organs were infiltrated with inflammatory cells (Sharfe et al., 1997). The autoimmune manifestations depend on the presence of both T and B cells and environmental antigens since, if the mice are kept under pathogen-free conditions, they do not develop autoimmunity. Activation-induced cell death (AICD) is central for the elimination of activated autoreactive cells, and this depends on IL-2 signaling. Defective AICD obviously plays a role in the development of autoimmunity. Humans with SLE have defective AICD that appears to be multifunctional: defective TNF $\alpha$  (Kovacs et al., 1996) and IL-2 production (Tsokos et al., 1996). The downregulation of IL-2 production in SLE patients was found to be mediated by Ser/Thr protein phosphatase 2A (PP2A). PP2A dephosphorylates transcription factor SP-1, which results in strong binding of cyclic-AMP responsive element modulator to the IL-2 promoter (Juang et al., 2011). T cells from patients with SLE have increased PP2A (Katsiari et al., 2005). Overexpression of PP2A in T cells in B6 mice does not lead to autoimmunity but only to granulocytosis and increased levels of IL-17 and, when challenged with an antiglomerular basement membrane antibody, they developed exuberant GN (Crispin et al., 2012). On the other hand, mice with PP2A-deficient regulatory T cells (Treg) develop severe lymphoproliferative autoimmune disease due to functional impairment of Treg (Apostolidis et al., 2016). IL-2 plays a central role in the development and maintenance of Treg cells, which have been proven to be of pathogenic relevance in the development of autoimmune disease (La cava, 2008). Low-dose IL-2 treatment in patients of chronic graft-versus-host disease (GVHD) (Koreth et al., 2011) and of hepatitis C virus-induced vasculitis (Saadoun et al., 2011) was reported to be effective with an accompanying increase of Treg cells. *Vaccinia virus*-mediated in vivo IL-2 introduction ameliorates disease progression in MRL/lpr mice (Gutierrez-Ramos et al., 1990). These results indicate that correction of IL-2 production could have therapeutic potential by restoring the function of T cells.

The TNF/TNF receptor (TNFR) system acts on the homeostasis of the immune system in different ways. Among them, TNFSF13B (BAFF, BlyS) and TNFRSF13B (TACI) are implicated in the development of autoimmune disease. BAFF is critical for B-cell survival and BAFF-transgenic or TACI-knockout mice show lupus-like disease. Moreover, serum BAFF is elevated in both BWF1 and MRL/*lpr* mice and blocking BAFF function with a soluble TACI-IgGFc protein can inhibit proteinuria and prolong survival (Gross et al., 2000). Surprisingly, T cell-deficient BAFF-transgenic mice can develop lupus-like disease indistinguishable from that of BAFF-transgenic mice and the development of the disease is dependent on myeloid differentiation factor 88 (MyD88) (Groom et al., 2007; Mackay et al., 1999). Clinical trials (phase II/III) using the chimeric molecule TACI-Ig (Atacicept) in SLE show effectiveness for inhibition of new flare (Isenberg et al., 2015) and the clinical use of anti-BAFF/BlyS (Belimumab) for active SLE patients was recently approved (Navarra et al., 2011).

The successful clinical introduction of treatment with anti-TNF $\alpha$  confirmed the biological relevance of TNF $\alpha$  function in chronic inflammatory diseases, particularly RA and Crohn's disease. The introduction of a modified human TNF-globin hybrid transgene in mice was the first demonstration in animal models that TNF has arthritogenic properties. These mice (Tg197) spontaneously develop (with 100% penetrance and a predictable time of onset) a chronic, erosive, inflammatory polyarthritis with histological lesions resembling human RA (Kontoyiannis et al., 1999; Keffer et al., 1991). Adenylate-uridylate-rich (AU-rich) elements (Holmdahl et al.) are important for TNF $\alpha$  mRNA destabilization and translational repression in hematopoietic and stromal cells. Development of two specific pathologies in mutant mice—chronic inflammatory arthritis and colitis akin to Crohn's disease—suggests a defective function in analogous human pathologies. These mice have proven to be quite informative in dissecting the pleiotropic effects of TNF $\alpha$  on immune responses and on the expression of various forms of autoimmune pathology.

## Complement and Complement Receptor Proteins

Activation of the classical pathway typically starts by interaction of C1q with immune complexes and the action of complement is the main effector mechanism of antibody-mediated immunity. The complement system also has an important role in clearing immune complexes from the circulation. It can also bind apoptotic cells and helps to eliminate these cells from tissue (Taylor et al., 2000). If the complement system fails in this function, waste material can accumulate and evoke an autoimmune response. Deficiencies of the classical pathway are associated with an increased risk to develop SLE or allied diseases in human (Manderson et al., 2004). More than 90% of the individuals with C1q and C1r/C1s deficiency develop an SLE-like disorder, and 10%–20% of the individuals with C2 deficiency develop SLE (Truedsson et al., 2007). These phenotypes in humans do not parallel in full those in mice. Deficiency of C1q in C57BL/6 mice does not lead to the development of autoimmunity. By contrast, C1q-deficient MRL/MpJ mice display accelerated disease onset and increased levels of ANA and of GN, particularly in females which developed severe crescentic GN. Moreover, C1q-deficient mice on a B6x129 genetic background were shown to develop higher levels of autoantibodies compared to strain-matched controls and to develop GN by 8–10 months of age (Manderson et al., 2004; Botto et al., 1998). Thus the expression of autoimmunity in C1q-deficient mice is strongly influenced by additional background genes (Botto and Walport, 2002; Botto et al., 1998).

The B6/*lpr* mouse develops minor autoimmune features. Deficiency in this strain of the complement receptor 1 and complement receptor 2 (CR1/CR2, CD35/CD21), encoded by the Cr2 gene, permits the development of intense autoimmune features (Boackle and Holers, 2003), indicating that complement receptors are important in the elimination of B cells that display reactivity with self-antigens. This explanation assumes that self-antigens initiate a strong B-cell signal, which leads to B-cell death and the absence of the CR2-mediated enhancement of the signal permits their survival (Tsokos et al., 1990; Dempsey et al., 1996). CR1 and CR2 have been proposed to play a role in the development of SLE. Patients with SLE have around 50% lower levels of these receptors on their B cells (Levy et al., 1992; Marquart et al., 1995). MRL/*lpr* mice exhibit lower levels of these receptors on B cells prior to the onset of overt disease, suggesting that the reduction of CR1/CR2 expression may be pathogenic (Takahashi et al., 1997). Also, evidence for the involvement of Cr2 in systemic autoimmunity comes from the NZM2410 mouse. The congenic interval corresponding to *Sle1c*, one of the SLE susceptibility loci, *Sle1*, contains the Cr2 gene. NZM2410/NZW Cr2 exhibits a single nucleotide polymorphism that introduces a novel glycosylation site, resulting in higher molecular weight proteins. This polymorphism, located in the C3d binding domain, reduces ligand binding and receptor-mediated cell signaling. Molecular modeling based on the CR2 structure in complex with C3d has revealed that this glycosylation interferes with receptor dimerization (Boackle et al., 2001).

Since disruption of the C1q, C4, and CR1/CR2 leads to reduced selection against autoreactive B cells and to impaired humoral responses, C1 and C4 could act through CR1/CR2 to enhance humoral immunity and suppress autoimmunity, but each complement component appears to act independently. High titers of spontaneous ANA and SLE-like autoimmunity develop in all C4<sup>-/-</sup> mice and most male mice but not in Cr2<sup>-/-</sup> mice. The fact that the clearance of circulating immune complexes is impaired in preautoimmune C4<sup>-/-</sup>, but not Cr2<sup>-/-</sup> mice, favors the role of nuclear antigen–ANA immune complexes in the development of autoimmune disease (Chen et al., 2000).

## Clearance of Dead Cells

Effective degradation of nucleotides from dead cells and digestion of cellular components by macrophages allow noninflammatory clearance and a recycle of dead cells (Nagata et al., 2010). DNaseI is the major nuclease present in the blood, urine, and secretions. DNaseI deficiency in nonautoimmune background mice was reported to increase the incidence of SLE manifestations, including positive ANA, anti-DNA, and immune complex GN (Napirei et al., 2000). Reduced DNaseI activity is observed in the sera of lupus patients, which may contribute to SLE susceptibility (Tsukumo and Yasutomo, 2004). Intriguingly, an identical heterozygous nonsense mutation in DNASE1 was detected in two SLE patients (Yasutomo et al., 2001).

Deficiency in the clearance of apoptotic cells is proposed to be one of the causes of SLE. Unengulfed apoptotic cells are present in the germinal centers of the lymph nodes of some SLE patients and macrophages from these patients often show a reduced ability to engulf apoptotic cells (Gaapl et al., 2006). Milk fat globule-EGF factor 8 (MFG-E8) protein functions as a bridging protein between phosphatidylserine (PS) on apoptotic cells to avb3 or avb5 integrins on phagocytic cells (Hanayama et al., 2002). MFG-E8 is primarily expressed on CD68-positive tangible body macrophages within germinal centers. MFG-E8-deficient female mice on a B6x129 gene background develop SLE-like autoimmune disease with anti-dsDNA, ANA, and GN by 40 weeks of age (Hanayama et al., 2004).

T-cell immunoglobulin and mucin domain-containing 4 (Tim-4) is another PS receptor. Peritoneal resident macrophages highly express Tim-4 that mediates phagocytosis of apoptotic cells. Tim-4-deficient mice develop lupus-like disease with the elevation of autoantibody titers; however, GN or other organ damages were not reported (Miyanishi et al., 2007; Rodriguez-Manzanet et al., 2010).

TAM family members (Tyro3, Axl, and Mer), which are tyrosine kinase receptors expressed on antigen-presenting cells, promote clearance of apoptotic cells and mice expressing a kinase-dead mutant of Mer (MerKD) develop SLE-like autoimmunity (Scott et al., 2001; Cohen et al., 2002). TAM receptors negatively regulate the innate immune reaction and TAM-deficient dendritic cells overproduce IL-6, IFN, and TNF $\alpha$  that might be responsible for the induction of autoimmunity (Lemke and Rothlin, 2008).

Genome-wide association studies in human revealed that autophagy-related genes are predisposed SLE disease susceptibility, including Atg5 and Atg7. Therefore autophagy and autophagy-relevant proteins have been implicated to autoimmunity (see Chapter 18: Effector Mechanisms in Autoimmunity). Microtubule-associated protein light chain 3 (LC3) is a key autophagy-related protein that is recruited to the double-membrane autophagosome. Recently, LC3 was found to be recruited to the single-membrane phagosome, called LC3-associated phagocytosis (LAP), distinct from endocytosis or autophagy. LAP vesicles contain engulfed particles including dying cells, indicating an important role for the clearance of dead cells. A number of autophagy-related genes such as Atg5, Atg7, Beclin-1, Rubicon, and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase-2 (Nox2) are involved in LAP processes. Mice with macrophage-deficient of these autophagy-related genes were recently reported to exhibit lupus-like autoimmune diseases. Importantly, autoimmunity was observed in mice lacking proteins required for both LAP and autophagy (Atg5, Atg7, Beclin-1) or LAP alone (Nox2, Rubicon) but not in animals lacking proteins required for autophagy but dispensable for LAP (FIP200, ULK1) (Martinez et al., 2016). Previous report showed that Nox2-deficient and -heterozygous MRL/lpr mice had exacerbated lupus, indicating a protective role of Nox2 in autoimmune disease (Campbell et al., 2012). Taken together, this noncanonical autophagy process LAP might control immune regulation for preventing autoimmune reaction.

## Innate Immune Cell Signaling

Recent studies demonstrate that DNA and RNA in apoptotic material can activate B cells and dendritic cells through TLR9, TLR7, and TLR8 (Leadbetter et al., 2002; Boule et al., 2004; Vollmer et al., 2005). As described

above, overexpression of TLR7 is responsible for the development of autoimmune diseases in BXSB mice. These results indicate that TLR signaling is linked to the development of autoimmune disease and aberrant activation of innate immunity may contribute to systemic autoimmune diseases including RA and SLE (Marshak-Rothstein, 2006).

While TLRs recognize pathogen-associated molecular patterns (PAMPs) at the cell surface or in endosomes, RIG-I-like receptors such as RIG-I and MDA5 are recognized by intracellular viral RNAs. Constitutive active MDA5-carrying knock-in (*Ifih1<sup>gs/+</sup>*) mice develop severe autoimmune diseases with high autoantibody titer and GN (Funabiki et al., 2014).

TANK (also known as I-TRAF) is a TNF receptor–associated factor (TRAF)–binding protein and binds to TRAF1, 2, 3, 5, and 6, all of which are crucial for TLR signaling. TANK is a negative regulator of proinflammatory cytokine production induced by TLR signaling and TANK-deficient mice spontaneously develop lupus-like autoimmune diseases with fatal GN, ANA, and anti-dsDNA. Autoantibody production in TANK-deficient mice is abrogated by antibiotic treatment or the absence of IL-6 or MyD88, indicating that TANK controls TLR signaling by intestinal commensal microbiota (Kawagoe et al., 2009).

Zc3h12a (regnase-1) is an RNase activated by TLR signaling that promotes the degradation of mRNA. Zc3h12a-deficient mice have early mortality associated with severe hemolytic anemia, lymphoproliferation, and ANA with an increased number of activated B cells, T cells, and plasma cells due to excessive cytokine transcription notably IL-6 and IL-12 (Matsushita et al., 2009). Zc3h12a deficiency also induces hyperactivation of CD4<sup>+</sup> T cells due to impairment of degradation of IL-2, Ox40, and c-Rel. Consequently, mice with regnase-1-deficient CD4<sup>+</sup> T cells develop severe autoimmunity with the elevation of antinuclear antibody (Uehata et al., 2013).

## INDUCED MODELS OF SYSTEMIC AUTOIMMUNITY

Information has been acquired over many years from the study of models based on induction of autoimmunity, including immunoregulatory events that lead to the expression of clinical disease and proximal events associated with triggering of autoimmune disease.

### Pristane-Induced Lupus Model

The isoprenoid alkane pristane (2, 6, 10, and 14 tetramethylpentadecane) induces autoantibodies characteristic of SLE, including anti-Sm, anti-dsDNA, and antiribosomal P in BALB/c and SJL/J mice and CD1d deficiency exacerbates lupus nephritis induced by pristane (Satoh and Reeves, 1994). Pristane induces type I IFN production from Ly6C<sup>hi</sup> monocyte through TLR7 and myeloid differentiation factor 88 (MyD88) pathway and triggers autoantibody production (Lee et al., 2008). Also, IL-12 and IFN $\gamma$ , but not IL-4, are involved in the development of pristane-induced lupus, indicating that T-helper type 1 responses are dominant. For unexplained reasons, the *lpr* and *gld* mutations protect mice from the production of antibodies routinely induced by pristane. In addition to nephritis, hemorrhagic pulmonary capillaritis and arthritis have also been observed in pristane-treated mice (Chowdhary et al., 2007; Wooley et al., 1989). The arthritis symptoms in this model include synovial hyperplasia, perostitis, and progressive marginal erosions. Pristane-induced arthritis is TNF $\alpha$  mediated, as treatment with neutralizing anti-TNF $\alpha$  antibody ameliorates the arthritis symptoms (Beech and Thompson, 1997).

### Graft-Versus-Host Reaction–Induced Autoimmunity

Graft-versus-host-induced models of systemic autoimmunity involve the injection of parent cells into F1 offspring and clarified early events in the induction of autoimmunity. When lymphocytes from DBA mice are transferred into (B6 X DBA) F1 mice, donor CD4<sup>+</sup> cells are stimulated by recipient MHC class II cells, which presumably present a chromatin-associated nuclear antigen and produce initially IL-2 and later on IL-4 and IL-10, while the generation of CD8<sup>+</sup> CTL cells is silenced. These responses result in chronic GVHD with autoantibody and immune complex–mediated GN. When donor B6/H-2bm12 lymphocytes, whose MHC class II locus confers a three amino acid substitution in H-2<sup>b</sup>, are transferred into B6 hosts, there also is a development of chronic GVHD with autoantibodies and GN. This model works equally with opposite donor and recipient strains (Morris et al., 1990).

## Collagen-Induced Arthritis Model

Injection of allogeneic CII or certain peptides of this protein in complete or incomplete Freund's adjuvant into susceptible strains of rats or mice results in collagen-induced arthritis (CIA) resembling RA. Disease susceptibility is strongly linked to MHC class II molecules. H-2<sup>d</sup> mice are susceptible to CIA when immunized with bovine, chicken, and human CII, whereas H-2<sup>r</sup> mice are susceptible with bovine or porcine CII but not with chicken or human CII (Stuart et al., 1983; Watson et al., 1987). C57BL/6 (H-2<sup>b</sup>) mice are also susceptible but the incidence and severity are not severe. CD4<sup>+</sup> cells and various cytokines including IL-1 and TNF $\alpha$ , as well as antibody to CII, have been shown to participate in the expression of CIA (Rosloniec et al., 2010).

## Proteoglycan-Induced Arthritis Model

Immunization of BALB/c mice with partially deglycosylated human aggrecan induces chronic progressive polyarthritis and spondylitis (Glant et al., 2003). This proteoglycan (aggrecan)-induced arthritis (PGIA) resembles RA, as judged by observation, laboratory tests, radiography, and histopathology of the peripheral joints. The occurrence of PGIA depends on the development of cross-reactive T- and B-cell responses between the immunizing human and self (mouse) cartilage aggrecan. CIA and PGIA are two most commonly used RA models for QTL mapping for the identification of RA susceptibility loci.

## Collagen Antibody-Induced Arthritis Model

Collagen antibody-induced arthritis (CAIA) is induced by injection of specific monoclonal CII antibodies (Holmdahl et al., 1986). The model was developed based on the findings that serum from arthritic mice or RA patients could transfer arthritis to naïve mice (Wooley et al., 1984; Stuart and Dixon, 1983). CAIA resembles CIA but is more acute and has a rapid onset, a few days after injection. Normally, the disease heals after a month and mice remain healthy. CAIA is inducible independently of MHC and T- and B-cell interaction (Nandakumar et al., 2004).

## CONCLUSION

Animal models of systemic human autoimmune disease have served us well for understanding autoimmunity. Human systemic autoimmune diseases are highly heterogeneous both at the clinical and pathogenic level to the point that we do not serve the field properly by lumping them along antedated criteria-counting approaches. We have presented a critical review of the animal models which have been used to understand disease processes and perform preclinical trials of putative new drugs and biologics.

1. No animal model represents any systemic autoimmune disease.
2. Spontaneous models of disease can be used to obtain early insight on the consequences of lost tolerance in terms of organ damage.
3. Spontaneous models may serve preclinical testing of new rationally developed new drugs and biologics although their predictive clinical value has been rather disappointing.
4. Animals which develop systemic autoimmune disease after modulation of a specific molecule known to be important in the control of maintenance of tolerance or of the immune response may only serve to address specific mechanistic questions.
5. In the study of these animals, the concepts of autoimmunity and autoimmunity-associated organ damage should be carefully considered separately.
6. Construction of animals in which modulated molecules previously identified important in the aberrant function of SLE or RA immune cells may provide valuable information on the development of putative-specific new drugs.
7. These novel animals constructed with intelligence generated from the study of human cells should provide definitive information on the relative contribution of each aberrantly expressed molecule in the expression of human systemic autoimmune disease. The B6. CD2. PP2Ac mouse is such an example (Crispin et al., 2012).

## INTRODUCTION

Systemic lupus erythematosus (SLE) is systemic autoimmune disease causing significant morbidity and mortality worldwide, particularly in the women of child-bearing age. It is typically associated with antinuclear antibodies (ANA), in particular antidouble-stranded DNA (anti-dsDNA) antibodies, which form immune complexes and can cause multiorgan damage by activating various cell types in genetically susceptible individuals.

Due to the chronic and heterogenous nature of the condition, clinical trials of novel therapeutics or treatment strategies are challenging, with some newer drugs failing to meet their primary endpoint in trial. SLE manifestations are protean, with the treatment of lupus nephritis (LN) being a priority area for study given its association with end-stage renal failure (ESRF). SLE remains a disease with significant unmet need, but there is hope that the study of larger, well-characterized cohorts along with further genetic and experimental medicine studies, will lead to new treatments and improved patient outcomes.

## EPIDEMIOLOGY

Studies of the incidence and prevalence of SLE have been hampered by the lack of high-quality census data, population mobility, and also the diagnostic definition of SLE. As well as census data, countries such as the United Kingdom have disease registries that have also helped to clarify the incidence and prevalence of the disease. Incidence rates vary worldwide from just over 2 per 100,000 in Denmark (Hermansen et al., 2016) to 4 per 100,000 in the United Kingdom (Rees et al., 2016), 7 per 100,000 in the United States (Furst et al., 2013), and 8 per

100,000 in Taiwan (Chiu and Lai, 2010). Differences in incidence are due, at least in part, to genetics, but study design also has an impact on the data available. Recent systematic reviews of the incidence and prevalence of SLE worldwide (Rees et al., 2017) and the effect of ethnicity and genetic ancestry (Lewis and Jawad, 2017) further discuss these complicated issues.

A large recent study from the United Kingdom examined a primary care research database and showed an incidence of 4.9 per 100,000 person-years. The incidence was 5.8 times higher in females at all ages, with a peak onset of 40–49 years for females and 60–69 for males. Although the study was carried out in the United Kingdom, data linkage allowed the assessment of ethnicity, with Afro-Caribbeans having the highest incidence (31.46/100,000 person-years) compared to Caucasians (6.73/100,000 person-years) (Rees et al., 2016). This and other studies have demonstrated an increase in prevalence from the historical figures of 40 per 100,000 to almost 100 per 100,000: it is likely this is largely due to a true increase in disease prevalence, but better patient survival and increased case identification may also contribute.

Studies in the United States have confirmed the higher incidence and prevalence in African American patients with 186 per 100,000 females being affected by the disease compared to 87 per 100,000 Caucasian females (Somers et al., 2014). Furthermore, African American had an earlier disease onset and disease severity was increased, with 40% of the patients having renal disease and 15% ESRF compared to 19% and 5%, respectively, in Caucasian patients.

Hispanic and South Asian populations are also affected to higher degree compared to Caucasians and are more likely to progress to renal replacement therapy (Rees et al., 2016; Feldman et al., 2013). The same study, using the US Medicaid database, showed that Native American populations had a prevalence and incidence similar to Hispanic and Asian populations but lower than African Americans. The incidence of SLE in this study (23.2 per 100,000 person-years) was also higher than previous studies from the United States but may reflect the high-risk and poorer population covered by Medicaid.

A large study from Taiwan showed an incidence rate of 8.1 per 100,000 person-years (Chiu and Lai, 2010) which is higher than the general incidence rate from UK studies but lower than those from the United States. Earlier studies from Africa may have underestimated the rate of SLE (Tiffin et al., 2014), but the studies of African, South Asian and Caribbean migrants to the United Kingdom show higher rates of SLE compared to Caucasians (Johnson et al., 1995).

## PATHOGENESIS OF DISEASE

### Genetic and Associated Studies

SLE is a classical polygenic disease, with multiple genetic variants with small effect sizes contributing to disease risk, although monogenic causes are now increasingly recognized as the causing cases of SLE, particularly in younger patients. This section considers the contributions made by genetic studies in the understanding of disease pathways and ethnic differences and goes on to describe transcriptomic studies, including the interferon signature, in SLE.

There is an increased risk of SLE and other autoimmune diseases such as rheumatoid arthritis (RA) in the siblings of patients with SLE (Alarcón-Segovia et al., 2005). A high sibling recurrence ratio ( $\lambda_s$ ) of 29 was observed in SLE compared to, for example, 5 in RA, and a polygenic additive model was thought to be most suitable for SLE (Alarcón-Segovia et al., 2005). Early twin studies suggest a monozygous concordance rate of up to 69% but were likely subject to overreporting bias, as subsequent twin-registry studies demonstrated 25% of monozygotic twins and 2% of dizygotic twins were disease concordant (Deapen et al., 1992). A large study of all national health insurance records in Taiwan suggested a heritability of over 40% for SLE by comparing relative risk of SLE in twins, first-degree relatives, and spouses without genetic similarity (Kuo et al., 2015).

Deficiencies in early complement proteins from the classical pathway, such as C1q and C4, have been linked to pediatric SLE (as well as predisposing to infection). However, these mutations are rare, and the mutation does not have complete penetrance, indicating that a combination of genetic and/or environmental factors is required. Mutations in TREX1, a DNA exonuclease, have also been associated with lupus, with the accumulation of intracellular single-stranded DNA and subsequent Toll-like receptor (TLR)-driven secretion of interferon as a postulated mechanism (Lee-Kirsch et al., 2007; Stetson et al., 2008). In addition, genes in pathways implicated in type I

interferon production, nucleic acid sensing, clearance of self-antigen, apoptosis, and tolerance are causes of monogenic lupus and have been recently reviewed (Lo, 2016).

Early linkage disequilibrium studies showed that various regions of the genome associated with risk of SLE and other autoimmune diseases, with the MHC and STAT4 being implicated early (Remmers et al., 2007). The first genome-wide association studies (GWAS) included predominantly European cases, and controls confirmed the findings of early linkage studies and added substantially to them. The regions and genes associated with SLE included HLA-DRB1, IRF5, STAT4, FCGR2A, and PTPN22 [International Consortium for Systemic Lupus Erythematosus Genetics (SLEGEN) et al., 2008]. Association of variants at loci containing BLK, ITGAM-ITGAX, and BANK1 genes implicated B cells in the pathogenesis of SLE (Hom et al., 2008; Kozyrev et al., 2008). Currently, 62 loci have strong evidence of genetic association with SLE, with recent estimates suggesting these explain around 27% of the heritability of SLE (Morris et al., 2016).

Studies in Han Chinese populations and populations of mixed Asian ancestry replicated findings from original GWAS and further identified loci containing ETS1, WDFY1, IKZF1, and others which may be specific to this ethnic group (Han et al., 2009; Yang et al., 2010). Ethnic differences in SLE incidence and severity may therefore be driven by genetic differences, and balancing selection may provide an evolutionary explanation for some of these. Genetic variants that reduce the expression or function of Fc $\gamma$ RIIb, an inhibitory Fc receptor, predispose to SLE in mice and humans (Niederer et al., 2010). Interestingly, they also protect against malaria, consistent with the increased frequency of the main SLE-associated FCGR2B variant in African and Asian populations (Willcocks et al., 2010).

## Transcriptional Analysis in Systemic Lupus Erythematosus

Transcriptomic studies of whole blood or cell subsets from patients with SLE have given insight into mechanisms of disease or prognostic factors. Comparison of the transcriptomes of peripheral blood mononuclear cells (PBMCs) from patients with pediatric SLE, juvenile arthritis, and healthy controls found that genes that were differentially regulated in SLE were overrepresented in the interferon (IFN) pathways, and that this “interferon signature” correlated with disease activity (Bennett et al., 2003). A subsequent study confirmed the existence of an interferon signature, and divided patients with SLE into “interferon-high” and “interferon-low” groups, with the “interferon-high” group having more severe and active disease (Baechler et al., 2003). These studies thus emphasized a role for type I interferons in SLE and suggested they could be therapeutic targets (see Other agents and Treatment Options).

Transcriptional studies of purified cell subsets can overcome the “noise” caused by the variable cellular contents of PBMC between individuals. One such study found signature in purified CD8 T cells that correlated with time to flare in SLE, anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV), and inflammatory bowel disease, and was associated with CD8 T-cell exhaustion (McKinney et al., 2015, 2010). This could be of practical value if predicting a poor course could allow preemptive intensive therapy, and demonstrates the benefits of studying cell subsets, something now taken to a higher level with single-cell transcriptomic analysis.

## Autoantibodies in Systemic Lupus Erythematosus

Over 100 autoantibodies (Sherer et al., 2004) have been described in patients with SLE and include ANA, described further below, as well as antibodies targeting blood cells (e.g., antiplatelet), endothelial cells, and antigens in the nervous system to name a few. Development of autoantibodies predates disease onset (Arbuckle et al., 2003), and some may drive disease features such as fetal transfer of anti-Ro antibodies resulting in congenital heart block.

ANA are a diverse group of autoantibodies that are categorized according to their antigenic targets: DNA and DNA-binding proteins and histones; RNA and RNA-associated proteins; as well as autoantibodies associated with phospholipids and cell membrane proteins. Certain ANA are strongly associated with particular autoimmune rheumatic diseases: antitopoisomerase I with progressive systemic sclerosis, anticentromere with the limited cutaneous form of systemic sclerosis, and anti-Jo1 with myositis, although many more autoantibodies have been discovered in the latter disease.

Almost every patient with SLE is positive for ANA, which may also include specific antibodies associated with organ involvement (see the following table). Anti-dsDNA and anti-Sm are the most specific for SLE, anti-C1q is associated with aggressive LN, and anti-Ro, when present during pregnancy, can lead to congenital heart block and neonatal lupus.

ANA	Clinical association
Anti-dsDNA, anti-Sm, anti-C1q	Lupus nephritis
Anti-Ro	Neonatal lupus, congenital heart block, subacute cutaneous lupus
Anti-Ro and anti-La	Secondary Sjögren's syndrome and sicca symptoms
Anti-RNP	
Anti-P	Neuropsychiatric manifestations
Anti-β2-glycoprotein 1	Antiphospholipid syndrome

ANA, Antinuclear antibodies; anti-dsDNA, antidualle-stranded DNA; RNP, ribonucleoprotein.

Anti-dsDNA antibodies are the most widely assayed autoantibody in SLE and are more specific for SLE than ANA. DNA can be released from dead and dying cells by three main methods: apoptosis (an active process resulting in apoptotic bodies and microparticles containing DNA), necrosis, and via the development of “neutrophil extracellular traps”—so-called NETosis (Brinkmann et al., 2004).

Free DNA and dsDNA antibodies combine to form antigen–antibody complexes, which are deposited in sites such as the skin and kidney to nonspecifically activate the immune system and cause tissue damage via antibody dependent cellular cytotoxicity and complement activation. DNA-containing immune-complexes can also activate immune cells by signaling through surface and endosomal TLRs.

ANA can be measured with a variety of assays; however due to the wide variety of targets, not every autoantibody is detected during screening and specific autoantibody testing may be needed if clinical suspicion of a particular manifestation is high. ANA was originally measured using the “gold standard” indirect immunofluorescence assay (IIFA) first described in the 1950s (Coons and Kaplan, 1950). This assay involves serial dilutions of sera and a determination of the staining pattern on Hep-2 cells. The reproducibility and interpretation of this time-consuming assay can be variable, and so higher throughput standardized assays such as enzyme-linked immunosorbent assays (ELISA) or chemiluminescence assays have been employed to improve consistency between laboratories worldwide. Using the IIFA method, with increasing age up to 13% of the healthy population can develop a positive ANA (Mariz et al., 2011). In individuals with autoimmune diseases, however, the ANA titer is higher with a nuclear homogenous, nuclear coarse speckled, nuclear centromeric, or nuclear fine-speckled pattern occurring. Healthy individuals could also exhibit a nuclear fine-speckled pattern, but at a lower titer, whilst a nuclear dense fine-speckled pattern only occurred in healthy individuals (Mariz et al., 2011).

The IIFA method using HEp-2 or Hep-2000 cells has been recognized as the gold standard for ANA screening (Agmon-Levin et al., 2014). Thereafter anti-dsDNA antibodies should be measured in a consistent manner using an ELISA, Farr method or *Crithidia luciliae* immunofluorescence test. ELISA-based methods allow standardization and quantitative monitoring during disease course and treatment. The *C. luciliae* assay or Farr assay offer the best specificity at the time of diagnosis, although these are rarely done now as both assays are time consuming and the latter requires the use of radioactive material.

Antibodies to extractable nuclear antigens, such as those that bind RNA and RNA-binding proteins, can also be present in SLE, but are also seen in other autoimmune diseases. Anti-Ro and Anti-La antibodies are associated with Sjögren's syndrome and anti-Ro is associated with congenital heart block and neonatal lupus. Anti-RNP antibodies bind to complexes of RNA with small nuclear ribonucleoproteins, but are not specific for SLE as they are also present in mixed connective tissue disease.

ANA testing remains a hallmark in the diagnosis and management of SLE, but their frequent occurrence in the healthy population precludes their use as a screening test. Certain ANA are associated with organ-specific manifestations of disease, but whether these define genetically distinct disease subsets [as has been shown in RA (Padyukov et al., 2011) and ANCA associated vasculitis (Lyons et al., 2012)] or can be used to stratify management remains to be determined.

## Cellular Players in Systemic Lupus Erythematosus

The adaptive immune system is clearly implicated in the pathogenesis of SLE given the central role of autoreactive B and T cells (Moulton et al., 2017). However, dysregulation of the innate immune system is also

critical. A complete review of the cellular pathogenesis of SLE is outside the scope of this chapter, which will concentrate only on well-described cell types, while accepting that many others (including, e.g., innate lymphoid cells, natural killer (NK) and stromal cells, and tissue resident lymphocytes) are also likely to be involved in pathogenesis.

The break of tolerance to self in SLE occurs many years before clinical presentation. Studies using serum repositories from armed forces personnel in the United States have shown that ANA are usually present up to a decade before clinical manifestations, and that anti-dsDNA antibodies are present on average 2.2 years before diagnosis (Arbuckle et al., 2003). However, a retrospective review of medical records also show that clinical features are present before diagnosis, and symptoms such as arthritis and seizures can precede diagnosis by almost 2 years (Heinlen et al., 2007). Nevertheless, as with other autoimmune diseases such as RA and type 1 diabetes, autoantibodies are present before the onset of clinical disease.

### **Adaptive Immunity**

#### **B CELLS**

SLE is characterized by autoantibody production, and SLE-associated genetic variants occur in genes, such as BLK, BANK1, and ITGAM, together implicating B cells in disease pathogenesis. B-cell tolerance is maintained at a series of central and peripheral “checkpoints,” at which autoreactive B cells are deleted or functionally silenced through a process termed anergy (Goodnow, 2007). Defects in central tolerance, anergy, and peripheral (germinal center) tolerance have all been implicated in predisposing to SLE (Malkiel et al., 2016; Yurasov et al., 2005), and B-cell survival factors such as the B-lymphocyte stimulator (BlyS) are elevated in patients with SLE (Petri et al., 2008) which might contribute to persistence of autoreactive B cells.

B cells contribute to disease by producing autoantibodies but may also play a role in antigen presentation to autoreactive T cells. In addition, populations of CD27-negative memory B cells are expanded in patients with SLE (but not in RA or chronic hepatitis C), although their role in pathogenesis is not clear (Wei et al., 2007). “Regulatory” B cells, which can suppress Th1 responses via IL-10, appear impaired in SLE (Blair et al., 2010). These findings suggest that, in addition to producing autoantibodies, B cells may also predispose to SLE by contributing to immune dysregulation more generally.

#### **T CELLS**

T cells are important in the pathogenesis of SLE. Their roles are diverse and include B-cell help via CD4 T helper cells, in particular T follicular helper (Tfh) cells, cellular cytotoxicity via CD8 T cells and roles for T regulatory cells and Th17 cells. Only a few key features will be highlighted here.

CD4 T cells can drive B cell differentiation more efficiently than IL21, B cell activating factors or TLR ligands. Upon activation, CD4 T cells from patients with SLE persistently express CD40 ligand resulting in more B cell activation and differentiation. Recently, a subset of CD4 T cells, the Tfh cell, which is found in the follicular zone of lymphoid organs, has been shown to drive B-cell maturation and class-switched antibody production by secreting IL-21. Tfh cells, and others that secrete IL-21, have been associated with the formation of extrafollicular germinal centers in organs inflamed by SLE, such as kidney.

Tfh cells express the chemokine receptor CXCR5 and PD1 and are found at increased frequency in the lymph nodes of patients with SLE, as are Tfh-like cells in the blood (Choi et al., 2015). In SLE patients CD4 helper T cells have a defect in IL-2 production, which may reduce the effectiveness of regulatory T cells in controlling inflammation (Lieberman and Tsokos, 2010). Consistent with this, low-dose IL-2 therapy increased regulatory T-cell numbers and improved disease activity in a proof of concept study in humans (He et al., 2016). CD8 T cells have been indirectly implicated in SLE, as their exhaustion is associated with an improved prognosis (McKinney et al., 2015). An increase in the number of Th17 cells, and in IL-17 levels, has been observed in patients with SLE. Consistent with these cells playing a role, ustekinumab, an IL-12/23 blocker which interrupts signaling upstream of IL-17, has shown some efficacy in the treatment of SLE (van Vollenhoven et al., 2017a).

### **Innate Immunity**

#### **DENDRITIC CELLS**

Dendritic cells are “professional” antigen presenting cells and also help prime lymphocytes and other immune cells. Two major subtypes exist: myeloid and plasmacytoid dendritic cells (mDC and pDC), with both thought to have roles in the pathogenesis and perpetuation of disease in SLE.

In particular, pDCs have an important role in the production of type I interferons. Immune complexes can activate pDCs via TLRs, and this leads to the production of IFN $\alpha$  and other proinflammatory cytokines (Blanco et al., 2008). pDCs have been shown to accumulate in the end organs where damage occurs, such as the kidney, and play a role in orchestrating tissue damage (Tucci et al., 2008). IFN $\alpha$  activity is elevated prior to the diagnosis of SLE, and both type I and II IFNs appear to play poorly defined roles in the initiation and perpetuation of disease (Munroe et al., 2016). Type I IFNs are implicated in the wider pathogenesis of SLE, activating neutrophils, promoting mDC differentiation and increasing B-cell responsiveness. Type I IFN may also be important for the malaise and intractable fatigue prominent in SLE. Type I IFN has been targeted clinical by agents such as sifalimumab (Khamashtha et al., 2016) and rontalizumab (Kalunian et al., 2016) with promising but inconclusive results, and further trials are underway, many using variants on the IFN transcriptomic signature described above as a biomarker.

### **Neutrophils and Extracellular Traps**

Neutrophils are first-line cells in host protection against bacteria and are activated by complement and cytokines to phagocytose pathogens. Neutrophils can undergo a particular type of cell death called NETosis, where their cellular contents including DNA form networks of fibers (Brinkmann et al., 2004) that in health trap bacteria but in autoimmunity might lead to prolonged presentation of self-antigen (Kessenbrock et al., 2009). Neutrophils also carry a toxic payload of lytic enzymes and which could exacerbate tissue damage.

### **Animal Models of Systemic Lupus Erythematosus**

Although animal models do not fully recapitulate human disease, they are useful in exploring mechanisms of disease in a controlled system. Mouse models, in particular the New Zealand Black (NZB)/New Zealand White (NZW) and Murphy Roths Large (MRL)/*lpr*, have been invaluable to our early understanding of SLE, as they share similar histopathological features and syntenic genetic susceptibility loci to human disease.

The first generation of a cross between NZB and NZW, known as NZB/NZW F1, develop a lupus-like illness (Andrews et al., 1978). Female mice are more often affected and they develop lymphadenopathy and splenomegaly as well as ANA. In addition, these mice develop a glomerulonephritis that is immune complex-mediated and so have been used as a model of chronic SLE. Further congenic crosses resulted in the New Zealand mixed (NZM) strains each of which has slight differences in pathology (Rudofsky et al., 1993). The NZM2410 strain showed particularly severe pathology. Three congenic lines were generated through backcrossing onto a C57BL/6 background: B6.Sle1 (Mohan et al., 1998), B6.Sle2 (Mohan et al., 1997; Morel et al., 2000), and B6.Sle3 (Nguyen et al., 2002). These contained genetic loci that are syntenic to those implicated in human SLE, including the major histocompatibility complex (MHC) region, Fc receptor, and signalling lymphocyte activation molecule (SLAM) family loci to name but a few. Each had subtle immune abnormalities, but when intercrossed developed SLE, demonstrating how genetic variants combine to cause polygenic disease.

The MRL strain was developed in Japan and developed chronic autoimmune and vasculitis features, and a substrain derived from it—the MRL/*lpr*—developed SLE-like disease more rapidly, along with glomerulonephritis, prominent lymphadenopathy, and abnormal T-cell accumulation. The *lpr* variant was found to be due to disruption of the *Fas* gene resulting in reduced T-cell apoptosis (Adachi et al., 1993). Disease in the BXSB mouse is accelerated in the BXSB-Yaa strain, with more aggressive disease in males, as *Yaa* is a translocation of the X chromosome region containing TLR7 on to the Y chromosome (Murphy and Roths, 1979; Maibaum et al., 2000), effectively doubling the dose of this and neighboring genes in males (Santiago-Raber et al., 2008).

## **DISEASE FEATURES**

Precise disease delineation in SLE is difficult because the variety of clinical manifestations and disease subsets can be poorly defined or indeed cryptic. The Systemic Lupus International Collaborating Clinics (SLICC) 2012 criteria are the latest published for the classification of SLE (Petri et al., 2012). These improved on the American College of Rheumatology (ACR) 1982 and 1997 criteria (Tan et al., 1982; Hochberg, 1997) by, for example, allowing a diagnosis of SLE with biopsy proven LN with either positive ANA or dsDNA antibodies. Furthermore,

they were found to be more sensitive than the 1997 ACR criteria and were shown to be useful in clinical practice rather than solely in the realm of clinical trials ([Inês et al., 2015](#)). Although at least four criteria are needed for

**SLICC Classification Criteria for Systemic Lupus Erythematosus 2012**

≥ 4 Criteria are required (at least one from clinical and one immunologic) or biopsy proven lupus nephritis with either ANA positive or anti-dsDNA antibodies

Clinical	Immunologic
Acute cutaneous lupus	ANA
Chronic cutaneous lupus	Anti-dsDNA
Oral or nasal ulcers	Anti-Sm
Nonscarring alopecia	Antiphospholipid antibodies
Arthritis	Low complement
Serositis	Direct Coombs' test positive (but not in the presence of hemolytic anemia)
Renal	
Neurologic	
Hemolytic anemia	
Leucopenia	
Thrombocytopenia	

ANA, Antinuclear antibodies.

the diagnosis of SLE, in the early stages of disease these may not be present. If SLE is suspected but insufficient features are present for a formal diagnosis, a forme fruste diagnosis of “incomplete lupus” can be used ([Ugarte-Gil and Alarcón, 2016](#)). Drug-induced SLE can be caused by hydralazine, sulfasalazine, and TNF $\alpha$  inhibitors, etc., and needs careful assessment as both immunologic and clinical features can evolve even once the medication has been stopped.

Constitutional symptoms such as fever, weight loss, and fatigue may precede clinical diagnosis and can be associated with a wide differential diagnosis, which can delay diagnosis and treatment initiation. Furthermore, these symptoms can be some of the most troubling and intractable for patients and have a bearing on the psychosocial wellbeing of the patient and their family and carers.

SLE, Systemic lupus erythematosus.

## Cutaneous and Mucosal Disease

Acute malar rash is a classical feature of lupus and may be photosensitive. Other forms of SLE-associated rash include bullous lupus, epidermal necrolysis, and a maculopapular lupus rash. Subacute lupus rashes may require input from dermatologists as they can be psoriaform and occasionally be associated with depigmentation and telangiectasia.

Chronic forms include, but are not limited to, a discoid rash, lupus panniculitis, and chilblain lupus. Mucosal surfaces can be involved with oral ulcers of the tongue, palate, and buccal area. Nasal ulceration is also a feature although infectious causes should be ruled out. Both hair loss and fragile hair can occur but reversible causes

such as iron deficiency should be excluded. SLE can be diagnosed on the basis of three forms of mucocutaneous disease and a positive ANA, and therefore a careful examination of the skin and mucus membranes must always be carried out.

### **Musculoskeletal Manifestations**

Synovitis of at least two joints or tenderness of at least two joints with early morning stiffness is part of the SLICC SLE arthritis criteria. Jaccoud's arthropathy of SLE occurs in 5%–10% of patients, and while it is not erosive it can have some clinical features in keeping with RA, such as ulnar deviation and swan-neck deformities. These deformities are due to ligamentous laxity, although in some patients an overlap syndrome can be present where they also have rheumatoid factor and antibodies against citrullinated peptides. Synovitis and radiographic erosion can be present in these circumstances, necessitating consideration as a more inflammatory arthritis in these cases.

Although not an autoimmune manifestation of disease, avascular necrosis can be a complication of steroid therapy. Commonly affected sites are the hip and tibial plateau, and the investigation of choice is MRI to detect early change when radiographs may be normal. Management of avascular necrosis in younger patients is challenging, and efforts are made to delay joint replacement surgery with conservative management where possible.

Myositis is an uncommon manifestation of SLE, but myalgia is more widespread and may also be related to medication such as statins that are used to manage comorbidities. Elevated creatine kinase levels raise the possibility of myositis, and muscle tissue biopsy can help to rule out other conditions. Long-term steroid use causes steroid-related myopathy that can be disabling and affect quality of life.

### **Cardiac**

Pericarditis and pericardial effusion are the commonest cardiac manifestations of SLE. Myocardial and endocardial inflammation, such as Libman–Sacks endocarditis, can also occur. Comorbidities are common, in the form of ischemic heart disease and infective endocarditis in patients who are on high-dose and long-term corticosteroids. SLE patients are at risk for accelerated cardiovascular disease and have a higher rate of arterial and venous thromboembolic events compared to the healthy population (Mok et al., 2005).

### **Vascular**

Secondary Raynaud's phenomenon occurs in 20% of patients with SLE and may need management with nifedipine or iloprost. In the case of digital ulceration, sildenafil and bosentan may be indicated. Antiphospholipid antibody positivity can be determined by measuring lupus anticoagulant, medium-to-high titer of IgA, IgG, or IgM antiphospholipid antibody or positive IgA, IgG, or IgM anti- $\beta_2$  glycoprotein antibody. Catastrophic antiphospholipid syndrome can result in devastating thrombosis and can be associated with recurrent miscarriage.

### **Pulmonary**

Exudative pleural effusions can occur during disease flare and may need drainage. Pleuritis can be challenging to manage and the possibility of pulmonary embolism should be considered in the differential diagnosis. D-Dimers may be nonspecifically raised in inflammation and therefore may not be helpful.

### **Renal**

The International Society for Nephrology/Renal Pathology Society (ISN/RPS) 2003 classification for LN (Weening et al., 2004) superseded the World Health Organization 1995 classification. LN is a presenting feature in up to 35% of patients with SLE, and although overall SLE survival is 92% at 10 years, this is reduced to 88% at 10 years in the presence of LN. Survival is poorer for African Americans, Hispanics, and Asians, and despite treatment, 10%–20% of patients with LN will progress to ESRF (Group KDIGO/KW, 2012; Bertasias et al., 2012; Hahn et al., 2012).

Indications for biopsy include an unexplained fall in renal function, proteinuria ( $\geq 0.5 \text{ g}/24 \text{ h}$  or 3+ on urine dipstick) and active urinary sediment or hematuria, although there is no international consensus (Wilhelms et al., 2016). Biopsies are then classified according to the ISN/RPS criteria and treatment initiated according to diagnostic class. Treatment should not be delayed if renal biopsy is not readily available, and in patients with refractory disease, repeat biopsy should be considered.

**International Society of Nephrology/Renal Pathology Society 2003 classification of LN**

Class	Description with subtypes	Histological changes
Class I	Minimal mesangial LN	Normal on LM. Mesangial immune deposits by EM or IF
Class II	Mesangial proliferative LN	Mesangial hypercellularity or mesangial matrix expansion with mesangial immune deposits. Isolated subepithelial or subendothelial deposits by EM or IF
Class III	Focal LN (<50% of glomeruli) III (A): active lesions III (A/C): active and chronic lesions III (C): chronic lesions	Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis, with or without mesangial alterations. Focal subendothelial immune deposits by EM or IF
Class IV	Diffuse LN ( $\geq 50\%$ glomeruli) Diffuse segmental (IV-S) or global (IV-G) LN IV (A): active lesions IV (A/C): active and chronic lesions IV (C): chronic lesions	Active or inactive diffuse, segmental, or global endocapillary or extracapillary glomerulonephritis, with or without mesangial alterations. Diffuse subendothelial immune deposits by EM or IF
Class V	Membranous LN (can occur in combination with class III or IV)	Global or segmental subepithelial immune deposits (EM or IF) or morphological sequelae by LM with or without mesangial alterations
Class VI	Advanced sclerosing LN ( $\geq 90\%$ globally sclerosed glomeruli without residual activity)	Globally sclerosed glomeruli

EM, Electron microscopy; IF, immunofluorescence; LM, light microscopy; LN, lupus nephritis.

In general, classes I and II disease do not require immunosuppression, although some guidelines suggest that proteinuria in the context of class II disease should be treated with immunosuppressants. Patients with class III or IV disease require aggressive immunosuppression, and regimes using glucocorticoids, cyclophosphamide, and other immunosuppressants, including that biologics are discussed in the treatment section. Class V disease in the presence of class III or IV disease should also be treated with aggressive immunosuppression, although there is inconsistency in guidance for the treatment of class V disease alone. Class VI disease is not treated with immunosuppression, in general, although it may be required in the presence of extrarenal manifestations, and preparation should be made for renal replacement therapy.

Patients with active LN should be monitored regularly and have their body weight, blood pressure, serum creatinine, proteinuria, complement levels, and anti-dsDNA antibody levels measured. In addition, management of comorbidities should include blood pressure control ( $< 130/80$  mmHg), treatment of hyperlipidemia with statins, and management of proteinuria with renin–angiotensin–aldosterone system inhibition.

The ISN/RPS classification does not take account of tubulointerstitial lesions, although they have been shown to have prognostic value independent of glomerular lesions. Vascular lesions such as immune complex deposition, lupus vasculopathy, thrombotic microangiopathy (TMA), and overt vasculitis are not taken account of in the ISN/RPS criteria. TMA can occur in thrombotic thrombocytopenia, and some guidelines advise to treat it with plasma exchange. Anticoagulation may be needed in the context of significant proteinuria ( $> 3$  g/24 h) or in antiphospholipid antibody–associated nephropathy.

### **Neuropsychiatric**

Neuropsychiatric lupus is a difficult syndrome to diagnose and manage and the prevalence of the condition is unclear. Neurological manifestations of SLE can range from seizures through cranial nerve palsies and peripheral neuropathies to acute confusional states and psychosis. A standardized nomenclature exists for neuropsychiatric SLE (Kozora et al., 2004), but a major unmet need is the lack of specific biomarkers to differentiate neuropsychiatric lupus from its differentials.

## Hematologic

Hemolytic anemia, leucopenia, and thrombocytopenia all occur as features of SLE and can be difficult to manage in the context of treatments such as cyclophosphamide or other disease modifying drugs, many of which can cause bone marrow suppression.

# THERAPEUTICS IN SYSTEMIC LUPUS ERYTHEMATOSUS

## Measurement of Disease Activity

Measuring disease activity in a multisystemic disorder such as SLE is particularly challenging but is necessary to measure treatment responses both in routine clinical care and in the context of research trials and longitudinal studies. In addition to the time taken to fill out these measures by patients and clinical staff, there is often a significant administrative burden of calculating scores, especially for more extensive measures such as BILAG (British Isles Lupus Assessment Group) 2004 (Isenberg et al., 2005).

The BILAG score assesses nine systems and requires a degree of training in order to administer it efficiently. The test itself can take up to 20 minutes depending on the complexity of disease, but the administrative time taken to record the data can be up to double that. The SLEDAI-2K (Gladman et al., 2002) instrument assesses nine systems but uses a simple point-based additive scale, and so is faster to administer. Both the BILAG and SLEDAI-2K can be used to quantify severity of disease flares and so have clinical utility and can help direct therapeutic escalation decisions. Alongside the score based methods, ESR and C-reactive protein (CRP) should be measured and if both are elevated, the possibility of concomitant infection should be considered. Rising antibodies to ds-DNA and falling levels of C3 and C4 may herald an imminent lupus flare, especially if there is a change from baseline (Fernando and Isenberg, 2005).

Prediction of SLE flares to allow preemptive treatment has proven difficult. In a large post hoc analysis of the belimumab trials, rising dsDNA antibody levels, proteinuria, CRP, and BlyS levels predicted flare (Petri et al., 2013), but studies from the Hopkins lupus cohort showed that decreased dsDNA antibody levels and decreased complement levels were most common around the time of flare (Ho et al., 2001a,b; Petri et al., 2009) and earlier studies from the BILAG group showed similar results (Symmons et al., 1988). Others have found no association with dsDNA antibody or complement levels but did find an association with baseline ESR, anemia, lymphopenia, and ANA titer (Mirzayan et al., 2000). Predicting flare in SLE based on clinical or simple antibody parameters thus leads to conflicting conclusions, and a biomarker predicting flares remains a significant unmet need for patients.

Cumulative damage can be captured using the SDI (SLICC/American College of Rheumatology Damage Index) (Gladman et al., 1996). This tool assesses 12 organ systems and is generally only used in “steady states” of disease. At diagnosis each patient has a score of 0 and subsequent accumulation of damage is a predictor of mortality (Rahman et al., 2001). As with other measures, the length of time to complete the assessment is increased in complex patients with multiorgan involvement.

Disease subsets in SLE are likely to exist, although there is no consensus on classification. Common “phenotypes” include clinically active but serologically quiescent disease (Gladman et al., 2003); serologically active but clinically quiescent disease (Steiman et al., 2010); and serologically quiescent, clinically quiescent disease (Steiman et al., 2012). These phenotypes may overlap during the course of disease in a patient and show that we need validated biomarkers to help characterize disease pathology and prognosis in a particular patient, at a particular time.

“Treating to target” refers to treating until a predetermined disease activity state has been achieved, rather than for a fixed treatment “course,” and has been an effective strategy in diseases such as hypertension, diabetes, and RA. Consensus statements from expert groups have established the principles of treating to target in SLE (van Vollenhoven et al., 2014) and have stated that the aim for each patient should be to treat to remission. In 2016 a consensus definition was established for a lupus low disease activity state (LLDAS) (Franklyn et al., 2016). Essentially this state required five components: a SLEDAI-2K  $\leq 4$ , a SLEDAI physician global assessment of  $\leq 1$  (scale 0–3), no new lupus disease activity compared to the last assessment, a prednisolone dose  $\leq 7.5$  mg daily, and well-tolerated biologic or immunosuppressive agents. Those who achieved more than 50% of their time in LLDAS had reduced organ damage compared to those who did not. However, LLDAS is not equal to remission and therefore international frameworks have been developed to help define and validate an accepted definition of remission in SLE (van Vollenhoven et al., 2017b).

### **Management of Comorbidities**

In addition to managing the direct manifestations of SLE, reduced disease activity and also treatment side effects can lead to significant comorbidity. Premature atherosclerosis results in increased cardiovascular disease. In addition, the metabolic syndrome is more prevalent in patients with SLE compared to matched controls. Osteoporosis can be induced by glucocorticoids, and therefore monitoring of bone mineral density and of vitamin D levels is required in patients who are at high risk. Immunosuppression carries risks that include infection and malignancy, and some drugs can cause infertility (e.g., cyclophosphamide) or are teratogenic (e.g., mycophenolate).

### **Disease Modifying Drugs**

#### ***Hydroxychloroquine***

Antimalarial medication such as hydroxychloroquine (HCQ) and chloroquine are anchor drugs in the treatment of SLE during the acute and quiescent phase. HCQ is used in both discoid lupus and SLE, and has been associated with renal remission in patients who are treated with mycophenolate mofetil (MMF) for membranous LN ([Kasitanon et al., 2006](#)). Furthermore, a randomized trial of withdrawal of HCQ by [Canadian Hydroxychloroquine Study Group \(1991\)](#) showed that patients who are taking HCQ and have stable SLE are at a 2.5 times lower risk of having a disease flare.

HCQ has also been shown to be protective against thrombosis in a cohort study of SLE patients from Spain and also demonstrated a survival benefit in those taking the drug ([Ruiz-Irastorza et al., 2006](#)). A further study using a multiethnic cohort from the United States demonstrated a survival benefit but also took account of a propensity score, which aims to control for the fact that patients taking HCQ often had milder disease and higher socioeconomic status ([Alarcón et al., 2007](#)).

Optimizing drug levels of HCQ does not appear to confer added benefit, although this area requires further investigation ([Costedoat-Chalumeau et al., 2013](#)). Systematic reviews of the literature have also shown that toxicity is infrequent and the drug is relatively safe in pregnancy-controlling disease activity without seemingly having an effect on the new-born ([Ruiz-Irastorza et al., 2010](#)). Recent guidelines regarding retinal toxicity suggest a maximum daily HCQ dose of  $\leq 5.0$  mg/kg real weight with the risk of toxicity up to 5 years being  $<1\%$  and up to 10 years being  $<2\%$ . Risk factors for toxicity include higher dose, longer duration of use, preexisting renal or retinal disease, and the use of tamoxifen ([Marmor et al., 2016](#)). These guidelines recommend baseline fundoscopy to rule out preexisting maculopathy and then to commence annual screening after 5 years of drug treatment; sooner if major risk factors are present.

#### ***Azathioprine***

Azathioprine has commonly been used as a steroid-sparing agent, especially in the context of lupus with renal involvement. The BILAG multicenter trial comparing cyclosporin and azathioprine showed that there was no difference between the two agents with regard to either steroid reduction from baseline or disease flares during the course of the trial ([Griffiths et al., 2010](#)). Azathioprine has been used as a maintenance therapy following high-dose steroid and cyclophosphamide induction therapy for LN. However, the ALMS trial showed that mycophenolate was superior to azathioprine in preventing disease relapses and in maintaining a renal response ([Dooley et al., 2011](#)).

Although mycophenolate was shown to be superior to azathioprine, it is contraindicated during pregnancy whereas azathioprine has been shown to be relatively safe. Switching mycophenolate to azathioprine in pregnant patients, with quiescent LN, rarely led to renal flares ([Fischer-Betz et al., 2013](#)). Azathioprine is also well tolerated and leucocytopenias are an uncommon reason for cessation of therapy. Adequate dosage of azathioprine is a contentious issue, with not all services measuring thiopurine methyltransferase levels. Measurement of azathioprine metabolites may help to determine whether patients fail because of true disease resistance or inadequate dosage and therefore undertreatment ([Croyle et al., 2015](#)). Therefore in particular circumstances, such as during pregnancy or in mycophenolate intolerance, there is still a role for azathioprine in the treatment of SLE.

#### ***Mycophenolate***

MMF has been used for over a decade in the treatment of LN and was originally used in patients who were resistant to other therapies ([Karim et al., 2002](#)). Subsequent trials have demonstrated that MMF can, at least in some circumstances, be of comparable efficacy to intravenous cyclophosphamide when used as induction therapy

in LN (Appel et al., 2009; Ginzler et al., 2005). Furthermore, a Cochrane review of treatment for LN analyzed 50 clinical trials in LN and concluded that mycophenolate was as effective as cyclophosphamide and was also associated with less alopecia and ovarian failure (Henderson et al., 2012).

MMF is also more effective as a maintenance therapy for LN compared to azathioprine, although it is contraindicated in pregnancy (Dooley et al., 2011). In addition to treating renal manifestations, it has also been shown to be effective at controlling extrarenal disease in SLE (Ginzler et al., 2010). Enteric-coated mycophenolate sodium has a better gastrointestinal tolerability profile, with a recent trial showing that it is more effective than azathioprine at treating SLE and preventing relapses as measured by the SLEDAI-2K and BILAG scoring system (Ordi-Ros et al., 2017).

### **Calcineurin Inhibitors**

Although cyclosporin A and tacrolimus have been used in solid organ transplant for many years, their role in SLE treatment has been less clear. Calcineurin inhibitor-related side effects such as hypertension, gingival hyperplasia, and hirsutism occur less with tacrolimus than with cyclosporin. A trial of tacrolimus versus MMF as induction therapy in LN showed no difference between the two agents (Mok et al., 2016). These treatments can be useful when mycophenolate, azathioprine, or cyclophosphamide cause significant leucopenia or other toxicity.

Drug monitoring of calcineurin inhibitors often makes their use in clinical practice more complicated than mycophenolate, although newer agents such as voclosporin have a higher therapeutic window. Pilot trials of voclosporin and mycophenolate as a combination therapy in LN have suggested greater efficacy (Dooley et al., 2016) but also more serious adverse events, and larger trials of voclosporin are underway in lupus. Topical tacrolimus can also be used to treat discoid lupus and cutaneous manifestations of lupus (Wang et al., 2015).

### **Intravenous Steroids and Cyclophosphamide**

Cyclophosphamide has been a mainstay of treatment in acute LN and has been shown to be superior to steroids alone (Gourley et al., 1996) or azathioprine monotherapy in establishing remission (Steinberg and Steinberg, 1991). The Euro-Lupus trial demonstrated that low-dose intermittent cyclophosphamide was as effective as high dose at achieving remission in patients with active LN (Houssiau et al., 2002). Cyclophosphamide is, however, associated with ovarian failure in females, and this is a significant problem in a disease with a female:male ratio of 9:1. Therefore in certain cases cyclophosphamide has been superseded by mycophenolate as induction therapy.

## **Biologic Agents and Small Molecule Inhibitors in Systemic Lupus Erythematosus**

### **RITUXIMAB**

B cells and the antibodies they produce play a central role in the pathogenesis of SLE, and it is therefore not surprising that B-cell depletion has been considered as a therapeutic option. Rituximab is a chimeric monoclonal antibody against CD20 and which depletes B cells but not plasma cells, and both case reports and series suggested a beneficial role in renal and extrarenal SLE (Smith et al., 2006).

Formal trials of the use of rituximab in SLE have not been successful. The EXPLORER trial of rituximab in moderate-to-severely active SLE failed to reach the primary endpoint, which was the ability of rituximab or placebo to achieve a complete or partial clinical response at week 52 (Merrill et al., 2010). Many believe this was due to defects in trial design rather than true lack of efficacy, perhaps including trial size, background immunosuppression, and high steroid use, along with difficulty of measuring outcomes in a heterogeneous disease like SLE. Subsequent analyses showed that rituximab was superior to placebo in reducing the risk of severe flares (defined as BILAG A) and also the total number of flares (Merrill et al., 2011). However, this was a post hoc analysis and therefore could not be used to support regulatory authorization for the use of rituximab in SLE. The LUNAR trial, which assessed the role of rituximab in active proliferative LN, also failed to achieve the primary endpoint of renal response at 52 weeks (Rovin et al., 2012). However, clinical experience, together with long-term follow-up data and post hoc analyses, has meant that, despite negative phase three clinical trials, rituximab is often used “off-label” in renal and extrarenal SLE.

Based on regimens from the transplant community, rituximab is being trialed as a treatment for LN but without tapered oral steroids (RITUXILUP), after a cohort study found that the majority of LN patients achieved a complete or partial response by 37 weeks, suggesting that oral steroids can be avoided (Condon et al., 2013). These and subsequent trials could lead to a step-change in the treatment of SLE without steroids, but longer term

follow-up data will be crucial, especially in the case of a B-cell depleting therapy that can result in secondary hypogammaglobulinemia.

### BELIMUMAB

Belimumab inhibits the BLyS, which is a key factor on B-cell survival and has been shown to be upregulated in patients with SLE. BLyS inhibition has the effect of reducing CD20-positive B cells, short-lived plasmablasts, and anti-dsDNA autoantibodies. The BLISS-52 trial showed that belimumab was superior to placebo with higher SLE Responder Index improvement at week 52 (Navarra et al., 2011) and no significant safety signals. The SLE responder index is defined as a  $\geq 4$  point reduction in SELENA-SLEDAI score, no deterioration from baseline in a physician global assessment and no new BILAG A scores and no more than one new BILAG B score. Belimumab was therefore licensed for the treatment of antibody-positive SLE active despite standard of care therapy. Subsequent analysis of the BLISS trials showed that the effect of belimumab was greatest in those with highest disease activity, and it therefore provides another licensed treatment option in patients who are nonresponsive or cannot tolerate other therapies (van Vollenhoven et al., 2012). The role of belimumab in the treatment of LN is being examined in on-going clinical trials, but questions around treatment length still need to be answered, with some patients experiencing severe flares on discontinuation of medication.

### ATACICEPT

Atacicept is a fusion protein of the Transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI) receptor with human IgG. TACI binds both BLyS and APRIL (a proliferation-inducing ligand), and therefore it was thought that inhibiting both would have a more potent effect in patients with active SLE. The first trial of atacicept, APRIL-SLE, was stopped early because of two deaths in the higher dose treatment arm due to lung infections possibly related to drug (Isenberg et al., 2015). There was no difference in the primary endpoint between placebo and 75 mg atacicept, although post hoc analysis suggested a benefit of 150 mg atacicept versus placebo. The ADDRESS II trial reexamined efficacy and safety in patients with active SLE who had up-to-date vaccination status for *Streptococcus pneumoniae* and influenza prior to enrolment. The trial failed to reach the primary endpoint but a subsequent prespecified subpopulation analysis showed benefit in those with high disease activity (Merrill et al., 2018). Upper respiratory tract infections and diarrhea were more common in the atacicept-treated groups. Further evaluation of this drug is required.

### **Other Agents and Treatment Options**

Ustekinumab, a monoclonal antibody against the p40 subunit of IL-12 and IL-23, is effective in the treatment of psoriasis and psoriatic arthritis. In a phase II trial, ustekinumab was associated with a higher Systemic Lupus Erythematosus Responder Index (SRI) response compared to placebo at 24 weeks in patients with active SLE (van Vollenhoven et al., 2017a). Ustekinumab targets T cell-derived cytokines, thus opening a new therapeutic pathway. Although TNF $\alpha$  blockade is commonly used in diseases such as RA, it is not commonly used in SLE. A small study from the Smolen group showed that it may be effective at controlling LN, but over half of the infliximab-treated patients experienced serious adverse events (Aringer et al., 2009). Janus kinase (JAK) inhibitors are also licensed for RA and offer an oral small molecule treatment approach. The evaluation of JAK inhibitors such as tofacitinib is underway in lupus and may be beneficial given their effect on interferon signaling. Epratuzumab, a monoclonal antibody targeting CD22 on B cells, that results in altered signaling without significant reduction in B-cell numbers, failed to show benefit over standard of care in SLE (Clowse et al., 2017).

GWAS and transcriptomic studies have implicated type I interferons and associated pathways in the pathogenesis of SLE, although therapeutic targeting has given mixed results. Sifalimumab, a human monoclonal antibody that binds to IFN- $\alpha$ , met the primary endpoint in patients with moderate-to-severely active SLE (Khamashta et al., 2016). Rontalizumab, another human monoclonal antibody that targets all subtypes of IFN- $\alpha$ , failed to meet primary endpoints in a trial of moderate-to-severe lupus (Kalunian et al., 2016). Anifrolumab, a type I IFN receptor antagonist, reduced disease activity compared to placebo in patients with moderate-to-severely active SLE (Furie et al., 2017). A greater effect size was seen in patients with a high interferon signature at baseline, although the treatment was associated with more herpes zoster infections.

Bortezomib, a proteasome inhibitor, has been shown to be clinically effective in refractory SLE in a small case series, with plasma cell depletion and a reduction in anti-dsDNA antibodies, although controlled trials are awaited (Alexander et al., 2015). Other measures such as plasma exchange (Kronbichler et al., 2016) may be used in refractory SLE and reduction of antibodies by targeting FcRN is under evaluation. Autologous hematopoietic stem-cell transplantation (HSCT) can result in 50% disease-free survival, at 1 year, in patients with refractory disease but is associated with significant morbidity and mortality (12%) (Jayne et al., 2004). Mesenchymal stem-cell

transplant, in severe and treatment refractory patients, resulted in 27% of patients in complete remission after 5 years with fewer adverse events compared to HSCT (Wang et al., 2018).

## FUTURE PERSPECTIVES

SLE is a clinically and pathologically diverse disease with significant unmet needs in terms of biomarkers for diagnosis and prognosis and effective treatment options with acceptable tolerability. The major challenge in achieving each of these goals might lie in disease stratification; the identification of disease subsets that are driven by distinct pathological processes and therefore may respond to specific targeted therapeutics. The genetics and “omics” revolution might assist in the identification of such disease subgroups, whilst also giving insight into new therapeutic targets. In addition to new targets, current clinical trial design where a therapy needs to be effective in “all types” of SLE will need to evolve if we are to realize the benefit of these approaches. In the future, adequate power to detect differences in patient subpopulations will be a critical issue in order to overcome past issues of clinical trials in SLE.

SLE is still a relatively rare disease, and this, together with the likely existence of unrecognized disease subgroups, makes the conduct of clinical trials difficult. Novel methods of recruitment, such as via social media, need to be considered. Screening for disease is possible in certain populations, such as African American females, and screening for renal LN in the same manner as for hypertension in the barbershop trial (Victor et al., 2018) might address a significant clinical problem in a novel manner.

Despite research and development into biologics for SLE, only one agent, belimumab, has a license for use in this disease. Nonetheless many other novel agents are currently under development. Patients with SLE and those caring for them, now more than ever, have the ability to take part in clinical trials of these newer agents, such as those targeting type I IFN and IL-23. Increased patient participation in translational research, patient stratification, and target identification through genetics/genomics and modern clinical trial design should result in better outcomes for this chronic disease.

## DEFINITION AND CLASSIFICATION

Systemic sclerosis (SSc), historically called scleroderma, is an autoimmune connective tissue disease with complex and poorly understood pathogenesis. SSc has protean clinical manifestations, follows a chronic and commonly progressive course, and is associated with substantially diminished quality of life, disability, and excess mortality. In addition to skin involvement, the hallmark of the disease, virtually every organ can be affected (Fig. 31.1). A recently adopted set of classification criteria are highly sensitive and specific for SSc (Table 31.1). According to these criteria, skin thickening of the fingers of both hands extending proximal to the metacarpophalangeal joint is

**FIGURE 31.1** Clinical features of systemic sclerosis. (A) Facial features with oral furrowing and telangiectasia; (B) palmar telangiectasia; (C) calcinosis on the digital tip; (D) calcinosis on the elbow; (E and F) digital ulcer leading to gangrene. *Clinical pictures courtesy of Dr. Maureen D. Mayes*

**TABLE 31.1** Classification Criteria for Diagnosis of Systemic Sclerosis

Item	Subitem	Weight/score
Bilateral skin thickening—fingers extending proximal to MCP joints		9
Skin thickening of fingers only	Puffy fingers	2
	Sclerodactyly (skin thickened distal to MCP joints)	4
Fingertip lesions	Digital tip ulcer or pitting scar	2
		3
Mucocutaneous telangiectasia		2
Abnormal nailfold capillary pattern		2
Lung involvement	PAH	2
	Interstitial lung disease	2
Raynaud's phenomenon		3
SSc-specific autoantibodies	ACA	3
	Scl-70	
	RNA polymerase III	

ACA, Anticentromere; MCP, metacarpophalangeal joint; PAH, pulmonary arterial hypertension.

sufficient for the diagnosis of SSc. If proximal skin thickening is absent, a constellation of symptoms presented in Table 31.1 is used, and more than nine points is required for the classification as SSc (van den Hoogen et al., 2013).

SSc shows marked patient-to-patient variability in its patterns of skin involvement, complications, autoantibody profiles, disease progression, response to treatment, and survival (Allanore et al., 2015). In its earliest stages, SSc is marked by prominent immune and inflammatory features, but over the time as the disease advances, irreversible structural alterations in multiple vascular beds and visceral organ dysfunction and failure due to fibrosis and atrophy emerge.

Indurated skin (*scleroderma*) is the distinguishing hallmark of SSc. However, similar indurative skin changes can also be seen in localized forms of scleroderma. The localized sclerodermas represent a family of fibroinflammatory conditions that affect the skin and underlying tissue (hypodermis and occasionally underlying muscle and bone) but spare internal organs. In this chapter, we focus on the systemic form of scleroderma or SSc. In addition to localized scleroderma, skin induration can also occur in a diverse group of metabolic, inherited, and autoimmune disorders that should not be confused with SSc (Table 31.2).

SSc is customarily divided into two partially overlapping subsets that are defined by the pattern of skin involvement, along with clinical and serological features (Table 31.3). The natural history of these two SSc subsets is quite distinct. Patients with diffuse cutaneous SSc (dcSSc) typically have extensive, and often rapidly progressive, skin induration ascending from the distal fingers (sclerodactyly) to proximal limbs (above elbows and/or knees) and the trunk. Interstitial lung disease (ILD) and acute scleroderma renal crisis occur in these patients and characteristically develop relatively early in the disease course. In contrast, limited cutaneous SSc (lcSSc) tends to be indolent and is characterized by Raynaud's phenomenon preceding other disease manifestations, sometimes by years. In lcSSc, the skin induration shows little progression and remains confined to the fingers, distal limbs, and face. Many patients with lcSSc display a characteristic constellation of clinical findings (calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and mucocutaneous telangiectasia) that lead to the designation *CREST syndrome*. However, CREST features can also be present in patients with dcSSc. In contrast to dcSSc, visceral organ involvement in lcSSc tends to follow an indolent course, with digital ischemic ulcers and pulmonary arterial hypertension (PAH) as late complications. Some individuals may present with Raynaud's phenomenon accompanied by characteristic clinical, capillaroscopic, and serological features of SSc in the absence of detectable skin induration (*sine scleroderma*).

## EPIDEMIOLOGY

The reported incidence and prevalence of SSc vary significantly in different geographic regions. This might reflect true variability in disease frequency based on geographic and ethnic backgrounds but might also reflect differences in the case definition and ascertainment methods used. A large-scale survey in the Detroit area from 1988 to 1991 indicated an incidence rate of 21 new cases/year and a prevalence rate of 276 cases per million adults. A diagnosis was verified based on the 1980 American Rheumatism Association (ARA) classification criteria (Leroy et al., 1980) or presence of sclerodactyly in addition to two other CREST features (Mayes et al., 2003). A Canadian study using physician billing and hospitalization databases reported a prevalence of 443 per million in the province of Quebec in 2003 (Bernatsky et al., 2009). Epidemiological data from Europe reveal a north-south gradient for SSc, with Southern European countries having a higher frequency. An Italian retrospective study (Lo Monaco et al., 2011) from outpatient clinics from 1999 through 2007 reported annual incidence and prevalence rates of 43 and 341 cases per million, respectively (Leroy and Medsger, 2001). These rates decrease to an annual incidence and prevalence rates of 32 and 254 per million cases, respectively, when the more restrictive 1980 ARA classification criteria were applied. A study from Iceland reported an annual incidence of 3.8 per million during the period 1975–90 and prevalence of 71 per million (Geirsson et al., 1994). Epidemiological studies from Northeast England (Allcock et al., 2004) and Norway show similar prevalence data (88 and 99 cases per million, respectively). The most recent epidemiological study from Europe reported a prevalence of 228 cases per million in the Alsace region of France (Meyer et al., 2016). SSc seems to be less frequent in Asia. For instance, a recent study based on the Taiwan National Health Registry data indicated that the annual incidence rate and prevalence of SSc were 10.9 and 56.3 cases per million (Kuo et al., 2011). Of note, the 2013 classification can diagnose milder cases, potentially leading to higher SSc incidence and prevalence estimates in future epidemiological studies (van den Hoogen et al., 2013).

SSc has a female preponderance with most estimates of female-to-male ratios ranging from 3:1 to 9:1 [reviewed in Chifflot et al. (2008); Coral-Alvarado et al. (2009)]. In a large European SSc database (EUSTAR) 86% of the patients were female (6.2:1 ratio) (Meier et al., 2012). The female predominance in SSc is similar to other autoimmune rheumatic diseases such as systemic lupus erythematosus and rheumatoid arthritis. It is unclear why SSc occurs more frequently in females. Hormonal influences and pregnancy-related events have been postulated. A case-sibling study investigating the influence of birth order and gravity/parity in 974 sibships showed that the risk of SSc increased with increasing birth order (OR 1.25 for birth order 2–5; OR 2.22 for birth order 6–9; and OR 3.53 for birth order 10–15). Furthermore, gravidity/parity in 168 sibships showed that a history of one or more pregnancy was associated with SSc (Cockrill et al., 2010). These results are congruent with the notion that

**TABLE 31.3** Prominent Features of Limited Versus Diffuse Cutaneous Systemic Sclerosis (SSc)

Feature	Limited cutaneous SSc	Diffuse cutaneous SSc
Skin involvement	Indolent; limited to fingers, distal to elbows, face	Rapid onset. Diffuse: fingers, extremities, face, trunk; progression
Raynaud's phenomenon	Antedates skin involvement, sometimes by years; may be associated with critical ischemia in the digits	Onset coincident with skin involvement; critical ischemia less common
Calcinosis cutis	Common, may be prominent	Less common, mild
Musculoskeletal	Arthralgia, small joints of hands	Carpal tunnel syndrome, joint contractures; tendon friction rubs
Interstitial lung disease	Slowly progressive, generally mild	Frequent, early onset and progression, can be severe
Pulmonary arterial hypertension	Frequent, late, may occur as an isolated complication	Often occurs in association with interstitial lung disease
Scleroderma renal crisis	Uncommon	Occurs in 15%; generally early (<4 years from disease onset)
Calcinosis cutis	Common and often prominent	Less common, mild
Characteristic autoantibodies	Anticentromere	Antitopoisomerase I (Scl-70), anti-RNA polymerase III

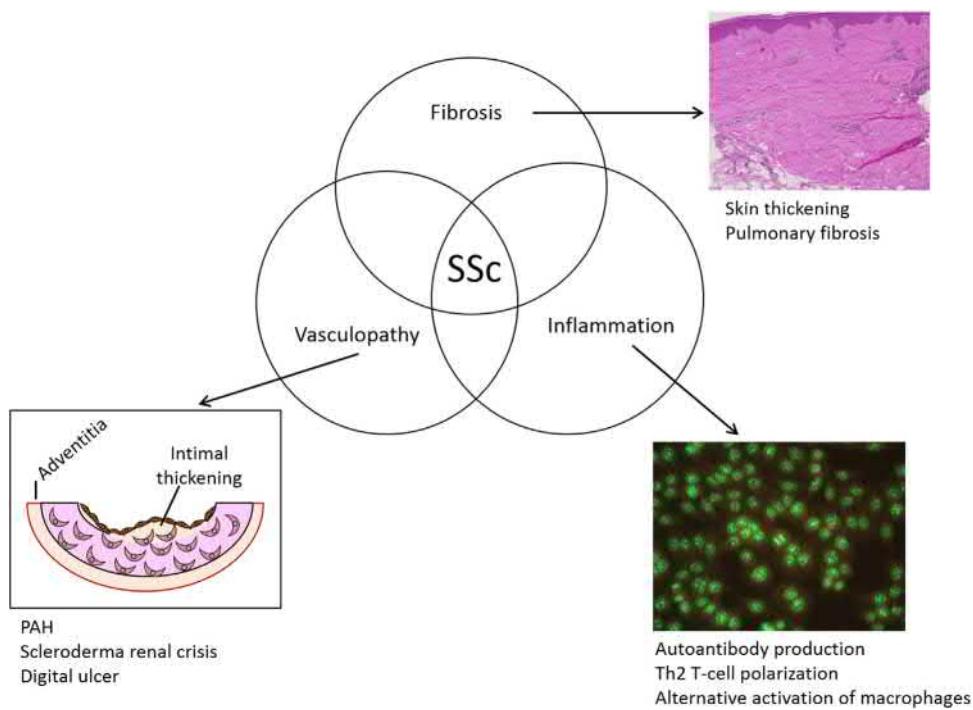

microchimerism might contribute to the female preponderance of SSc. Microchimerism occurs when cells are transferred between mother and fetus during pregnancy, resulting in the persistence of genetically distinct cell populations in the host (Bianchi et al., 1996). Male microchimerism was more frequent in peripheral blood cell mononuclear cells of parous women with SSc than of matched controls (Lambert et al., 2002), although this study had a small sample size (57 SSc and 57 controls). An alternative explanation for female predominance in SSc implicates preferential X-chromosome inactivation toward one parental source, leading to a deviation from the theoretical 1:1 inactivation ratio. The skewed pattern of X-chromosome inactivation in SSc has been confirmed in three independent studies with sample sizes ranging from 68 to 217 (Kanaan et al., 2016; Broen et al., 2010; Ozbalkan et al., 2005). It is worth noting that single-nucleotide polymorphisms (SNPs) of the genes for Interleukin-1 receptor-associated kinase-1 (IRAK1) and methyl-CpG-binding protein 2 (MECP2), both located on X-chromosome, have been linked to SSc. IRAK1 has an important immune function by modulating IL-1-mediated nuclear factor- $\kappa$ B (NF- $\kappa$ B) activation, whereas MECP2 encodes a nuclear protein that binds specifically to methylated DNA and plays a central role in the transcriptional regulation. A nonsynonymous IRAK1 variant (rs1059702) was most strongly associated with dcSSc and SSc-ILD (Dieude et al., 2011). A follow-up study found that the IRAK1 variant rs1059702 and MECP2 rs17435 were specifically associated with dcSSc in female patients. These two SNPs showed moderate linkage disequilibrium ( $r^2 = 0.6$ ). However, conditional logistic regression analysis indicated that the association of IRAK1 rs1059702 with dcSSc was explained by the effect of MECP2 rs17435. The IRAK1 variant rs1059702 was associated with the presence of ILD (Carmona et al., 2013). Of note, in both the studies, the odds ratios for association with the disease were less than 1.5, indicating that these significant associations have a low effect size.

The age of onset in SSc varies based on sex and ethnicity. African American patients have an earlier age of onset. In a large US study, the mean age at diagnosis did not differ based on sex. The mean age at SSc diagnosis was 48.1 for Whites and 41.0 for Blacks (Steen et al., 1997). In the EUSTAR database (primarily White patients) the mean age at disease onset (earlier than the age at diagnosis) was 45.9 years (Meier et al., 2012).

SSc is associated with significant excess mortality. A metaanalysis of nine studies conducted between 1960 and 2010 found a pooled standardized mortality ratio (compared to the age and gender-matched general population) of 3.53 (Elhai et al., 2011), which was higher than the standardized mortality ratio (SMR) in other autoimmune rheumatic diseases (Toledano et al., 2012). Of note, the SMR of SSc had not changed significantly over time, although studies from single-center cohorts or national registries indicate improvement in SSc-related mortality over time (Ferri et al., 2002; Steen and Medsger, 2007). A study from Spanish Scleroderma Registry indicated that death from SSc-related causes decreased from 72% in the time period of 1990–99 to 48% within 2000–09 (Rubio-Rivas et al., 2017). The cause of SSc-related deaths has also changed over time. In a large single-center study of patients seen between 1972 and 1997, the frequency of death due scleroderma renal crisis decreased from 42% to 6%, while the proportion of deaths due to SSc-ILD increased from 6% to 33%. The frequency of deaths due to PAH also increased during this period (Steen and Medsger, 2007). Confirming these findings, a recent analysis of the EUSTAR database with 5860 SSc patients indicated that 55% of the deaths were attributable directly to SSc, while 41% were due to non-SSc causes. Nineteen percent were due SSc-related ILD, 14% due to PAH, 14% due to SSc-related myocardial involvement, 4% due to renal causes, and 3% due to gastrointestinal (GI) complications. Among the non-SSc-related death, 13% were due to infections (predominantly pneumonia), 13% due to malignancies, and 12% due to cardiovascular causes (Tyndall et al., 2010).

Environmental factors are thought to play an etiologic role in the SSc. Occupational silica exposure is the best established of the potential environmental triggers of SSc. A metaanalysis of 16 original studies indicated that silica exposure is a risk factor for SSc, especially in male patients (McCormic et al., 2010). However, most of the SSc patients (male or female) have not had occupational silica exposure. Environmental toxins have also been linked to scleroderma-like conditions. For instance, the toxic oil syndrome was linked to the consumption of contaminated rapeseed oil used for cooking in Spain, while the epidemic of eosinophilia-myalgia syndrome in the United States was traced to the ingestion of contaminated L-tryptophan dietary supplements. Although both of these novel toxic-epidemic syndromes were characterized by scleroderma-like chronic skin changes and variable visceral organ involvement, they were associated with clinical, pathologic, and laboratory features distinguishing them from SSc.

Viral exposures have been also investigated as a potential trigger of SSc. Cytomegalovirus and Epstein–Barr virus have been both implicated. However, epidemiological studies of the SSc link with viruses have been hampered by the fact that they are highly prevalent in the general population. Although case reports and series describing SSc in women with silicone breast implants had raised concern regarding a possible causal role of

**FIGURE 31.2** The pathophysiologic triad of vasculopathy, autoimmunity/inflammation, and fibrosis underlies protean clinical manifestations of systemic sclerosis.

silicone exposure in SSc, a metaanalysis did not show any relation between silicone breast implants and SSc or any other rheumatic disease (Janowsky et al., 2000).

## PATHOGENESIS

The complex pathogenesis of SSc reflects a distinct triad of pathomechanistic processes: inflammation/autoimmunity (van den Hoogen et al., 2013), microangiopathy (Allanore et al., 2015), and fibrosis in multiple organs (Leroy et al., 1980) (Fig. 31.2). The relative severity and contribution of these three interrelated processes to the overall clinical picture and disease activity varies among patients and during disease evolution over time (Gabrielli et al., 2009). Autoimmunity/Inflammation and altered vascular reactivity occur early in the disease course and, therefore, lead to subsequent vascular loss, fibrosis, and atrophy in multiple organs.

## GENETICS

SSc is a polygenic disease associated with several genetic susceptibility loci, with each having low-to-moderate effect size. The combination of environmental and stochastic factors converging upon individuals of a particular genetic background seems to ultimately lead to the development of the disease.

In a study of 703 SSc patients from three US cohorts, 11 multiplex families were identified, resulting in familial accumulation rate of 1.5%–1.7%. Compared to the estimated prevalence in the general population, familial relative risk in the first-degree relatives was 13 and the relative risk in siblings was 15, which represent the strongest risk factors for the disease established to date. However, the absolute risk for each family member remains <1% (Arnett et al., 2001). A follow-up study indicated that affected first-degree relatives with SSc had a significantly higher concordance for SSc-related antibodies and human leukocyte antigen (HLA) class II haplotypes than expected by chance, supporting the role of genetics in autoantibody expression (Assassi et al., 2007).

To date, only a single twin study has been carried out in SSc. This study based on 42 pairs of twins (24 monozygotic twins) showed low concordance for SSc (4.7%), while stronger concordance was observed for the presence of antinuclear antibodies (ANA), which was detected in 40% in dizygotic twins versus 90% in monozygotic

twins. These results suggest that genetic predisposition alone is not sufficient for the development of SSc, but it might establish a susceptible host with autoantibody expression (Feghali-Bostwick et al., 2003).

The advent of genome-wide association studies (GWAS) and large-scale international collaborations have dramatically improved our understanding of SSc genetics. While the strongest disease associations have been observed in the HLA region, over 20 susceptibility loci outside the HLA region have been also robustly linked to SSc. Unbiased genetic association studies have provided new insights into SSc pathogenesis and can potentially identify novel therapeutic targets. The majority of SSc risk genes appears to be involved in immune regulation and is also susceptibility loci for systemic lupus erythematosus and other autoimmune diseases (Martin et al., 2012). This finding is also supported by a study examining the aggregation of autoimmune diseases in 4612 first-degree relatives of 1071 SSc patients. The most striking increase for familial autoimmunity compared to the general population was observed in systemic lupus erythematosus ( $OR = 17$ ,  $P = .004$ ), indicating that common genetic risk factors (and potentially early environment factors) predispose to SSc and systemic lupus erythematosus (Arora-Singh et al., 2010).

Large-scale candidate gene studies, four GWAS (Allanore et al., 2011; Radstake et al., 2010; Zhou et al., 2009; Terao et al., 2017) and two Immunochip studies (Mayes et al., 2014; Zochling et al., 2014), have led to the identification of robustly validated SSc susceptibility loci. The strongest associations in the genome-wide studies were observed on chromosome 6 in the HLA class II region. This finding provides important support for the notion that SSc is fundamentally an autoimmune disease. A large study of HLA class II genes (*DRB1*, *DQB1*, *DQA1*, *DPB1*) was carried out in 1300 SSc cases (961 Caucasians) and 1000 controls (Arnett et al., 2010). SSc was associated with the *DRB1\*11:04*, *DQA1\*05:01*, and *DQB1\*03:01* haplotypes and the *DQB1* allele. However, many other alleles or haplotypes were associated with autoantibody subtypes of disease. For example, HLA-*DPB1\*13:01* had an OR of 14 in antitopoisomerase I (ATA)-positive SSc patients in comparison to unaffected controls. The notion that the HLA class II associations represent a pathogenic contribution mainly through regulating autoantibody expression was supported by a GWAS follow-up study. In this study, different patterns of genetic associations were found for ATA and anticentromere (ACA)-positive SSc patients within HLA region, while the genetic associations outside the HLA region tended to be in the concordant direction for the antibody subgroups, although the strength of association varied (Gorlova et al., 2011).

**Table 31.4** shows a selected list of non-HLA susceptibility loci which were associated with SSc in at least one large-scale discovery/replication cohort study. Most of the non-HLA susceptibility genes are involved directly in innate and adaptive immunity.

Several genes directly involved in type I interferon (IFN) signaling have been associated with SSc. Specifically, four IFN regulatory factors (IRFs) are risk loci for SSc (*IRF4*, *IRF5*, *IRF7*, and *IRF8*). Several *IFR5* SNPs have been shown to be associated with SSc (Radstake et al., 2010; Dieude et al., 2009a). In a follow-up study, the minor allele of one of these (rs4728142) was associated with longer survival and higher forced vital capacity (FVC). This gene variant was also associated with lower *IRF5* transcript levels in peripheral blood monocytes from both SSc patients and controls (Sharif et al., 2012). The genetic ablation of *IRF5* in mice ameliorated experimental scleroderma induced by subcutaneous bleomycin injections, with reduced fibroblast activation, Th2 skewing of the immune response, and attenuation of vascular pathology in the skin and the lungs (Saigusa et al., 2015). Similarly, *IRF4* (Lopez-Isac et al., 2016b), *IRF7* (Carmona et al., 2012), and *IRF8* (Gorlova et al., 2011; Arismendi et al., 2015) have been associated with SSc. These findings support an important role of type I IFN signaling in the pathogenesis of SSc.

Genes involved in T- and B-cell signaling have also identified as SSc risk loci. *CD247* encodes the zeta subunit of the T-cell receptor and is associated with SSc (Radstake et al., 2010). Similarly, *TNFSF4*, encoding the OX40 ligand involved in the interaction between T cells, antigen presentation, and activation of T and B cells was also identified as a risk locus in several independent studies (Arismendi et al., 2015; Coustet et al., 2012). In mouse models of scleroderma, pharmacological OX40L blockade prevented inflammation-driven skin, lung, and vascular fibrosis and induced the regression of established dermal fibrosis (Elhai et al., 2016). Similarly, *BLK* proto-oncogene, which transduces the downstream B-cell receptor signal, has been linked to SSc (Gourh et al., 2010; Ito et al., 2010). Moreover, two nonsynonymous and functional SNPs of *BANK1* (rs10516487 and rs3733197), which encodes the B cell–specific scaffold protein with ankyrin repeats, were linked to SSc in two independent studies (Dieude et al., 2009b; Rueda et al., 2010). The above studies potentially implicate adaptive immunity in SSc pathogenesis.

Recently identified SSc susceptibility loci have also “converged” on NF- $\kappa$ B and IL12, two signaling pathways involved in innate immunity. *TNFAIP3* encodes the A20 ubiquitin-editing enzyme, a zinc finger protein that is required for negative feedback control for NF- $\kappa$ B and Toll-like receptors (TLR) signaling. *TNFAIP3* was linked to

GWAS, Genome-wide association studies.

SSc susceptibility in two independent studies (Mayes et al., 2014; Koumakis et al., 2012a). Interestingly, decreased A20 expression was associated with enhanced transforming growth factor  $\beta$  (TGF- $\beta$ ) signaling and augmented fibrotic responses in normal dermal fibroblasts, suggesting an important role for A20 in fibrosis (Bhattacharya et al., 2016). An SNP in TNIP1 (ABIN), which can downregulate NF- $\kappa$ B signaling in part by interacting with TNFAIP3, was also identified as SSc risk locus in two independent studies (Allanore et al. 2011; Bossini-Castillo et al., 2013). However, both TNFAIP3 and TNIP1 are also strongly implicated in autoimmune diseases, including rheumatoid arthritis, lupus, psoriasis, and inflammatory bowel disease. Remarkably, NF- $\kappa$ B itself was identified as a risk locus for SSc (Arismendi et al., 2015). Five genes in the IL12 pathway have been also linked to SSc susceptibility. An *IL12RB2* intronic SNP was associated with SSc in a GWAS follow-up study (Bossini-Castillo et al.,

2012). Similarly, an SNP in the intergenic region of *SHIP1-IL12A* was linked to SSc with a relatively high OR (2.57) in the North American/European Caucasian Immunochip study (Mayes et al., 2014). Furthermore, an SNP in the RB1 subunit of IL12 was also linked to SSc risk in an Immunochip follow-up study (Lopez-Isac et al., 2014). Coexpression of IL12R $\beta$ 1 and IL12R $\beta$ 2 is required to form the high-affinity IL12 receptor, which induces activation of STAT4, itself linked to SSc susceptibility in four independent and follow-up GWAS (Allanore et al., 2011; Radstake et al., 2010). The tyrosine kinase TYK2 mediating the IL12 signaling was also associated with SSc susceptibility (Lopez-Isac et al., 2016a). While these studies implicate IL12 in SSc, the functional role of IL12 pathway variants and their pathogenic mechanisms remain to be investigated in mechanistic studies.

The majority of SSc susceptibility loci identified to date are located in intronic (noncoding) gene regions and have relatively modest effect size (typically <1.5). However, it is possible that these loci are in linkage disequilibrium with SNPs in gene coding regions. In addition, these loci might influence the transcription of noncoding regulatory RNAs such as microRNAs, circular RNAs, or long noncoding RNAs. Large-scale whole-exome or whole-genome sequencing studies in SSc are currently underway. It is anticipated that ongoing genetic efforts will reveal novel, rare mutations linked to risk of SSc, or specific disease endophenotypes, which might have substantially higher effect sizes. A further considerable challenge remains the functional characterization of the contribution of identified disease-linked genetic variants to the cellular and molecular alterations that underlie disease manifestations.

## PRECLINICAL DISEASE MODELS

Currently, no single animal model of SSc phenocopies the full spectrum of the human disease. Some existing models recapitulate selected features and therefore have substantial utility for understanding the pathobiology or preclinical evaluation of promising therapeutic interventions (Beyer et al., 2010).

Tight-skin mice (*Tsk1/+*) develop spontaneous skin fibrosis due to a fibrillin-1 mutation, which causes aberrant activation of TGF- $\beta$ . These mice do not develop lung fibrosis or characteristic vascular features. In humans, mutations in fibrillin-1 cause Marfan's disease and a familial scleroderma-like condition termed stiff skin syndrome; however, fibrillin-1 variants have not been linked to SSc. Skin and lung fibrosis accompanied by vasculopathy, inflammation, and autoimmunity can be induced in mice by subcutaneous injection of bleomycin, angiotensin, or HOCl, by transplantation of HLA-mismatched bone marrow or spleen cells, or by immunization with topoisomerase-1 (Marangoni et al., 2016). Targeted genetic modifications in mice are increasingly used for investigating individual molecules, pathways, and cell types in disease models. For example, mice constitutively overexpressing  $\beta$ -catenin, Fra-2, PDGFR-alpha, uPAR, IRF5, or adiponectin show either resistance, or hypersensitivity, to experimental scleroderma, and help shed light on specific aspects of SSc pathogenesis (Marangoni et al., 2017).

## MICROVASCULAR DISEASE IN SYSTEMIC SCLEROSIS

Vascular injury is a common early event in SSc that plays a primary role in pathogenesis. Widespread damage in multiple vascular beds ensues and underlies protean clinical manifestations of SSc.

The clinical sequelae of SSc microangiopathy include Raynaud's phenomenon and ischemic digital ulcers, watermelon stomach, mucocutaneous telangiectasia, scleroderma renal crisis, PAH, and myocardial involvement (Matucci-Cerinic et al., 2013).

Raynaud's phenomenon is an initially reversible vascular abnormality characterized by altered blood-flow response to cold challenge in small digital arteries. Raynaud's phenomenon is associated with autonomic and peripheral nervous system alterations, with impaired production of calcitonin gene-related peptide from sensory afferent nerves and heightened  $\alpha_2$ -adrenergic receptor sensitivity on vascular smooth muscle cells. Primary or idiopathic Raynaud's disease is common, generally nonprogressive and benign. In contrast, secondary Raynaud's phenomenon associated with SSc tends to be progressive and complicated by irreversible structural changes, culminating in digital tip ulcers, necrosis, and amputation.

The triggers for SSc-associated vascular endothelial cell injury are not fully known, but likely include viruses, circulating cytotoxic factors, chemokines, thrombogenic microparticles, and activation of the alternate complement pathways. Recent studies have also described functional autoantibodies targeting endothelial cells and phospholipids. Endothelial damage leads to dysregulated production of vasodilatory (nitric oxide and

prostacyclin) and vasoconstricting (endothelin-1) substances and upregulation of intercellular adhesion molecule 1 (ICAM-1). Injured microvessels show enhanced permeability and transendothelial leukocyte diapedesis, activation of coagulation cascades, elevated thrombin production, impaired fibrinolysis, and spontaneous platelet aggregation. Activated platelets release serotonin, platelet-derived growth factor (PDGF), and the potent vasoconstrictor thromboxane, contributing to further vascular damage.

In the vascular media, myointimal cells proliferate, the basement membrane is thickened and reduplicated, and adventitial fibrosis surrounding the blood vessels develops. The vasculopathic process affects capillaries, arterioles, and less commonly large vessels in many organs. In late-stage SSc, progressive luminal occlusion due to intimal and medial hypertrophy, combined with adventitial fibrosis, culminates in loss of small blood vessels (vascular rarefaction) and tissue ischemia. Revascularization or vasculogenesis, a process distinct from angiogenesis that normally restores circulation in ischemic tissue, is paradoxically impaired in SSc despite elevated levels of angiogenic factors. This is possibly related to reduced number and function of bone marrow–derived circulating endothelial progenitor cells. Capillary loss, fibro-obliterative vasculopathy of small and medium-sized arteries, coupled with impaired ability to repair and replace damaged vessels, underlie progressive SSc vascular disease.

## INFLAMMATION AND AUTOIMMUNITY

### Cellular Immunity

Inflammation and autoimmunity appear to play key roles in SSc. This is supported by the presence of disease-specific autoantibodies; the familial clustering of SSc with other autoimmune diseases ([Arora-Singh et al., 2010](#)); T and B cells with oligoclonal antigen receptors, in target organs; prominent type I IFN gene signatures ([Tan et al., 2006](#)); the elevated circulating levels of cytokines and chemokines such as interleukin-6 (IL-6), IL-4, IL-17, IL-33, CCL2, and CXCL4; and fibrosis resolution and vascular regeneration reported in some SSc patients treated with immunoablative hematopoietic stem-cell therapies. Genetic studies further reveal the strong associations of SSc with HLA, as well as numerous non-HLA-linked genes implicated in adaptive and innate immune responses ([Martin et al., 2012](#)).

In the early-stage (edematous) phase of the disease, mononuclear cell infiltrates comprising activated T and B cells, monocytes/macrophages, and dendritic cells are prominent in lesional skin and lungs even prior to vascular damage or fibrosis. Regulatory T cells, in contrast, are reduced in number. Dendritic cells can be found in close proximity to activated fibroblasts and myofibroblasts. By expressing TLR and secreting IFN, IL-10, thymic stromal lymphopoietin (TSLP), and CXCL4, they shape the adaptive immune response and contribute to loss of immune tolerance. Tissue-infiltrating T cells display restricted T-cell receptor signatures indicative of recognition of as-yet-unknown antigen, supporting the premise that an abnormal antigen might act as an initial trigger for the autoimmune response in SSc.

Peripheral blood T cells in SSc express chemokine receptors and  $\alpha_1$  integrin, which facilitates binding to endothelium and to fibroblasts, while endothelial cells express ICAM-1 and other vascular adhesion molecules that facilitate leukocyte diapedesis. T cells show a  $T_{H}2$ -polarized immune response and enhanced production of IL-4, IL-13, IL-33, and TSLP. These Th2 cytokines generally induce fibroblast activation, whereas the  $T_{H}1$  cytokine IFN- $\gamma$  is antifibrotic. Recent evidence also implicates altered Th17 and regulatory T-cell function in SSc. Type 2 innate lymphoid cells are a recently discovered lymphoid cell population that are also elevated in SSc skin biopsies. Alternately activated macrophages, which promote angiogenesis and tissue remodeling, are activated and increased in lesional skin and bind to fibroblasts.

Circulating B cells express CD19 and costimulatory molecules CD80 and CD86, suggesting chronic activation. Serum levels of a proliferation-inducing ligand (APRIL) and B cell–activating factor are elevated in SSc and associate with the extent of skin and lung involvement. Since B cells secrete IL-6, TGF- $\beta$ , and other profibrotic cytokines implicated in SSc, B-cell hyperactivity might directly contribute to the inflammatory and fibrotic processes, as well as the generation of disease-specific autoantibodies. Tissue transcriptome studies identified a distinct subset of SSc skin biopsies that show elevated expression of inflammation-related genes ([Martyanov and Whitfield, 2016](#)). Evidence of ongoing TLR signaling is prominent in both circulating immunocompetent cells as well as tissue-resident stromal cells within target organs and may reflect impaired ability to restrict innate immunity.

## Humoral Autoimmunity

Circulating ANA occur in the vast majority of patients with SSc and appear to predate clinical manifestations of the disease. Certain SSc-specific autoantibodies show robust associations with distinct disease endophenotypes and clinical/laboratory manifestations. Owing to their high degree of specificity, mutual exclusivity, association with particular disease patterns, and rates of progression, SSc-associated autoantibodies have gained substantial clinical utility as diagnostic and prognostic markers. Some SSc-specific antibodies appear to be associated with cancer (Joseph et al., 2014a). Antibodies directed against matrix metalloproteinases, fibrillin-1, and the surface receptors for angiotensin II, endothelin-1, muscarinic 3, and PDGF, have also been reported in patients with SSc, although their disease specificity, clinical utility, and potential pathogenic significance, if any, remain established.

A variety of mechanisms have been postulated to account for the emergence of these disease-specific autoantibodies in SSc. Proteolytic cleavage, altered expression or subcellular localization of normal proteins, or somatic mutations in the case of certain cancer-associated forms of SSc, might give rise to immune recognition of cryptic neoepitopes, breaking immune tolerance.

## Fibrosis

Tissue fibrosis is characterized by replacement of normal architecture with rigid avascular and acellular connective tissue (Ho et al., 2014). Fibrosis in SSc is caused by fibroblasts and myofibroblasts activated as a consequence of inflammation, autoimmunity, and microvascular damage. Fibroblasts are tissue-resident multifunctional stromal cells responsible for the functional and structural integrity of connective tissue. Resident fibroblasts are normally in a quiescent state. Upon their activation by extracellular cues, fibroblasts proliferate; migrate; induce a canonical secretome of collagens and other matrix molecules, growth factors, chemokines, and cytokines; and transdifferentiate into contractile myofibroblasts. Under normal conditions, these responses are spatially and temporally limited to completing physiologic repair and regeneration. When they become sustained and amplified, pathologic fibrosis results (Bhattacharyya et al., 2011). Paracrine fibrotic mediators including TGF- $\beta$ , IL-6, IL-13, Wnt ligands, lysophosphatidic acid, connective tissue growth factor, PDGF, hypoxia, reactive oxygen radicals (ROS), thrombin, and biomechanical forces have all been implicated in sustained fibroblast activation underlying SSc fibrosis. Damage-associated endogenous ligands for the innate pattern recognition receptors TLR4 (HMGB1, EDA-fibronectin, and tenascin-C) and TLR9 (mitochondrial DNA) further contribute to aberrant fibroblast activation underlying nonresolving fibrosis in SSc.

In addition to tissue-resident fibroblasts, endothelial cells, vascular mural pericytes, and other mesenchymal progenitor cells and preadipocytes are potential sources of activated myofibroblasts in fibrosis (El Agha et al., 2017). Although myofibroblasts are transiently found in normal wound healing, their persistence in lesional tissue, possibly due to mechanotransduction-mediated resistance to apoptosis, contributes to fibrosis (Nanchahal and Hinz, 2016).

Explanted fibroblasts from SSc skin biopsies display an abnormally activated phenotype ex vivo, with variably increased rates of extracellular matrix (ECM) production, spontaneous ROS generation, prominent alpha smooth muscle actin stress fibers, and a secretome characteristic of cellular aging. Persistence of the “scleroderma phenotype” during serial ex vivo passage is likely to reflect altered microRNA expressions, or acquired and stable cell type–specific epigenetic modifications such as DNA methylation or chromatin remodeling via histone acetylation. The heterogeneity of activated fibroblast populations within lesional skin and other tissues is just beginning to be investigated with the application of advanced technologies such as single-cell RNA sequencing.

## PATHOLOGY

The distinguishing pathological triad of SSc irrespective of the organ system affected is a capillary loss, and obliterative microangiopathy, combined with fibrosis. In early-stage disease, mononuclear inflammatory cell infiltrates can be detected around blood vessels in multiple organs. Obliterative microangiopathy is the prominent late finding in the lungs, kidneys, heart, and GI tract. Excessive buildup of a fibrotic extracellular matrix composed of collagens, proteoglycans, and other structural matrix macromolecules progressively disrupts normal architecture, resulting in impaired function and failure of affected organs. The process is most evident in the skin, lungs, cardiovascular and GI systems, tendon sheaths, perifascicular tissue surrounding skeletal muscle, and thyroid glands, while the brain, spinal cord, and liver are largely spared.

## Skin

The lesional skin is rigid and thickened, with broad bundles of homogenized collagen within the dermis oriented parallel to the epidermis. Loss of periadnexal and intradermal white adipose tissue and its replacement with a collagenous matrix can be striking. Perivascular mononuclear cell infiltrates may be seen early, while in established skin fibrosis inflammation is largely absent.

## Lungs

In SSc autopsy studies, evidence of interstitial lung involvement is nearly universal. The most common histopathological pattern is nonspecific interstitial pneumonia (NSIP), characterized by interstitial fibrosis and mild chronic inflammation. The pattern of usual interstitial pneumonia (UIP), with spatial/temporal heterogeneity of inflammation, fibrosis, and fibrotic foci that is characteristic of idiopathic pulmonary fibrosis, is less common in SSc-associated lung disease ([Herzog et al., 2014](#)). Fibrosis of the alveolar septae results in obliteration of the airspaces and loss of pulmonary blood vessels, impairing gas exchange. Intimal thickening of the pulmonary arteries underlies SSc-associated PAH, a frequent late complication, and is often associated with pulmonary emboli and myocardial fibrosis.

## Gastrointestinal Tract

Pathologic changes can be prominent at any level in the GI tract from the mouth to the rectum. In the lower esophagus, atrophy and fibrosis of the muscularis propria and characteristic vascular lesions are prominent, while the upper third of the esophagus is largely spared. Chronic gastroesophageal reflux can lead to esophageal inflammation, mucosal ulceration, and stricture formation. Barrett's metaplasia with an attendant risk of adenocarcinoma can occur. Collagenous replacement of the GI wall results in impaired smooth muscle contractility and diminished peristaltic activity, with bacterial overgrowth and small-bowel pseudo-obstruction as late sequelae.

## Kidneys

In the kidneys, vascular lesions affecting the interlobular and arcuate arteries predominate. Biopsies in acute scleroderma renal crisis show acute fibrinoid necrosis and intimal proliferation (onion-skin pattern) of the afferent arterioles, sometimes associated with ischemic glomerular collapse and sclerosis. These changes are strongly reminiscent of thrombotic microangiopathies (TMAs) such as thrombotic thrombocytopenic purpura (TTP) and atypical hemolytic-uremic syndrome, resulting in occasional misclassification. Additional findings include thrombosis, thrombocytopenia due to platelet consumption, and microangiopathic hemolysis. Presence of extensive vascular thrombosis, glomerular collapse, and peritubular capillary deposits is predictive of irreversible renal failure. As in other forms of TMAs, evidence of intravascular complement activation can be prominent, suggesting a potential pathogenic role of the complement system in scleroderma renal crisis ([Ghossein et al., 2016](#)).

## Heart

While cardiac involvement in SSc is often subclinical, prominent pathological involvement of the myocardium and pericardium is frequent. The characteristic arteriolar lesions are concentric intimal hypertrophy and luminal narrowing, accompanied by patchy contraction band necrosis, loss of cardiac myocytes, and myocardial fibrosis that are thought to be due to microvascular involvement and ischemia-reperfusion injury. Fibrosis of the conduction system, especially at the sinoatrial node, can be found. Pericardial involvement with chronic inflammatory infiltrates, fibrinous exudates, and pericardial effusions is common.

## Pathology in Other Organs

Skeletal muscle inflammation and, in the later stages, atrophy and fibrosis are common findings, which are similar to those in polymyositis ([Paik et al., 2015](#)). Inflammatory synovitis is seen in some patients with early SSc; with disease progression, the synovium becomes fibrotic, and in contrast to rheumatoid arthritis, pannus formation or bone resorption are uncommon. Fibrosis and atrophy of the thyroid and the minor salivary glands may

be seen. Placentas from SSc pregnancies show decidual vasculopathy, which is associated with poor perinatal outcomes and fetal death.

## CLINICAL FEATURES

### Overview

SSc can affect virtually any organ (Table 31.5). Although the widely employed dichotomous subgrouping of disease into dcSSc and lcSSc is clinically useful (Table 31.2), different endophenotypes with unique constellations of symptoms occur within each subgroup. The SSc-related autoantibodies are associated with certain disease manifestations and are the best predictive biomarkers identified thus far (Steen, 2005). SSc can coexist with other autoimmune diseases, most commonly rheumatoid arthritis, Sjögren's syndrome, polymyositis, systemic lupus erythematosus, and primary biliary cirrhosis.

### Initial Clinical Presentation

Characteristic initial presentation is quite different in patients with the diffuse and limited cutaneous forms of the disease. In dcSSc, the interval between Raynaud's phenomenon and the onset of other disease manifestations is typically short (weeks to months), and in some cases, Raynaud's phenomenon may even be preceded by other disease manifestations. Puffy fingers and soft tissue swelling accompanied by intense pruritus are signs of the early inflammatory "edematous" phase. The disease typically starts in fingers and face. Diffuse hyperpigmentation of the skin, carpal tunnel syndrome, arthralgias, fatigue, and decreased joint mobility are common. During the ensuing weeks to months, the inflammatory edematous phase evolves into the "fibrotic" phase, with skin thickening associated with loss of hair. Progressive flexion contractures of the fingers can follow. Inflammatory joint pain and associated morning stiffness in the wrists, elbows, shoulders, hip girdles, knees, and ankles can be present. While advancing skin involvement is the most visible manifestation of early dcSSc, important and clinically silent internal organ involvement can occur during this stage. Gastrointestinal reflux disease (GERD) can be an early symptom. The initial 4–5 years from disease onset generally delineates the period of most rapidly evolving pulmonary and renal damage. If significant organ failure does not emerge during this phase of dcSSc, the systemic process may stabilize, although certain organ manifestations such as ILD and GI involvement can progress even after the initial period.

Compared to dcSSc, the course of lcSSc tends to be more indolent. The interval between onset of Raynaud's phenomenon and other disease manifestations such as distal skin thickening, GERD, and calcinosis can be several years or even decades. Scleroderma renal crisis, significant ILD, and tendon friction rub are rare in lcSSc, while PAH, and overlap with keratoconjunctivitis sicca, polyarthritis, cutaneous vasculitis, and biliary cirrhosis can develop in the later stages of this disease subtype.

**TABLE 31.5** Clinically Significant Organ Involvement IN Systemic Sclerosis (SSc)

Feature	Limited cutaneous SSc (%)	Diffuse cutaneous SSc (%)
Skin involvement	90 <sup>a</sup>	100
Raynaud's phenomenon	99	98
Digital ischemic ulcers	50	25
Esophageal involvement	90	80
Interstitial lung disease	35	65
Pulmonary arterial hypertension	15	15
Myopathy	11	23
Clinical cardiac involvement	9	12
Scleroderma renal crisis	0–2	15

<sup>a</sup>Approximately 10% of the patients limited cutaneous SSc patients have SSc sine scleroderma.

## ORGAN INVOLVEMENT

### Raynaud's Phenomenon

Raynaud's phenomenon is the most frequent extracutaneous manifestation of SSc. It is characterized by episodes of reversible vasoconstriction in the fingers and toes, sometimes also affecting the tip of the nose and earlobes. Episodes ("attacks") can be triggered by cold temperature, as well as emotional stress and vibration, and characteristically start with digital pallor due to decrease in blood supply, followed by cyanosis of variable duration. Hyperemia ensues spontaneously or with rewarming of the digit and is typically the most painful phase of Raynaud's phenomenon. The progression of the three color phases reflects the underlying vasoconstriction, ischemia, and reperfusion. If Raynaud's phenomenon occurs without any underlying disease, it is classified as primary. Primary Raynaud's phenomenon (Raynaud's disease) is relatively common in the general population. A recent metaanalysis of 33 studies assessing 33,733 participants showed that the pooled prevalence of primary Raynaud's phenomenon is 4.85% ([Garner et al., 2015](#)). Secondary Raynaud's phenomenon occurs in SSc as well as in other connective tissue diseases, hematological conditions associated with hyperviscosity, and occupational disorders, and can complicate treatment with beta-blockers and anticancer drugs such as cisplatin and bleomycin. Distinguishing primary from secondary Raynaud's phenomenon is important, as secondary Raynaud's phenomenon can be an early symptom of SSc or other underlying conditions. Primary Raynaud's phenomenon is supported by the following: earlier age of onset; absence of an underlying cause; absence of digital tissue necrosis or ischemic ulceration; and a negative ANA. Secondary Raynaud's phenomenon tends to occur at an older age (>30 years), is more severe (episodes more frequent, prolonged, and painful), and is associated with ischemic digital ulcers and loss of digits.

Nailfold capillaroscopy using videocapillaroscopy, low-power stereoscopic microscope, or ophthalmoscope permits visualization of nailfold cutaneous capillaries. Primary Raynaud's phenomenon is associated with evenly spaced parallel vascular loops at the nailfolds, whereas in secondary Raynaud's phenomenon, widened capillaries, reduction of capillary density (drop-outs), irregular new capillary formations can be observed. Thus nailfold capillaroscopy can be a helpful bedside tool for differentiating primary from secondary Raynaud's phenomenon, moreover, nailfold capillaroscopic findings (enlarged capillaries and/or capillary loss with or without pericapillary hemorrhages) are included as criteria in the revised SSc classification ([van den Hoogen et al., 2013](#)).

### Skin Features

Bilateral symmetrical skin thickening is the hallmark of SSc that distinguishes it from other connective tissue diseases. Skin involvement starts in the fingers and characteristically advances from distal to proximal extremities in an ascending fashion. Some patients notice diffuse hyperpigmentation without sun exposure early in the course of the disease. In dark-skinned individuals, vitiligo-like hypopigmentation may occur. Because the pigment in the perifollicular areas is spared, the skin may have a "salt-and-pepper" appearance that is most prominent on the scalp, upper back, and chest. Dermal sclerosis obliterating hair follicles, sweat glands, and eccrine and sebaceous glands causes hair loss, decreased sweating, and dry and itchy skin on the extremities. Pruritus is a prevalent manifestation and is associated with decreased perceived health ([El-Baalbaki et al., 2010](#)). In a recent observational study, pruritus was present in 43% of the patients and was associated with more extensive skin and GI involvement ([Razykov et al., 2013](#)). Skin thickening can lead to fixed flexion contracture and shortening of tendons and muscle atrophy in the underlying tissue. Thick ridges at the neck due to firm adherence of skin to the underlying platysma muscle can limit neck extension.

In established SSc, the face assumes a characteristic "mauskopf" appearance with taut and shiny skin, and loss of wrinkles. In advanced disease, the patients display an expressionless Parkinsonian facies due to reduced mobility of the eyelids, cheeks, and mouth. Thinning of the lips with accentuation of the central incisor teeth and prominent perioral radial furrowing (rhytides) complete the picture. Reduced oral aperture (microstomia) can interfere with oral hygiene and dental care. This can be especially problematic because SSc patients are at risk for accelerated dental decay and gum disease due to xerostomia. The nose assumes a pinched, beak-like appearance.

In late-stage disease, the skin is thin and atrophic, and loss of subcutaneous fat tissue leads to a "bound-down," tethered skin. Dilated skin capillaries 2–20 mm in diameter (telangiectasia) that are reminiscent of hereditary hemorrhagic telangiectasia occur, most frequently on the face, hands, lips, and buccal mucosa. Presence of telangiectasia has been included in the revised SSc classification criteria ([van den Hoogen et al., 2013](#)). Moreover,

the number of telangiectasia correlates with the severity of microvascular disease and PAH. The breakdown of atrophic skin can lead to recurrent ulcerations at the extensor surfaces of the proximal interphalangeal joints and bony prominences such as elbows and malleoli. These ulcers can be painful, tend to heal slowly, and can become secondarily infected requiring treatment with antibiotics. Healing of ischemic fingertip ulcerations leaves characteristic fixed digital “pits.” Loss of soft tissue at the fingertips and associated resorption of the terminal phalanges (acro-osteolysis) due to ischemia can also occur.

Dystrophic calcifications in the skin, subcutaneous, and soft tissues (calcinosis cutis) in the presence of normal serum calcium and phosphate levels occur in up to 25% of the patients. In a multicenter observational study of 1290 SSc patients, ATA, anti-RNA polymerase III (RNAP), and U1-RNP autoantibodies were significantly less common in patients with calcinosis, while ACA, anti-PM/Scl, and anticardiolipin antibodies were more frequent. In the multivariable model, digital ulcers, female gender, telangiectasia, cardiac disease, GI involvement, ACA positivity, and osteoporosis were independent clinical variables associated with calcinosis (Valenzuela et al., 2016). Calcific deposits represent dystrophic calcifications composed of calcium hydroxyapatite crystals that vary in size from tiny punctate lesions to large conglomerate masses and can be readily visualized on plain radiographs or dual-energy CT. It is thought that tissue damage by inflammation, hypoxia, or local trauma trigger calcium deposition, but the exact underlying mechanism remains elusive. The distal finger pads, palms, extensor surfaces of the forearms, and the olecranon and prepatellar bursae are common locations for calcinosis. The lesions can cause pain and nerve compression, ulcerate through the overlying skin with drainage of chalky white material and secondary infections. Paraspinal sheet calcifications may lead to neurologic complications.

## Pulmonary Features

The two principal forms of lung involvement in SSc, ILD, and PAH, are common and the leading causes of disease-related mortality (Steen and Medsger, 2007; Tyndall et al., 2010). Survival is particularly poor in SSc patients with concurrent presence of these two processes. Less frequent pulmonary complications of SSc include recurrent aspiration complicating chronic GERD, pulmonary hemorrhage due to endobronchial telangiectasia, obliterative bronchiolitis, pleural reactions, restrictive physiology due to chest wall fibrosis, spontaneous pneumothorax, and drug-induced lung toxicity.

### **Interstitial Lung Disease**

While evidence of ILD can be found in up to 65% of the SSc patients by high-resolution computed tomography (HRCT), clinically significant ILD develops in 16%–43%; the frequency varies depending on the method used for its detection (Herzog et al., 2014). Black race, diffuse cutaneous involvement, severe GERD, presence of ATA, or absence of ACA has been shown to be risk factors for SSc-associated ILD. Low FVC or single-breath diffusing capacity of the lung for carbon monoxide ( $D_{LCO}$ ) at initial presentation can indicate the presence of clinically significantly ILD, which need to be confirmed by HRCT imaging. Esophageal dilatation with chronic GERD in SSc causes microaspiration, which can contribute to the development and progression of ILD. In an observational study of 270 SSc patients, increased esophageal diameter on HRCT was associated with more severe radiographic ILD, lower lung volumes, and lower  $D_{LCO}$  (Richardson et al., 2016).

Pulmonary involvement in SSc can remain asymptomatic until it is quite advanced. The most common presenting respiratory symptoms—exertional dyspnea, fatigue, and reduced exercise tolerance—are nonspecific, subtle, and slowly progressive. Chronic dry cough can be a prominent accompanying symptom. In a recent randomized controlled trial (Scleroderma Lung Study II), 61% of the patients with SSc-ILD reported frequent cough at baseline, which was associated with greater dyspnea, more extensive lung involvement on HRCT, lower  $D_{LCO}$ , and more frequent GERD symptoms (Tashkin et al., 2017). Physical examination may reveal fine “Velcro” crackles at the lung bases. Pulmonary function testing (PFT) is only moderately sensitive for detecting early pulmonary involvement. It helps to identify a restrictive respiratory pattern and exclude obstructive disease (e.g., chronic obstructive pulmonary disease). The characteristic constellation is low FVC, normal FEV1/FVC ratio, and decreased  $D_{LCO}$ . A disproportionately decreased  $D_{LCO}$  compared to the change in FVC might point to pulmonary vascular disease (i.e., PAH) in SSc. Oxygen desaturation with exercise is common.

Chest radiography can be used to rule out infection and other causes of pulmonary involvement, but compared to HRCT, it is relatively insensitive for detection of early ILD. HRCT may demonstrate bilateral lower lobe subpleural reticular linear opacities and ground-glass opacifications, even in asymptomatic patients with

normal PFTs. Mediastinal lymphadenopathy, pulmonary nodules, and traction bronchiectasis can also be found on HRCT. The typical radiographic finding is the NSIP pattern. However, a minority of patients show the UIP pattern on HRCT with prominent honeycombing.

### Pulmonary Arterial Hypertension

PAH resulting from the vascular remodeling of small ( $<500\text{ }\mu\text{m}$ ) pulmonary arteries develops in 8%–12% of the patients with SSc and occurs as an isolated abnormality or in association with ILD. PAH must be confirmed by right-heart catheterization and is defined based on the following hemodynamic parameters: mean pulmonary artery pressure  $\geq 25\text{ mmHg}$  at rest with a pulmonary capillary wedge pressure  $\leq 15\text{ mmHg}$  and pulmonary vascular resistance  $>3$  Wood units. The natural history of SSc-associated PAH is highly variable but can show rapid deterioration once right-heart failure develops. The observational Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma Registry of 131 SSc patients with PAH showed 1-, 2-, and 3-year cumulative survival rates of 93%, 88%, and 75%, respectively. On the multivariable analysis, age  $>60$  years, male sex, functional class IV,  $D_{\text{LCO}} < 39\%$  were significant predictors of mortality (Chung et al., 2014a). Mutations in TGF- $\beta$  receptor genes, including BMPR2, which are risk factors for both idiopathic and familial forms of PAH, are not risk loci for SSc-PAH (Koumakis et al., 2012b).

Often asymptomatic in early stages, SSc-PAH may present with symptoms of exertional dyspnea and reduced exercise tolerance. With progression, angina, near-syncope, and symptoms and signs of right-sided heart failure appear. Tachycardia, a loud pulmonic component of the  $S_2$  heart sound, pulmonic/tricuspid regurgitation murmur, palpable right ventricular heave, elevated jugular venous pressure, and dependent edema can be found on physical examination. Doppler echocardiography provides a widely used noninvasive screening method for estimating the pulmonary arterial pressure. While it can be used for screening of PAH, cardiac catheterization is virtually always required to make the diagnosis, because the specificity of Doppler echocardiogram for PAH is poor. Right-heart catheterization can also assess the degree of right-heart dysfunction and rule out other causes of increased right ventricular systolic pressure, including left-heart impairment due to diastolic dysfunction. Distinguishing PAH from pulmonary hypertension secondary to pulmonary fibrosis and hypoxia in SSc can be difficult. Serum levels of N-terminal probrain natriuretic peptide (NT proBNP) correlate with the presence and severity of PAH, as well as survival. While NT proBNP measurements can be useful in screening for PAH and in monitoring the response to treatment, its elevation is not specific for PAH and can be seen in both right and/or left-heart disease.

Despite more favorable hemodynamics, the prognosis of SSc-associated PAH is worse than idiopathic PAH, and treatment responses are poorer. This difference is thought to reflect frequent concurrence of ILD, GI, and cardiac disease in SSc. Moreover, patients with SSc-PAH have higher mortality than those with PAH due to other connective tissue diseases. In the Registry to Evaluate Early and Long-Term PAH Management database, SSc-PAH patients had a 3-year survival rate of 61% versus 81% in those with PAH associated with other connective tissue diseases. In multivariable analysis, male sex, age  $>60$  years, systolic BP  $\leq 110\text{ mmHg}$ , 6-minute walk distance  $<165$ , and elevated right arterial pressure and pulmonary vascular resistance were independent predictors of mortality in SSc-PAH (Chung et al., 2014b).

## GASTROINTESTINAL INVOLVEMENT

GI involvement occurs in up to 90% of the SSc patients and is equally prevalent in dcSSc and lcSSc (Table 31.6). The pathologic findings of smooth muscle atrophy accompanied by fibrosis and variable inflammatory infiltrates are similar throughout the length of the GI tract. GI involvement contributes to a reduced quality of life, malnutrition, fatigue, and increased mortality (Tyndall et al., 2010; Assassi et al., 2011).

### Upper Gastrointestinal Tract Involvement

Decreased oral aperture interferes with regular dental hygiene. Teeth are loosened due to the loss of periodontal ligament attaching teeth to the alveolar bone. In addition, dental and oral problems are often aggravated by xerostomia, shortened frenulum, and resorption of the mandibular condyles. Most of the patients with SSc develop symptomatic GERD with prominent heartburn, regurgitation, and dysphagia, and GERD can be a presenting symptom of the disease. GERD is caused by a combination of reduced lower esophageal sphincter

**TABLE 31.6** SSc-Related Autoantibodies and Their Demographic and Clinical Correlates

Antibody	Demographic and clinical associations
Antitopoisomerase I (Scl-70)	Diffuse disease, ILD, poorer survival
Anticentromere	Limited disease, calcinosis, better survival
Anti-RNA polymerase III	Diffuse disease, PAH, scleroderma renal crisis, GAVE, cancer
Anti-Pm-Scl	Limited disease, polymyositis and dermatomyositis, better survival
Anti-U3-RNP (antifibrillarin)	African American race, PAH, poorer survival

GAVE, gastric antral vascular ectasia; ILD, interstitial lung disease; PAH, pulmonary arterial hypertension.

pressure resulting in reflux, impaired esophageal clearance of refluxed gastric contents due to diminished motility, and delayed gastric emptying. Calcium channel antagonists and phosphodiesterase inhibitors that are commonly used in SSc to treat Raynaud's phenomenon can further worsen GERD. Esophageal manometry shows abnormal motility in most of the patients, even in the absence of GERD symptoms. Extraesophageal manifestations of GERD include hoarseness, chronic cough, and recurrent microaspiration, which can result in pulmonary infections and worsening ILD. A dilated patulous esophagus with intraluminal air is often seen on HRCT. While endoscopy is not always necessary to diagnose upper GI tract involvement in patients with SSc, this diagnostic modality is occasionally indicated to rule out opportunistic infections with *Candida*, herpes virus, and cytomegalovirus. Since SSc patients with Barrett's metaplasia, a complication of chronic reflux, are at risk for developing adenocarcinoma, such patients should undergo regular surveillance endoscopy with biopsy. SSc patients can also develop esophageal strictures which can cause severe dysphagia and weight loss. Esophageal strictures can be treated with endoscopic dilation.

Gastroparesis is common in SSc and is manifested by early satiety, abdominal distention, and aggravated reflux symptoms. Barium contrast studies are neither sensitive nor specific for evaluation of gastric involvement in this setting. Gastric antral vascular ectasia (GAVE) in the antrum can be detected. These subepithelial lesions, reflecting the diffuse small-vessel vasculopathy of SSc, are described as "watermelon stomach" due to their characteristic endoscopic appearance (Watson et al., 1996). GAVE lesions can intermittently bleed, leading to chronic anemia, or less commonly severe acute anemia. Asymptomatic GAVE lesions appear to be more common in SSc than initially thought. In a recent randomized controlled trial (Scleroderma: Cyclophosphamide or Transplant), 22% of the 103 SSc patients with early-stage diffuse cutaneous disease who underwent upper GI endoscopy were found to have evidence of GAVE (Hung et al., 2013). GAVE lesion with active bleed can be treated with endoscopic cauterization.

### Lower Gastrointestinal Tract and Anorectal Involvement

Weight loss and malnutrition due to impaired intestinal motility, malabsorption, and chronic diarrhea secondary to bacterial overgrowth are significant complications of SSc involvement of the lower GI tract, and can lead to fat and protein malabsorption, vitamin B<sub>12</sub>, and vitamin D deficiency. The disturbed intestinal motor function can also lead to intestinal pseudo-obstruction. The symptoms can be indistinguishable from those of delayed gastric emptying. The recurrent episodes of acute abdominal pain, nausea, and vomiting, and radiographic studies showing acute intestinal obstruction are presenting symptoms and signs. A major diagnostic challenge in the acute setting is differentiating pseudo-obstruction, which typically responds to supportive care and intravenous nutritional supplementation, from mechanical obstruction requiring surgical intervention. SSc patients are also at risk for bacterial overgrowth, characteristically presenting as severe diarrhea alternating with episodes of constipation.

Fecal incontinence is a commonly underrecognized GI manifestation of SSc and can be the source of considerable patient distress and embarrassment. An occasional radiologic finding is pneumatisis cystoides intestinalis, caused by air trapping in the bowel wall that may rarely rupture and cause benign pneumoperitoneum. In the setting of SSc, pneumatisis cystoides is usually benign and responds to conservative management (Kaneko et al., 2016). Primary liver involvement is rare in SSc. However, biliary cirrhosis is seen in 2% of the patients and is generally associated with ACA positivity (Assassi et al., 2009a).

## RENAL INVOLVEMENT: SCLERODERMA RENAL CRISIS

Scleroderma renal crisis is a major complication of SSc and was a leading cause of death in the preangiotensin-converting enzyme (ACE) inhibitor era. Patients present with accelerated hypertension accompanied by progressive failure. This complication develops in 5%–15% of the patients, and almost invariably occurs within 4 years of disease onset (Penn et al., 2007). Rarely, scleroderma renal crisis can be the presenting manifestation of SSc. Prior to the advent of ACE inhibitor therapy, short-term survival in scleroderma renal crisis was <10%. The pathogenesis involves obliterative vasculopathy and luminal narrowing of the renal arcuate and interlobular arteries, with consequent intravascular (microangiopathic) hemolysis. Progressive reduction in renal blood flow, aggravated by vasospasm, leads to augmented juxtaglomerular renin secretion and activation of angiotensin II, with further renal vasoconstriction resulting in a vicious cycle that culminates in accelerated hypertension. Risk factors for scleroderma renal crisis include early-stage disease, diffuse cutaneous involvement, and the presence of tendon friction rub (Avouac et al., 2016; Hudson et al., 2014). Up to 50% of the patients with scleroderma renal crisis have RNAP3 antibodies, whereas this complication is exceedingly rare in SSc patients with ACA antibodies. Palpable tendon friction rubs, pericardial effusion, new unexplained anemia, and thrombocytopenia may be the clinical signs of impending scleroderma renal crisis. Daily home monitoring of blood pressure and immediate notification of treating physician in case of hypertension are the recommended strategies in SSc patients at risk for scleroderma renal crisis. Treatment with prednisone has been linked to scleroderma renal crisis and should be avoided in high-risk patients. If prednisone is absolutely required, it should be prescribed in doses below <10 mg and given for short periods of time (Steen and Medsger, 1998). Patients with scleroderma renal crisis characteristically present with accelerated hypertension (generally >150/90 mmHg) and progressive oliguric renal insufficiency. However, approximately 10% of the patients with renal crisis do not have elevated blood pressure. Normotensive renal crisis is associated with poorer outcome, which might be related to delayed diagnosis.

Symptoms of elevated blood pressure such as headache, blurred vision, encephalopathy, congestive heart failure, and pulmonary edema may be present. Urinalysis typically shows mild proteinuria, granular casts, and microscopic hematuria; moderate thrombocytopenia and microangiopathic hemolysis with fragmented red blood cells can be seen. If scleroderma renal crisis is untreated, rapidly progressive oliguric renal failure generally ensues. Scleroderma renal crisis is occasionally misdiagnosed as TTP or other forms of TMAs. Prompt differentiation from TTP is important because these two conditions are treated differently, with early ACE-inhibitors effective in the former while plasma exchange used in the latter. When the differential between scleroderma renal crisis and TTP remains unsettled, cautious renal biopsy and determination of serum vWF-cleaving protease (ADAMTS13) activity can aid in establishing the correct diagnosis. Baseline oliguria or serum creatinine >3.0 mg/dL predicts poor outcome of renal crisis (permanent hemodialysis or early mortality). In addition, biopsy findings of extensive renal vascular thrombosis and glomerular ischemic collapse portend poor outcomes.

Rarely, rapidly progressive crescentic glomerulonephritis occurs in the setting of SSc and may be associated with myeloperoxidase-specific antineutrophil cytoplasmic antibodies. Asymptomatic renal function impairment occurs in up to half of SSc patients. This is associated with other vascular manifestations of SSc and rarely progresses to renal failure.

## CARDIAC INVOLVEMENT

Although it is often clinically silent and asymptomatic, cardiac involvement is detected in 10%–50% of the SSc patients screened with sensitive diagnostic tools. Clinically apparent cardiac involvement occurs more frequently in patients with dcSSc and inflammatory myositis. It can be primary, or secondary to SSc-associated PAH, ILD, or renal involvement, and is a marker of poor outcomes. All three anatomic components of heart, endocardium, myocardium, and pericardium may be affected separately or together. Pericardial manifestations include pericarditis, mild-to-moderate pericardial effusions, constrictive pericarditis, and, rarely, cardiac tamponade. Conduction system fibrosis may be manifested by heart block. Electrocardiogram (EKG) abnormalities are common in SSc patients and are associated with more severe heart and lung involvement. In particular, complete right bundle branch block in setting of SSc is highly predictive of mortality (Draeger et al., 2013).

Widespread microvascular involvement, recurrent vasospasm, and ischemia-reperfusion injury contribute to patchy myocardial fibrosis, which can lead to systolic or diastolic left ventricular dysfunction that may be

asymptomatic or progress to overt heart failure. Diastolic dysfunction, in particular, is common in SSc. In an observational study of 153 patients, left ventricular diastolic dysfunction was present in 23%, while left ventricular systolic dysfunction occurred in 5%, particularly in patients with longer disease duration (Hinchcliff et al., 2012). Acute or subacute myocarditis leading to left ventricular dysfunction may occur and are best identified using cardiac magnetic resonance imaging (cMRI), while endomyocardial biopsy is used less commonly. The typical cMRI finding is delayed enhancement which is thought to correspond to fibrotic bands found on histology. While conventional echocardiography has low sensitivity for detecting preclinical heart involvement in SSc, newer diagnostic modalities such as tissue Doppler echocardiography, cMRI, and nuclear imaging (single-photon emission CT) reveal a high prevalence of myocardial function or perfusion abnormalities. The serum levels of NT proBNP have utility as markers of primary cardiac involvement; however, this biomarker can also be elevated in other forms of SSc cardiac involvement and pulmonary hypertension.

## MUSCULOSKELETAL COMPLICATIONS

Musculoskeletal complications are very common in SSc. Carpal tunnel syndrome, generalized arthralgia, and stiffness are prominent in early disease and may be the presenting symptoms. The mobility of both small and large joints is progressively impaired, and fixed contractures develop at the proximal interphalangeal joints and wrists. Large joint contractures can be seen in dcSSc and, when they affect the knees or ankles, can lead to fixed contractures that interfere with walking. Tendon friction rubs in dcSSc are characterized by coarse leathery crepitation heard or palpated upon passive joint movement. Tendon rubs are due to extensive fibrosis and adhesion of the tendon sheaths and fascial planes at the affected joint and are associated with increased risk for renal crisis and progression of skin disease (Avouac et al., 2016). Synovitis can occur and is an independent predictor of skin progression (Avouac et al., 2016). Occasional SSc patients develop a seronegative erosive polyarthritis in the hands, and up to 10% have an overlap disease with seropositive rheumatoid arthritis. In SSc, detection of synovitis on physical examination can be hampered by the presence of puffy hands, and the swollen joint count has a poor interobserver reliability in this setting. Musculoskeletal ultrasound is therefore increasingly utilized for the diagnosis of SSc-related synovitis (Gordon et al., 2017). Muscle weakness is common in SSc, and multifactorial deconditioning, disuse atrophy, malnutrition, muscle inflammation, and fibrosis may all contribute. In patients with dcSSc, a chronic noninflammatory myopathy, characterized by atrophy and fibrosis with only mildly elevated muscle enzymes, may be commonly seen. Active inflammatory myositis with proximal muscle weakness and elevated muscle enzyme levels may also occur. Bone resorption is prominent in the terminal phalanges and can lead to loss of the distal tufts (acro-osteolysis). Resorption of the mandibular condyles can cause bite difficulties. Osteolysis may also affect the ribs and distal clavicles.

## LESS RECOGNIZED DISEASE MANIFESTATIONS

Dry eyes and dry mouth (sicca complex) are common complications of SSc. Biopsy of the minor salivary glands typically shows fibrosis rather than focal lymphocytic infiltration characteristic of primary Sjögren's syndrome. Hypothyroidism resulting from Hashimoto disease is common, particularly in lcSSc, and may be underrecognized. The central nervous system is generally not affected in patients with SSc, but unilateral or bilateral sensory trigeminal neuropathy has been recognized. Increased prevalence of peripheral neuropathy manifesting as loss of vibration sensation and/or inability to sense fine filaments has been reported (Frech et al., 2013). Erectile dysfunction is a frequent complication and may be an unrecognized initial manifestation of the disease. Inability to attain or maintain penile erection is caused by vascular insufficiency and fibrosis of corporal smooth muscle. Phosphodiesterase inhibitors have been safely used for the treatment of SSc-associated erectile dysfunction. Sexual performance is also adversely affected in women with SSc. While fertility does not appear to be significantly impaired in SSc, the rate of pregnancy complications is increased. In a prospective study of 99 pregnant patients with SSc, a higher frequency of preterm deliveries and intrauterine growth restrictions was reported. While disease remained stable in most of the SSc patients during pregnancy, four cases of disease progression within 1-year postpartum occurred, all in patients who were positive for ATA (Taraborelli et al., 2012).

## Cancer

Multiple epidemiologic studies indicate an increased cancer risk in patients with SSc. In particular, substantially increased risk of lung cancer (relative risk 4.3) and hematological malignancies (relative risk: 2.2) was confirmed in the metaanalysis (Bonifazi et al., 2013). Occasionally, cancer occurs in close temporal association with the onset of SSc, particularly in patients with RNAP antibodies. A close temporal relationship between disease onset and cancer diagnosis has also been recently described in SSc patients with rare anti-RNPC-3 antibodies with speckled immunofluorescence (Shah et al., 2017; Xu et al., 2016). In these contexts, SSc may represent a paraneoplastic syndrome that is triggered by the antitumor immune response.

## BIMARKERS AND AUTOANTIBODIES IN SYSTEMIC SCLEROSIS

SSc is associated with highly specific autoantibodies, which to date are the best biomarkers predictive of specific organ manifestations. SSc-specific autoantibodies tend to be mutually exclusive and highly specific (Arora-Singh et al., 2010; Steen 2005). However, multiple antibodies can be detected occurring in combination when determined by novel multiplex assays (Mehra et al., 2013). The relative frequency of the SSc-associated autoantibodies varies according to geographic regions and patient ethnicity.

The importance of SSc-autoantibodies in the clinical setting is underscored by the fact that presence of ACA, ATA, or anti-RNA polymerase III (RNAP) antibodies is included in the 2013 American College of Rheumatology/European League Against Rheumatism Classification Criteria (Table 31.1) (van den Hoogen et al., 2013).

Approximately 96% of the SSc patients have ANA. While ANA-negative SSc patients experience less vasculopathic complications (e.g., PAH, telangiectasia, ischemic digital ulcers, and pits) compared to ANA-positive SSc patients, they are more likely to have GI manifestations (Salazar et al., 2014).

Table 31.6 shows the frequency and prominent clinical associations of SSc-antibodies. ATA (also called anti-Scl-70) antibody is more common among Black and Asian patients, and is associated with diffuse cutaneous involvement and increased risk for progressive ILD (Steen, 2005; Nihtyanova et al., 2014; Assassi et al., 2010a; Wang et al., 2013; Steen et al., 2012). By contrast, ACA, more common in whites, is associated with limited cutaneous involvement, while clinically significant ILD is rare and survival rates are better. ACA is also associated with calcinosis and cooccurrence of biliary cirrhosis (Nihtyanova et al., 2014; Steen et al., 2012; Ioannidis et al., 2005; Assassi et al., 2009b). The frequency of anti-RNAP3 antibodies in SSc varies widely based on ethnicity and geographic region. With a prevalence of 15%–17%, it is more common in the United States, United Kingdom, and Australia (Nihtyanova et al., 2014; Nikpour et al., 2011; Nandiwada et al., 2016) than in the continental Europe (around 6%) (Sobanski et al., 2014), and appears to be rare in Asia (1%–4%) (Wang et al., 2013). RNAP is associated with diffuse cutaneous involvement and scleroderma renal crisis (odds ratios ranging from 5 to 17.5) (Nihtyanova et al., 2014; Nikpour et al., 2011; Nguyen et al., 2011) and GAVE (Ghrenassia et al., 2014). Clinically advanced ILD is rare in SSc patients with RNAP, while PAH was common in a large single-center study (Nihtyanova et al., 2014).

A higher prevalence of contemporaneous onset of cancer and SSc in patients with RNAP compared with the other two SSc-specific autoantibodies has been reported in five independent cohorts (Nikpour et al., 2011; Shah et al., 2010; Moinzadeh et al., 2014; Airo' et al., 2011; Lazzaroni et al., 2017). Levels of nucleolar RNA polymerase III were increased in tumor samples from SSc patients with RNAP but not in SSc patients with other SSc-specific autoantibodies (Shah et al., 2010). Moreover, alterations of the gene encoding polymerase III polypeptide A were found in the tumors from six out of eight SSc patients with RNAP, but none of eight RNAP-negative SSc patients, supporting a potential link between cancer-associated somatic mutations and an anticancer immune response driving disease in this serological subset (Joseph et al., 2014b).

Two less common SSc-related antibodies (anti-PM-Scl and anti-U3-RNP; also called antifibrillarin) with a nucleolar immunofluorescence pattern are increasingly recognized. PM-Scl antibody is associated with SSc overlap with other connective tissue diseases (particularly polymyositis-dermatomyositis), limited cutaneous involvement, calcinosis, and better survival (D'Aoust et al., 2014; Koschik et al., 2012). Anti-U3-RNP antibodies are found in about 5% of the White patients but are considerably more frequent among Black (18%–27%) and Native North American patients (Mejia Otero et al., 2017; Aggarwal et al., 2009). These antibodies are associated with PAH and increased mortality (Nihtyanova et al., 2014; Mejia Otero et al., 2017; Aggarwal et al., 2009).

The specificity and clinical utility of other SSc biomarkers remain less well-established. Elevation in the levels of C-reactive protein (CRP) in SSc was associated with more severe skin and lung involvement in two independent cohorts. More importantly, higher CRP was associated with faster ILD progression and shorter survival (Muangchan et al., 2012; Liu et al., 2013a). In a recent randomized trial of the anti-IL-6 agent tocilizumab, high CRP at baseline was used as a strategy to enrich the study population for patients with progressive disease (Khanna et al., 2016). There are contradicting results on the utility of serum proteins as markers of SSc-associated ILD. In a recent Japanese study, the elevated baseline serum levels of Krebs von den Lungen-6 (KL-6) in SSc were predictive of end-stage ILD (Kuwana et al., 2016). Other studies have identified the chemokine CXCL4, and serum amyloid A, as potential biomarkers for SSc-associated ILD (Lakota et al., 2015; van et al., 2013; Volkmann et al., 2016).

SSc is associated with distinct transcriptome profiles in both blood cells and tissue biopsies (Tan et al., 2006; Whitfield et al., 2003). A type 1 IFN gene expression profile in peripheral blood cells in SSc is similar to that noted in patients with SLE and correlates with the severity of skin, lung, and muscle involvement (Assassi et al., 2010b; Liu et al., 2013b). Furthermore, it has been suggested that SSc patients can be categorized on the basis of their skin gene expression profile, including a subgroup with a prominent inflammatory gene signature (Assassi et al., 2015; Milano et al., 2008). Emerging evidence suggests that SSc patients in this gene expression subgroup might have a better response to immunosuppression (Hinchcliff et al., 2013). Sufficiently powered longitudinal studies will be needed to determine whether tissue-specific transcriptome signatures robustly define specific SSc subsets and predict therapeutic responses and whether they contribute to clinical decision-making and selection of focused and effective treatments in a precision medicine approach (Varga and Hinchcliff, 2014).

## SCREENING AND FOLLOW-UP EVALUATION

Once the diagnosis of SSc is established, patients undergo initial screening for the presence of internal organ involvement. Screening includes Doppler echocardiography, chest HRCT, and PFT to detect evidence of cardiopulmonary involvement. In patients with SSc, HRCT is a sensitive method to detect early signs of ILD, even in patients with normal lung function, and is generally obtained at the initial visit. Bronchoalveolar lavage and lung biopsy are generally not required to establish the diagnosis of SSc-ILD but might be indicated in some cases of SSc to rule out infection or cancer in the setting of atypical imaging or clinical symptomatology. Basic metabolic panel and urinalysis can aid in identifying renal involvement, while muscle enzymes screen for myopathy or inflammatory myositis. Determination of ANA and SSc-related autoantibody profiles provides valuable prognostic information. The extent of skin involvement is typically assessed using the modified Rodnan Skin Score, a validated clinical outcome measure to assess skin thickness (distinct from skin tethering) in 17 distinct body surface areas assigned a score on a scale 0–3 (0 = normal skin; 1 = mild thickness; 2 = moderate thickness; 3 = severe thickness with inability to pinch the skin into a fold) (Furst et al., 2007; Furst et al., 1998). The modified Rodnan Skin Score is the sum of scores in the 17 assessed body areas.

Repeated assessment of the skin score during follow-up visits (optimally performed by the same examiner) can establish the temporal trajectory of skin involvement. PFT and echocardiographic assessments are generally performed on a regular (yearly) basis to monitor for development or progression of cardiopulmonary involvement. The FVC% predicted is a validated outcome measure for SSc-ILD and can be followed longitudinally to assess the course of ILD in this setting (Furst et al., 2007). The  $D_{LCO}$  is also decreased in ILD, but a decrease that is disproportionate (compared to  $D_{LCO}$ ) might indicate pulmonary vascular involvement. While the extent of radiologic lung fibrosis on HRCT has prognostic value for disease course and mortality (Goh et al., 2008), HRCT imaging is not repeated routinely due to concerns regarding radiation exposure. Repeat HRCT may be indicated in SSc if an unexplained decline in lung volumes on PFT, worsening dyspnea, or other respiratory symptoms occurs.

In light of the poor prognosis of untreated PAH, and better therapeutic response in early-stage disease, all SSc patients should be screened for PAH at initial evaluation, followed by serial reevaluation performed annually. Doppler echocardiography is an informative and widely used tool for PAH screening. Estimated pulmonary artery systolic pressure >40 mmHg at rest or tricuspid regurgitation jet velocities >3 m/s on echocardiography suggest the presence of PAH. However, as these findings are not specific, suspected PAH needs to be verified by hemodynamic measurements determined by right-heart catheterization. Right-heart catheterization is also necessary for excluding alternate causes of pulmonary hypertension such as diastolic dysfunction.

A multicenter cross-sectional study of 466 at-risk patients (disease duration >3 years and  $D_{LCO} < 60\%$ ) aimed at optimizing PAH screening strategies. In 19% of the patients, PAH was confirmed by right-heart catheterization. A two-step approach was proposed for determining which SSc patients should undergo right-heart catheterization. In step 1, a prediction score based on the presence of ACA, telangiectasia, right axis deviation on EKG, the  $FVC\% / D_{LCO}\%$  ratio, and elevated levels of serum urate and NT proBNP was developed for a referral to echocardiography. In step 2, a prediction score based on the score from step 1 and the presence of two echocardiographic variables (right atrium area and tricuspid regurgitation velocity) is used for proceeding to right-heart catheterization. This two-step algorithm had a sensitivity of 96% and specificity of 48% for detecting PAH in SSc patients. Interestingly, dyspnea and physical findings related to the right heart and WHO functional class were insufficiently predictive of PAH (Coghlan et al., 2014).

## MANAGEMENT OF SYSTEMIC SCLEROSIS

### General Principles

Although no therapy to date has been shown to significantly alter the natural history of SSc, selected interventions can be highly effective in alleviating specific symptoms, slowing progressive accrual of organ damage, and mitigating disability. In light of the marked patient-to-patient heterogeneity in SSc manifestations and natural history, a thoughtful “precision medicine” approach that is tailored specifically to each individual’s unique needs is recommended.

Our approach to the patient with SSc is guided by certain general principles: accurate and timely diagnosis and risk stratification based on clinical, laboratory, and serological evaluation at baseline; prompt recognition and staging of organ-based complications and assessment of their likelihood of progression; regular monitoring for new complications; and adjusting therapy. To reduce the risk of irreversible organ damage, we advocate a proactive approach with regular screening and initiation of appropriate intervention at the earliest possible opportunity. In light of the complex multisystemic nature of the SSc, a coordinated multispecialty team approach that integrates all appropriate specialists should be pursued. Treatment regimens typically include combinations of therapies that impact different aspects of the disease.

### Disease-Modifying Immunomodulatory Therapy

Immunosuppressive agents that are effective in other rheumatic and autoimmune diseases have generally shown only modest or no benefit in SSc. As an example, glucocorticoids reduce stiffness and aching in early-stage dcSSc, but fail to influence disease progression, and their use is associated with an increased risk of scleroderma renal crisis.

Both oral and intravenously administered cyclophosphamides were shown to slow progression of SSc-associated ILD, with stabilization and modest improvement of respiratory symptoms, pulmonary

function, HRCT findings, and skin induration. These benefits must be carefully balanced against drug-induced bone marrow suppression, opportunistic infections, hemorrhagic cystitis and bladder cancer, premature ovarian failure, and late secondary malignancies.

Mycophenolate mofetil was shown to ameliorate skin induration and ILD and is generally well tolerated in SSc (Tashkin et al., 2016). Tocilizumab, a monoclonal antibody directed against the IL-6 receptor, also showed modest benefit in randomized SSc clinical trials (Khanna et al., 2016). In addition, both open-label studies and small trials support the use of rituximab, a monoclonal antibody directed against the mature B-cell marker CD20. Randomized clinical trials in SSc evaluating the efficacy of abatacept, a fusion protein that inhibits T-cell costimulation, are currently underway. Extracorporeal photochemotherapy (photopheresis) has been shown to have modest clinical efficacy in ameliorating skin involvement in SSc, although the underlying mechanism of action remains largely unknown. Ablation of the immune system with high-dose chemotherapy followed by autologous hematopoietic stem-cell reconstitution (bone marrow transplantation) was associated with durable remission and improved long-term survival in several randomized clinical trials (van Laar et al., 2014). This form of immunomodulatory therapy carries morbidity and even potential treatment-related mortality, as well as significant cost, and is therefore still reserved for carefully selected patients. While cyclosporine, azathioprine, plaquenil, thalidomide, and rapamycin are often used in the treatment of SSc, their efficacy in this setting is currently inadequately supported by the literature.

### Therapy Targeting Fibrosis

Because tissue fibrosis underlies progressive multorgan damage in SSc, drugs that interfere with the fibrotic process or speed its resolution represent rational therapeutic options (Distler et al., 2017). Recent studies show modest benefit of two novel drugs, pirfenidone and the multikinase inhibitor nintedanib, in patients with idiopathic pulmonary fibrosis. Whether these

*(cont'd)*

antifibrotic drugs have comparable efficacy and tolerability in SSc-associated ILD and other manifestations of the disease, is currently under investigation.

### Vascular Therapy

The goal of vascular therapy is to reduce the frequency, duration, and severity of vasospastic episodes, enhance ischemic ulcer healing, prevent critical ischemic episodes, and slow the progression of generalized obliterative vasculopathy. Dihydropyridine calcium channel blockers (such as amlodipine and diltiazem) are effective in ameliorating Raynaud's, but their use can be limited by palpitations, dependent edema, and worsening gastroesophageal reflux. While widely used for treating Raynaud's, ACE inhibitors do not appear to reduce the frequency or severity of episodes. In contrast, angiotensin II receptor blockers such as losartan are effective and well tolerated in this setting. Patients unresponsive to these therapies may require the addition of 5-phosphodiesterase inhibitors (e.g., sildenafil), topical nitroglycerine, and in severe cases, intermittent IV infusions of prostaglandins such as treprostinil. Low-dose aspirin and dipyridamole inhibit platelet aggregation and may have a role as adjunctive agents. Patients with non-healing ischemic digital ulcerations may respond to the endothelin-1 receptor antagonists, digital sympathectomy, and intradigital injections of botulinum (Botox) or nerve block. Empirical long-term therapy with statins and antioxidants may retard microvascular damage and obliteration, but their efficacy in SSc has not been demonstrated. While there is limited evidence-based information regarding the treatment of cardiac complications of SSc, nondihydropyridine calcium channel blockers are often used for atrial arrhythmias, and nonselective alpha/beta-blockers such as carvediol for improving myocardial perfusion and left ventricular systolic function.

### Treatment of Gastrointestinal Complications

Common SSc-associated oral problems include reduced saliva production, and decreased oral aperture, gum recession, periodontal disease, and teeth loss. Gastroesophageal reflux may occur in the absence of symptoms. Patients should be instructed to elevate the head of the bed, eat frequent small meals, and avoid known reflux exacerbants such as alcohol, caffeine, or bedtime meals. Proton pump inhibitors are commonly used, sometimes at relatively high doses. Prokinetic agents such as metoclopramide, erythromycin (a motilin agonist), domperidone, and prucalopride may be helpful but are frequently associated with side effects. Surgical antireflux procedures such as Nissen fundoplication can result in secondary achalasia

and generally should be avoided in patients with SSc. Recurrent episodic bleeding from GAVE may be controlled with endoscopic ablation using laser or argon plasma photocoagulation, although recurrences are common. When GI dysmotility is advanced, enteral feeding and decompression via percutaneous gastrostomy or jejunostomy might be required. Bacterial overgrowth secondary to dysmotility of the small bowel causes bloating and diarrhea and may lead to malabsorption and severe malnutrition. In such cases, repeated short courses of rotating broad-spectrum antibiotics such as metronidazole, erythromycin, and rifaximin can be effective by eradicating bacterial overgrowth. Fecal incontinence may respond to antidiarrheal medication, biofeedback therapy, sphincter augmentation, and sacral neuromodulation.

### Treatment of Interstitial Lung Disease

While ILD is a very frequent SSc complication and is a leading cause of death, its course is unpredictable. Some patients with SSc-ILD show little progression of lung disease over time. It is therefore important to identify patients at high risk for ILD deterioration in the absence of treatment. Treatment with cyclophosphamide, given IV or orally for 6–12 months and in combination with low-dose prednisone, or mycophenolate mofetil for up to 2 years, have been shown to slow declining lung function and improve respiratory symptoms (Tashkin et al., 2016). The tolerability and efficacy of antifibrotic agents recently approved for idiopathic pulmonary fibrosis, alone or in combination with immunomodulatory therapies, are currently under investigation for SSc-associated ILD. Carefully screened patients who show continued progression of ILD despite maximal medical therapy might be candidates for lung transplantation. Recurrence of ILD in the lung allograft in SSc patients has not been reported.

### Management of Renal Crisis

The outcome of scleroderma renal crisis has improved considerably since the introduction of ACE inhibitors. Outcomes are largely determined by the extent of renal damage at initiation of aggressive antihypertensive therapy, and prompt recognition of impending or early scleroderma renal crisis is therefore paramount (Woodworth et al., 2016). SSc patients deemed at high risk for renal crisis (early-stage disease, progressive skin involvement, palpable tendon friction rubs, and positive anti-RNA polymerase III antibodies) should monitor their blood pressure daily and promptly report significant alterations. Glucocorticoids should be used sparingly if at all. Patients

(cont'd)

presenting with scleroderma renal crisis should be hospitalized and started on short-acting ACE inhibitors such as captopril. In cases of persistent hypertension, addition of calcium channel blockers, angiotensin II receptor blockers, endothelin-1 receptor blockers, prostacyclins, direct renin inhibitors, and complement pathway inhibitors such as eculizumab could be considered, although so far the evidence for their efficacy comes mostly from case reports. While up to two-thirds of patients with scleroderma renal crisis necessitate dialysis, substantial renal recovery can occur for up to 2 years, and 50% ultimately discontinue dialysis. Outcomes for SSc patients undergoing kidney transplantation for renal crisis are comparable to other indications, and recurrence is rare.

### Treatment of Pulmonary Arterial Hypertension

Despite considerable recent advances in management, PAH still carries a poor prognosis in SSc and accounts

for 30% of the deaths. Treatment is generally started with an oral endothelin-1 receptor antagonist such as bosentan or a phosphodiesterase 5 inhibitor such as sildenafil alone or in combination. Recently, the soluble guanylate cyclase stimulator riociguat, which acts via nitric oxide, and the selective prostacyclin receptor agonist selexipag, were shown to improve PAH symptoms and survival. The prostacyclin analogs epoprostenol or treprostинil can be given by continuous IV or SC infusion, or via intermittent nebulized inhalations. Studies demonstrate that early combination therapy in SSc-PAH with different classes of drugs acting additively or synergistically, is associated with improved outcomes. Lung transplantation remains an option for SSc patients who fail medical therapy for PAH, with survival rates (64% at 2 years) comparable to those of patients transplanted for idiopathic ILD or PAH.

## NATURAL HISTORY AND PROGNOSIS

The natural history of SSc is highly variable and not well predictable. Patient with dcSSc characteristically develop organ complications early and tend to follow a more rapidly progressive course than those with lcSSc. Inflammatory symptoms, such as edema, aching, and pruritus, dominate early-stage disease but generally subside and skin induration reaches a plateau after 2–4 years. However, it is during the early disease stage that life-threatening visceral organ involvement develops. For instance, scleroderma renal crisis almost invariably occurs within the first 4 years of disease. In late-stage disease (>6 years), the skin is usually thin and atrophic, except on the fingers (sclerodactyly). Relapse, progression, or recurrence of skin thickening after the plateau stage has been reached is uncommon. Patients with lcSSc tend to follow a trajectory that is markedly different from dcSSc. In these patients, Raynaud's phenomenon characteristically precedes other disease manifestations by years or even decades. Skin involvement is limited and shows little progression, while visceral organ complications such as PAH and biliary cirrhosis generally develop late and tend to follow an indolent course.

The risk of premature death is substantially increased in all forms of SSc, and age- and gender-adjusted mortality rates are eightfold higher compared to the general population. More than 50% of the SSc patients will die from their disease. In dcSSc, 5- and 10-year survival rates are 70% and 55%, respectively, whereas in lcSSc, 5- and 10-year survival rates are 90% and 75%, respectively. Predictors of poor prognosis include male gender, African American race, older age at onset of disease, extensive skin thickening with truncal involvement, palpable tendon friction rubs, and progressive visceral organ involvement. Laboratory predictors at baseline evaluation include an elevated ESR, anemia, proteinuria, and ATA antibodies. In one study, SSc patients with extensive skin involvement, vital capacity <55% predicted, significant GI involvement (pseudo-obstruction or malabsorption), clinical cardiac involvement, or scleroderma renal crisis had a 9-year survival <40%. Nevertheless, survival rates are improving. For instance, overall 10-year survival rates have increased from <60% in the 1970s to >66%–78% in the 1990s. This positive trend, which is likely reflecting both earlier diagnosis and detection of complications, and better management, is expected to continue.

### GENERAL INTRODUCTION AND HISTORICAL ASPECTS

In 1983, a discrete syndrome was described by Graham Hughes in which lupus patients with antiphospholipid antibodies (aPL) were prone to arterial/venous thrombosis, recurrent abortions, neurological manifestations, and occasional thrombocytopenia (Hughes, 1983). In the following years, the Hughes' syndrome was delineated as a systemic disease that can affect both children and adults and can present as a primary disorder or as secondary to other autoimmune disease (Shoenfeld et al., 2009). The definition of this classical

**TABLE 32.1** Summary of the Sydney Consensus Statement on Investigational Classification Criteria for APS<sup>a</sup>

Antiphospholipid antibody syndrome is present if at least one of the clinical criteria and one of the laboratory criteria that follow are met

#### Clinical criteria

1. Vascular thromboses: One or more documented episodes of arterial, venous, or small vessel thrombosis—other than superficial venous thrombosis—in any tissue or organ. Thrombosis must be confirmed by objective validated criteria. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall
2. Pregnancy morbidity:
  - a. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
  - b. One or more premature births of a morphologically normal neonate before the 34th week of gestation because of (1) eclampsia or severe preeclampsia defined according to standard definitions or (2) recognized features of placental insufficiency, or
  - c. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded

#### Laboratory criteria

1. LA present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (Scientific Subcommittee on LAs/phospholipid-dependent antibodies)
2. aCL antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high level (i.e., 40 GPL or MPL, or the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA
3. Anti-b2-glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma (in level, the 99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA, according to recommended procedures

<sup>a</sup>Miyakis et al. (2006).

aCL, anticardiolipin; LA, Lupus anticoagulant.

autoimmune syndrome has greatly advanced from the original reports and classification criteria for antiphospholipid syndrome (APS) formulated in Sapporo, Japan, in 1998 to the current ones published in 2006 (Miyakis et al., 2006; Cervera and Ra, 2008) (Table 32.1). For the determination of APS, at least one classical clinical criterion [i.e., vascular thrombosis or pregnancy morbidity (PM)] and one serological criterion [i.e., the persistent presence of anticardiolipin (aCL) and/or anti-b2-glycoprotein-I antibody (anti-B2GPI) of IgG or IgM isotype at medium-to-high titers or lupus anticoagulant (LAC)] have to be met. Several new aPL specificities were found, including antibodies directed against domains of B2GPI or coagulation cascade proteins such as prothrombin itself or complexes of prothrombin with phospholipids (i.e., phosphatidylserine/prothrombin complex) (Bertolaccini et al., 2014).

## EPIDEMIOLOGY

aPL may be detected in up to 1%–5% of the general population, but only the minority of aPL-positive individuals develop APS. aPL appearing in healthy subjects are usually detected transiently at low levels and are frequently clinically insignificant (Shoenfeld et al., 2008a; Biggioggero and Meroni, 2010). They are normally found in older individuals and in association with infections, vaccinations, malignancies, and exposure to certain drugs. The prevalence of aPL in systemic lupus erythematosus (SLE) patients ranges between 30% and 40% (Biggioggero and Meroni, 2010).

The Antiphospholipid Syndrome Alliance For Clinical Trials and International Networking conducted a literature review and analyzed the frequency of aPL in patients with PM, stroke (ST), myocardial infarction (MI), and deep venous thrombosis (DVT) (Andreoli et al., 2013a). According to this review, aPL were positive in about 6% of the patients with PM, 13.5% of the patients with ST, 11% of the patients with MI, and 9.5% of the patients with DVT (Andreoli et al., 2013a).

It has been estimated that the incidence of APS is approximately 5 new cases per 100,000 individuals per year and the prevalence is 40–50 cases per 100,000 individuals (Cervera, 2017).

Secondary APS is estimated to appear in 10%–15% of SLE patients and less in other autoimmune diseases. In contrast with aPL-positive healthy individuals, patients with APS either primary or secondary typically present with persistent (more than 12 weeks), high-level aPL seropositivity and significant related morbidity and mortality (Cervera et al., 2009). Catastrophic APS (CAPS) is rare and occurs in less than 1% of all APS cases (Asherson et al., 2003).

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

APS is usually diagnosed following obstetric or thrombotic morbidity. Nonetheless, the clinical spectrum of APS is considered nowadays to be wider and includes systemic and organ-specific symptoms induced by both thrombotic and immune-mediated mechanisms (Shoenfeld, 2007; Marai et al., 2004). In addition, a wide spectrum of clinical presentations may arise due to occlusions in one or several vessels.

The clinical manifestations of 1000 patients with APS that were in the follow up for 10 years within the Euro-Phospholipid project are summarized in **Table 32.2**.

**TABLE 32.2** The Most Common APS Manifestations, According to the “Euro-Phospholipid Project” (at the Beginning of the Study)

Manifestations	%
Peripheral thrombosis	
Deep vein thrombosis	38.9
Superficial thrombophlebitis in legs	11.7
Arterial thrombosis in legs	4.3
Venous thrombosis in arms	3.4
Arterial thrombosis in arms	2.7
Subclavian vein thrombosis	1.8
Jugular vein thrombosis	0.9
Neurologic manifestations	
Migraine	20.2
Stroke	19.8
Transient ischemic attack	11.1
Epilepsy	7.0
Multiinfarct dementia	2.5
Chorea	1.3
Acute encephalopathy	1.1
Pulmonary manifestations	
Pulmonary embolism	14.1
Pulmonary hypertension	2.2
Pulmonary microthrombosis	1.5
Cardiac manifestations	
Valve thickening/dysfunction	11.6
Myocardial infarction	5.5
Angina	2.7
Myocardiopathy	2.9
Vegetations	2.7
Coronary by-pass rethrombosis	1.1
Intraabdominal manifestations	
Renal manifestations (glomerular thrombosis, renal infarction, renal artery thrombosis, renal vein thrombosis)	2.7

*(Continued)*

**TABLE 32.2** (Continued)

Manifestations	%
Gastrointestinal manifestations (esophageal or mesenteric ischemia)	1.5
Splenic infarction	1.1
Cutaneous manifestations	
<i>Livedo reticularis</i>	24.1
Ulcers	5.5
Pseudovasculitic lesions	3.9
Digital gangrene	3.3
Cutaneous necrosis	2.1
Osteo-articular manifestations	
Arthralgia	38.7
Arthritis	27.1
Avascular necrosis of bone	2.4
Ophthalmologic manifestations	
Amaurosis fugax	5.4
Retinal artery thrombosis	1.5
E.N.T. manifestations	
Nasal septum perforation	0.8
Hematological manifestations	
Thrombocytopenia (< 100,000 per $\mu\text{L}$ )	29.6
Hemolytic anemia	9.7
Obstetric manifestations (pregnant female = 590)	
Preeclampsia	9.5
Eclampsia	4.4
<i>Abruptio placentae</i>	2.0
Fetal manifestations (pregnancies = 1580)	
Early fetal losses (< 10 weeks)	35.4
Late fetal losses ( $\geq 10$ weeks)	16.9
Live births	47.7
Prematures	10.6

Adopted from Cervera, R., Piette, J.C., Font, J., Khamashta, M.A., Shoenfeld, Y., Camps, M.T., et al., 2002. Antiphospholipid syndrome: clinical and immunologic manifestations and patterns of disease expression in a cohort of 1,000 patients. *Arthritis Rheum.* 46, 1019–1027.

## Obstetric Antiphospholipid Syndrome

Obstetric complications are a hallmark of APS including fetal and maternal complications and are now recognized as a distinct entity from vascular APS.

Early recurrent miscarriages (less than 10 weeks of gestation) occur in about 1% of the general obstetric population, and out of them 15% are associated with APS.

Fetal complications in obstetric APS (OAPS) patients include prematurity, intrauterine growth restriction due to placental insufficiency, and early and late pregnancy loss. According to the Euro-Phospholipid Project study, during a 10-year period, the prevalence of these events in APS pregnancies was 48%, 26%, 16.5%, and 5%,

respectively (Cervera et al., 2015). Fetal death is considered to be the most specific feature of OAPS, and strong association between fetal loss and the presence of aPL was found (Abou-Nassar et al., 2011; Silver et al., 2013). The most common maternal manifestation of APS is preeclampsia, followed by eclampsia and abruptio placentae.

The assessment of risk for PM in aPL-positive patients is difficult in general because similar clinical manifestations may be associated with different patterns and combinations of aPL. According to the classification criteria, only women with PM and medium-to-high titer aPL should be diagnosed with OAPS. However, patients with low titer aPL can experience poor pregnancy outcomes similar to high titer patients, and therefore current classification criteria do not incorporate all the OAPS cases (Ofer-Shiber and Molad, 2015).

The presence of an associated systemic autoimmune disease, in particular SLE, a history of previous thrombotic events, and complement reduction, has been identified as being predictive of a poor pregnancy outcome (Fredi et al., 2015). In addition, there is evidence that LA and triple positivity may serve as markers of worse outcome (Alijotas-Reig et al., 2015; Yelnik et al., 2016). Angiogenic biomarkers measured as early as the 12th week of pregnancy, in combination with clinical criteria, may be useful to identify patients with aPL at risk of severe adverse pregnancy outcomes (Kim et al., 2016). The possible association between aPL and sterility remains unknown.

No thrombosis or SLE was found in babies born to mothers with APS included in European aPL Forum despite the transplacental transfer of maternal aPL autoantibodies (Mekinian et al., 2013).

One study has reported high prolactin levels in 12% of APS patients, and this hyperprolactinemia was associated with reproductive failure, including early and late pregnancy loss, and intrauterine growth retardation (Praprotnik et al., 2010).

## Thrombotic Antiphospholipid Syndrome

Venous and/or arterial thrombosis are distinctive characteristics of APS (Taraborelli et al., 2012), and vessels in any site and of any size may be involved (Saponjski et al., 2011). Such thrombotic events are the main causes of morbidity and mortality in APS, and they tend to recur particularly in untreated patients (Taraborelli et al., 2012).

The confirmation of thrombosis by an objective method is a requirement of the Sapporo criteria, nowadays performed by a diversity of invasive and noninvasive methods such as angiography, ultrasound, computed tomography (i.e., 64 multislice computed tomographic angiography), and others (Saponjski et al., 2011). Histopathology may also be utilized to confirm the diagnosis of APS-associated thrombosis once there is no evidence of inflammation in the vessel wall (Taraborelli et al., 2012).

DVT, pulmonary embolism (PE), and STs are the most commonly reported. In line with these data, thrombosis was the most common manifestation of APS in the 1000 patients involved in the Euro-Phospholipid project (Cervera et al., 2002). Venous thrombosis in particular DVT of the lower limbs was a presenting symptom in 39% of the patients. Thrombotic events appeared in 166 (16.6%) patients during the first 5-year period of observation and in 118 patients (15.3%) during the second 5-year period. Among these thrombotic events that developed during the 10-year period, the most common were STs (5.3% of the total cohort), transient ischemic attack (TIA) (4.7%), DVT (4.3%), and PE (3.5%). These events were observed in similar proportions during both periods of the study (Cervera et al., 2009, 2015).

Furthermore, thrombotic APS manifestations occurring in atypical sites may cause additional clinical syndromes, including acute coronary syndromes; hepatic arterial or venous (Budd–Chiari syndrome) thrombosis; portal, mesenteric, or splenic ischemia; and pancreatic and adrenal insufficiency secondary to acute vascular infarction.

## Noncriteria Antiphospholipid Syndrome Manifestations

The first definitive classification criteria for APS were formulated during the 8th International Congress on aPL held in Sapporo and were published in 1999 (Wilson et al., 1999). A subsequent revision was later completed during the 11th International Congress on aPL held in Sydney (Miyakis et al., 2006). Initially, these criteria were designed for scientific clinical studies and included major manifestations of APS. Subsequently, they have been adapted for the diagnosis of APS in routine clinical practice.

According to the APS Clinical Features Task Force of the 14th International Congress on aPL, additional common non-criteria manifestations including thrombocytopenia, heart valve disease, renal microangiopathy

(aPL nephropathy), chorea, and longitudinal myelitis may be added to the APS classification criteria (Abreu et al., 2015). However, these features are not yet included in the International Consensus Criteria (Sapporo criteria).

### **Neurological Antiphospholipid Syndrome**

Neurological manifestations were detailed in the original description of APS and have since remained a main cause for morbidity and mortality among patients affected by this syndrome (Hughes, 1983). In APS, ST is the most common and severe complication and is the only manifestation included in APS criteria (Appenzeller et al., 2012). APS-related STs often occur in young patients and have a tendency to recur without an adequate therapy (Andreoli et al., 2013a).

In the Euro-Phospholipid Project Group, it has been demonstrated that the prevalence of ST and TIAs in 1000 APS patients at the beginning of the study was 19.8% and 11.1%, respectively (Cervera et al., 2002). During the 10 years follow-up, STs and TIA occurred in 5.3% and 4.7% of the total cohort, correspondingly (Cervera et al., 2015). In addition to local thrombosis mediated by aPL, valvular heart disease may become a source of emboli and related cerebrovascular events (Andreoli et al., 2013a).

Yet, in the last 30 years, aPL positivity has been correlated with a wide variety of non-ST neurological expressions including headache, cognitive dysfunction, psychosis, depression, dementia, migraine, convulsions, chorea, transverse myelitis, Guillain–Barré syndrome, and a multiple sclerosis-like illness (Chapman et al., 2003; Katzav et al., 2003; Shoenfeld et al., 2004; Rodrigues et al., 2010).

Some syndromes, such as migraine or cognitive dysfunction, are frequently described in APS whereas other neurological manifestations are rare. In addition, cognitive dysfunction is strongly associated with aPL, more than any other neurological non-ST APS presentation (Coín et al., 2015). One study reported that epilepsy was strongly associated with STs and TIA, presence of SLE, valvulopathy, and livedo reticularis (Shoenfeld et al., 2004). A different rare severe manifestation of APS is transverse myelitis, which requires early aggressive immunosuppressive treatment (Sherer et al., 2002).

In addition, APS should be considered in all the unexplained cases of retinal arterial and venous thromboses, as well as in the cases of unusual ocular inflammations, particularly in young individuals (Arnson et al., 2010).

### **Hematologic Antiphospholipid Syndrome**

Thrombocytopenia occurs in 20%–40% of APS patients (Cervera et al., 2002, 2011b) and is associated with systemic involvement (Krause et al., 2005a). According to the Euro-Phospholipid Project Group, thrombocytopenia appeared in 8.7% of the APS patients during the 10 years follow-up (Cervera et al., 2015). It is usually moderate, with platelet counts greater than 50K, rarely associated with major bleeding episodes, and does not require therapeutic intervention.

aPL-positive patients who develop thrombocytopenia without fulfilling the clinical criteria for APS have a potential risk of developing thrombosis. Smoking, LAC, and higher titers of aPL were found to be risk factors for the development of thrombocytopenia (Demetrio Pablo et al., 2017). Hyperferritinemia was found to be linked to thrombocytopenia, LAC, and aCL in SLE patients and it may serve as an early marker for secondary APS in this cohort (Zandman-Goddard et al., 2013).

Autoimmune hemolytic anemia is less frequent and was previously reported to occur in 6%–10% of APS patients (Taraborelli et al., 2012; Rottem et al., 2006). According to Euro-Phospholipid Project, it has appeared in 4% of the patients within during 10 years follow-up (Cervera et al., 2015). A significant association between the presence of aPL and a positive Coombs test as well as the cooccurrence of both autoimmune thrombocytopenia and hemolytic anemia (named Evans syndrome) has been described (Rottem et al., 2006; Cervera et al., 2011b). Lymphopenia and neutropenia are well-recognized features of SLE and therefore are found more commonly in patients with APS associated with SLE.

### **Dermatologic Antiphospholipid Syndrome**

There are several different dermatologic features of APS. Although these features are nonspecific and not included in the classification criteria, they are common (49% of APS patients) and may be the first clinical presentations in 30%–40% of the cases (Francès et al., 2005). The most frequent is livedo reticularis, a red or bluish alteration of the skin with a net-like pattern attributed to blood stasis in capillaries and venules (Toubi et al., 2005). The pathophysiology of livedo reticularis is not well characterized, but the relationship with arterial thrombosis such as Sneddon's syndrome suggests a possible role for an interaction of aPL with the endothelial cell or other cellular element in blood vessels (Taraborelli et al., 2012). Livedo reticularis may be a prognostic marker of a

more severe disease, which may be possibly used as a criterion for APS (Toubi and Shoenfeld, 2007). It is associated with arterial and venous thrombosis and PM, irrespective of the presence of aPL (Francès et al., 1999, 2005; Toubi et al., 2005).

Cutaneous necrosis is observed in 5.5% of the patients with APS and the most commonly involved sites are the upper and lower extremities, helices of ears, cheeks, trunk, and forehead. These lesions may appear in the postphlebitic state (following a thrombosis) or caused by a circumscribed skin necrosis. A rare association has been found between cryoglobulinemia and APS in patients with cutaneous necrosis (Shachaf and Yair, 2016).

APS should be in the differential for pyoderma gangrenosum-like lesions unresponsive to the usual treatment. Subungual splinter hemorrhages may be seen along with thrombotic events elsewhere (Francès et al., 2005).

Cutaneous digital gangrene, with preceding ischemic symptoms, has also been observed in up to 7.5% of the patients with APS. Many nonspecific skin lesions of which some resemble vasculitis (pseudovasculitis) including red macules, purpura, cyanotic lesions on the hands and feet, ecchymoses, and painful skin nodules as well as primary anetoderma have also been reported.

### **Cardiac Antiphospholipid Syndrome**

The heart is one of the organs targeted in APS. Cardiac features include asymptomatic valve lesions, cardiac vegetations causing recurrent STs, accelerated atherosclerosis, MI, intracardiac thrombus, pulmonary hypertension, cardiomyopathy, and diastolic dysfunction (Soltész et al., 2007).

Valve abnormalities, vegetations, and/or thickening, termed Libman–Sacks endocarditis, are the most common manifestations described in 30%–50% of the patients (Ziporen et al., 1996; Blank et al., 2004; Cervera et al., 2011a). It should be noted that the valve damage is more frequent in patients with secondary APS and is highly associated with the presence of aPL (Nesher et al., 1997). aPL represent an independent risk factor for valvular heart disease in SLE patients, along with the disease itself (Watad et al., 2017). In addition, aCL IgG/IgM positivity was connected to valvular abnormalities in primary and secondary APS patients, and higher levels of those antibodies were correlated with an increased risk for these manifestations (Djokovic et al., 2014). Valve abnormalities can lead to an increased risk of embolism and may rarely (4%–6%) require replacement. The mitral valve is most commonly affected followed by the aortic valve.

The presence of cardiac valve pathology may be a risk factor for several types of CNS involvement in primary APS including epilepsy, migraine, STs, and TIA (Krause et al., 2005b).

Pulmonary hypertension is the second common cardiac manifestation in APS and occurred in about 11% of APS patients in one study (Pardos-Gea et al., 2015). It has been previously demonstrated that pulmonary hypertension occurs mostly due to venous thromboembolic disease with PE.

Myocardial ischemia may result from coronary thromboembolism, accelerated atherosclerosis of the coronary arteries, or microvascular injury. MI is diagnosed in 5.5% of the patients with APS (Cervera et al., 2002) and is also significantly associated with the presence of aPL (Cervera et al., 2011a). Similarly, clinically silent myocardial ischemia have been found in young patients with primary APS, and it have also been associated with elevated levels of the IgG class of both aCL and anti-B2GPI antibodies (Padjas et al., 2016). Accelerated atherosclerosis has been found in APS patients more frequently than in the general population (Shoenfeld et al., 2005) and may be driven by different immunopathological factors associated with disease itself.

Ventricular dysfunction in APS is rare and may result from valvular disorders, myocardial ischemia, or probably from the direct effect of the aPL on the myocardium. Primary APS seems to be related to diastolic dysfunction while SLE and APS appear to be associated with systolic dysfunction. Moreover, the right ventricle seems to be more involved than left ventricle, especially in primary APS (Tektonidou et al., 2001). Owing to the high incidence of cardiac involvement, echocardiographic follow-up is recommended for all APS patients (Cervera et al., 2011a). Cardiovascular magnetic resonance may be able to identify a high prevalence of occult myocardial scarring and endomyocardial fibrosis in APS and may have a great value in the diagnosis and follow-up of both clinically overt and silent cardiac diseases in APS patients (Mavrogeni et al., 2015).

### **Pulmonary Antiphospholipid Syndrome**

PE and infarction constitute the most frequent pulmonary manifestation of APS. In one study that included 1000 APS patients, PE was the presenting manifestation in 14% of them and additional 3.5% developed this condition during 10 years of follow-up (Cervera et al., 2002, 2015). Leaving aside this classical thrombotic manifestation, other pulmonary expressions including pulmonary hypertension, acute respiratory distress syndrome

(ARDS), intraalveolar hemorrhage, and fibrosing alveolitis have been described in the clinical spectrum of APS features (Stojanovich et al., 2012a). Notably, the presence of aPL correlated with distinct pulmonary types of involvement, such as the link between aCL and pulmonary arterial thrombosis, adult respiratory distress syndrome, and fibrosing alveolitis (Stojanovich et al., 2012a). In patients, with CAPS, small vessel thrombosis and systemic inflammatory response may lead to ARDS (Erkan et al., 2010).

Diffuse alveolar hemorrhage may occasionally present as the initial manifestation of APS and cause cough, dyspnea, and fever with or without hemoptysis and, in some cases, progress to acute respiratory failure (Cartin-Ceba et al., 2014). The aPL positivity may help in the identification of SLE patients who are at risk for developing pulmonary hypertension and pulmonary arterial hypertension (Zuily et al., 2017).

### **Renal Antiphospholipid Syndrome**

APS-mediated thrombosis can affect different parts of the kidney depending on the type and size of the vessels. These thrombotic events may result in various manifestations that reflect the site and size of the involved vessel. Large vessel involvement is usually in the form of thrombosis and/or stenosis that present as marked hypertension, renal dysfunction, and pain. In the case of occlusive lesions, both *in situ* thrombosis and embolization from heart lesions can take place (Taraborelli et al., 2012).

Renal involvement in APS also includes small vessel vaso-occlusive nephropathy defined as “APS nephropathy” or “aPL-associated nephropathy.” The major clinical presentations of this condition are hypertension, hematuria, proteinuria (ranging from mild to nephrotic level), and renal insufficiency (Tektonidou, 2014). Investigation in such cases should include a renal biopsy (Chaturvedi et al., 2011; Tektonidou, 2014).

In a histological view, aPL-associated nephropathy is characterized by acute lesions with thrombotic microangiopathy, and less commonly, chronic lesions with fibrous, intimal hyperplasia, organizing thrombi with or without recanalization, fibrous occlusions of arteries or arterioles, and focal cortical atrophy. Similar clinical and histological characteristics have been found within all the different groups of patients with positive aPL (primary APS, SLE-related APS, CAPS, and SLE/non-APS with positive aPL) (Tektonidou, 2014).

In SLE patients undergoing kidney biopsy, aPL-associated nephropathy, isolated or concomitant with SLE nephritis, should be considered. Moreover, it has been demonstrated that the inclusion of renal vascular lesions in the histological classification system of lupus nephritis improves renal outcome predictions. Thus thrombotic microangiopathy was associated with the poorest renal outcome among the other renal vascular lesions (Wu et al., 2013). aPL screening should be performed when aPL-associated nephropathy lesions are found in kidney biopsy, after the exclusion of other reasons for similar histological lesions such as malignant hypertension, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, scleroderma, or human immunodeficiency (Tektonidou, 2014).

### **Catastrophic Antiphospholipid Syndrome**

The term CAPS was first used in 1992 to define an accelerated form of APS resulting in multiorgan failure (Asherson, 1992). CAPS is characterized by widespread intravascular thrombosis within a short period of time resulting in multiorgan failure (Carmi et al., 2017). CAPS usually involves multiple small vessels, but sometimes large vessels may be concomitantly occluded as well (Erkan et al., 2010).

The international “CAPS Registry” was created in 2000 by the European Forum on Antiphospholipid Antibodies and included a large cohort of 500 patients with CAPS (Rodríguez-Pintó et al., 2016). In this cohort, 60% had primary APS and 40% had APS associated with another autoimmune disease, mainly SLE (75%). In 65% of CAPS episodes, the most common precipitating factor was infections (49%), especially in young patients. In this cohort, several organs and systems were involved, including kidneys (73%), lungs (60%), brain (56%), heart (50%), and skin (47%). Among laboratory features, thrombocytopenia was the most common (67%). Schistocytes, the markers of thrombotic microangiopathic hemolytic anemia, were present in 22%. LAC, aCL IgG, and anti-B2GPI IgG antibodies were the most frequently observed aPL (83%, 81%, and 78% respectively). Interestingly, in a series of 14 patients with CAPS, high levels of ferritin have been reported in 71% of the cases (Agmon-Levin et al., 2013). In the aforementioned CAPS Registry, the 12-year mortality rate in the general cohort was 37%, while a higher mortality of 48% was found in SLE patients secondary to severe cardiac and brain involvement (Rodríguez-Pintó et al., 2016).

## THE ANTIPHOSPHOLIPID ANTIBODIES

### Criteria-Relevant Antiphospholipid Antibodies

aPL is a group of over 20 different autoantibodies directed against a variety of antigens including negatively charged phospholipids, phospholipid-binding proteins, and factors related to hemostasis (de Groot et al., 2012). However, the revised laboratory criteria for the classification of APS include only LAC, aCL, and anti-B2GPI antibodies (Miyakis et al., 2006).

In recent years, the role of these three aPL in the pathogenesis of APS and their relation to APS manifestations have been challenged.

#### **Lupus Anticoagulant**

LAC defines a heterogeneous group of immunoglobulins that inhibits phospholipid-dependent coagulation reactions in vitro and is detected by prolongation of functional coagulation assay.

LAC is associated with severe clinical manifestations and considered the most important acquired risk factor for thrombosis and fetal loss. Thus a high incidence of LAC was found in patients with ST, DVT, and both early and late PM (Andreoli et al., 2013a). These findings have been further demonstrated by a recent metaanalysis showing that LAC is associated with a higher risk for thrombotic events in comparison with aCL and anti-B2GPI antibodies (Reynaud et al., 2014). Finally, LAC positivity has been shown to be the strongest predictor of poor pregnancy outcomes after 12 weeks of pregnancy (Lockshin et al., 2012; Yelnik et al., 2016). A “weak” positive LAC result (a measurement that results in value just above the mean + 2SD) should be considered positive when making clinical decisions, according to the 14th International Congress on Antiphospholipid Antibodies Task Force (Bertolaccini et al., 2014).

#### **Anticardiolipin**

The thrombotic risk of aCL antibodies, particularly high titer IgG aCL, has been previously demonstrated in patients with primary APS and APS associated with SLE (Long et al., 1991; Danowski et al., 2009). However, the importance of aCL in OAPS has been recently challenged by the several studies, which observed that isolated aCL positivity had no significant influence on adverse pregnancy outcomes in aPL-positive women with and without SLE (Lockshin et al., 2012; Yelnik et al., 2016). aCL antibodies were associated with an increased risk of venous thromboembolism and arterial thrombosis in patients without SLE, but this trend was less statistically significant than a similar association between LAC and thrombotic events (Reynaud et al., 2014).

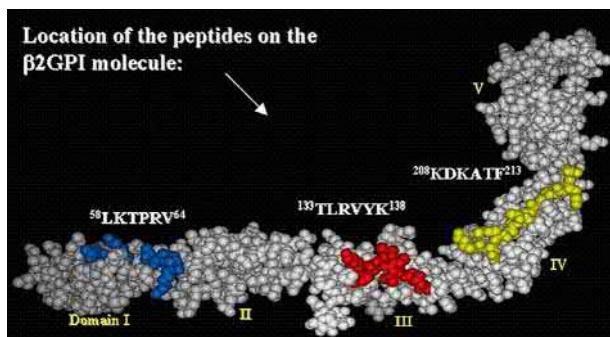

The effects of aCL antibodies' isotypes and their ability to predict different clinical manifestations of APS remain controversial issues. The IgG aCL isotype has been shown to be an independent risk factor for thrombosis, especially venous, in several previous and recent studies (Danowski et al., 2009; Domingues et al., 2016). Although IgM aCL is included in the Sydney APS Classification Criteria, the clinical importance of isolated IgM aCL is under debate. One study hasn't shown an increased incidence of venous or arterial thrombosis in patients with IgM aCL positivity (Danowski et al., 2009), and a different study has shown an association between IgM aCL and venous thrombosis (Samarkos et al., 2006).

It has been lately shown that the risk for jugular venous thrombosis and cerebral venous sinus thrombosis was correlated with the titer of aCL IgM, and no correlation with aCL IgG was found (Stojanovich et al., 2012b).

#### **Anti-b2-Glycoprotein-I Antibody**

Originally, it was assumed that aPL bind to phospholipids and were thus named “aPL antibodies.” However, in the 1990s it has been shown that aPL recognize phospholipids indirectly via phospholipid-binding plasma proteins (Galli et al., 1990). B2GPI is the most important phospholipid-binding protein, present either in a circulating form or bound to cells (de Groot et al., 2012). The B2GPI molecule has five homologous domains (I–V) (Fig. 32.1).

B2GPI participates in the innate immune responses [i.e., lipopolysaccharide (LPS) scavenging and clearance of unwanted anionic microparticles] and has antithrombotic properties. It has been proposed previously that B2GPI is the most important antigenic target (Meroni et al., 2011). However, the predominant role of anti-B2GPI in the pathogenesis and clinical manifestations of APS has been recently challenged. According to a critical analysis of published data regarding the pathogenic role of anti-B2GPI, this antibody may not play a central role in the pathogenesis and clinical manifestations of APS (Lackner and Müller-Calleja, 2016). Thus no association has been

**FIGURE 32.1** The plasma protein B2GPI is a phospholipid-binding protein. It is constructed of five domains (I–V) that can present in a circular nonactive form or in an active, open J-shaped conformation, as presented in the figure. Each of the 5 homologous domains of B2GPI includes approximately 60 amino acids, and certain peptides in each domain have been identified as autoantigens (3 of which are detailed in this figure). Anti-B2GPI antibodies can form a complex with B2GPI and activate intracellular signaling only in its open conformation while cryptic epitopes are exposed. *With acknowledgment to Prof. Miri Blank (The Zabludovitz Center for Autoimmune Diseases, Israel).* B2GPI, B(2)-glycoprotein I.

found between anti-B2GPI antibodies, both IgG and IgM, and adverse pregnancy outcomes in women with aPL and/or SLE (Lockshin et al., 2012; Yelnik et al., 2016).

Large systematic literature review and metaanalysis have showed that anti-B2GPI antibodies were associated with an increased risk of arterial thrombosis (OR 3.12, 95% CI 1.51–6.44) but only a nonsignificant trend was identified for venous thromboembolism (Reynaud et al., 2014).

In addition, in one recent study, anti-B2GPI antibodies were the most common antibodies in patients with thrombotic APS and had the highest sensitivity and negative predictive value with regard to APS diagnosis during the first visit (Ahluwalia et al., 2016). Higher titers of anti-B2GPI, both IgM and IgG, were observed in patients with SLE and secondary APS compared to negative aPL SLE patients and positive aPL SLE patients without APS clinical features. In this study, anti-B2GPI positivity was accompanied by almost a sixfold increased risk of secondary APS in SLE patients (Dima et al., 2015).

### Noncriteria Antiphospholipid Antibodies

Only three aPL are regarded as APS-relevant criteria, despite the fact that more than 30 different antibodies have been described in APS patients (the so-called autoantibody explosion in APS) (Shoenfeld et al., 2008b).

#### ***Antiphospholipid Antibodies of the IgA Isotype***

These are present in up to 40% of SLE patients and are especially common in Afro-Caribbean individuals. aCL antibodies of the IgA isotype were found to be thrombogenic in mice, and anti-B2GPI IgA was documented in a subgroup of seronegative women with recurrent pregnancy losses. IgA class aPL were also an independent risk factor for cardiovascular mortality and thrombotic events in hemodialysis patients (Serrano et al., 2012) and SLE patients (Swiss et al., 2010). Interestingly, unlike IgG directed at domains IV (DIV) and V (DV) of B2GPI, IgA antibodies that bind to these domains may contribute to thrombosis atherosclerosis (Iverson et al., 2006) and early pregnancy loss (Staub et al., 2006).

Several studies failed to show the usefulness of IgA aCL and IgA anti-B2GPI testing, owing to several reasons, including the low prevalence of these antibodies, the fact that they are found along with other aPL in most cases, and, mainly, the failure to enhance the diagnostic accuracy of routine testing (Meijide et al., 2013). Recent studies suggest that isolated IgA anti-B2GPI may identify additional patients with clinical features of APS and hence recommended testing for these antibodies when other aPL are negative and APS is suspected (Murthy et al., 2013). Based on the published evidence, IgA aPL testing may contribute to the risk assessment of thrombosis or/and PM in selected cases, mainly in SLE patients (Andreoli et al., 2013b). The above-discussed clinical utility of IgA aCL and IgA anti-B2GPI has been a subject of debate in the 14th International Congress on Antiphospholipid Antibodies Task Force (Bertolaccini et al., 2014).

### **Low Level Antiphospholipid Antibodies**

The value and clinical significance of low positive aPL values have been the topic of several publications. According to the 2006 classification criteria update, medium-to-high titers of the IgG and/or IgM isotypes of aCL and/or anti-B2GPI antibodies and/or a positive test for LAC should be present on two consecutive occasions, at least 12 weeks apart. The threshold between low and medium aCL or anti-B2GPI antibody titer is 40 GPL or MPL units, or the 99th percentile of the values obtained from the reference subjects for both aCL and anti-B2GPI antibodies, respectively. It has been previously reported that high levels of aPL are correlated with a worse outcome (Simchen et al., 2011). However, even lower levels should be taken into consideration by the treating physician.

Thus a recent study in this field has demonstrated that persistent low titers of aCL and/or anti-B2GPI antibodies were present in the patients with OAPS (Gardiner et al., 2013). In another study, the overall risk for vascular and obstetrical manifestations of APS was found to be similar both in patients with low titer of aCL/anti-B2GPI IgG/IgM antibody and in patients with moderate-to-high titers. This indicates that low titer aCL/B2GPI IgG/IgM tested positive twice 12 weeks apart may be sufficient for diagnosing APS in routine clinical practice (Ofer-Shiber and Molad, 2015).

Moreover, technical aspects may play a role while evaluating aPL levels. Given the variability of aPL assays, it is difficult to find a standard numerical cutoff value distinguishing between low- and medium-high titers of antibodies. The definition of medium-positive antibody titers depends on the performance characteristics of the particular assay, the statistical method, and the reference population. The most appropriate approach was summarized in the 14th International Congress on Antiphospholipid Antibodies Task Force, and according to it, the significance of a low positive aPL result depends on the whole risk profile of the patient with respect to clinical manifestations (Bertolaccini et al., 2014).

### **Autoantibodies to Domain 1 of b2-Glycoprotein-I Antibody**

The role of anti-B2GPI antibodies directed at different domains of B2GPI has become a focus of attention. Antibodies directed against domain I of B2GPI (anti-B2GPI-DI) have been previously found to be associated with an increased risk of thrombosis and pregnancy complications (de Laat et al., 2005, 2009) and represent one of the noncriteria aPL. Recent promising data support this association between anti-B2GPI-DI and APS clinical manifestation (Pengo et al., 2015a). Additional studies have highlighted the strong association between IgG anti-B2GPI-DI antibodies and thrombosis. Thus assessment of IgG anti-B2GPI-DI in 35 patients with primary APS and 51 patients with secondary APS indicated that anti-B2GPI-DI antibodies, but not non-DI anti-B2GPI antibodies, were significantly correlated with thrombotic events (OR 3.27; 95% CI 1.59–6.71) (Zhang et al., 2016). In this report, IgG anti-B2GPI-DI antibodies were detected in 48.6% of the patients with primary APS and in 45.1% of the patients with secondary APS, and their levels were significantly increased in APS patients in comparison with controls. IgG anti-B2GPI-DI antibodies were found in 81.4% of APS patients with positive anti-B2GPI antibodies, supporting the idea that DI is the major epitope in B2GPI.

Recently, the domain profile of anti-B2GPI antibodies has been evaluated in a large cohort of patients. In this work, no association has been found between anti-B2GPI-DI or anti-B2GPI-DIV/DV antibodies and APS clinical criteria. However, a high ratio ( $>1.5$ ) of anti-B2GPI-DI to anti-B2GPI-DIV/DV may predict systemic autoimmunity and, consequently, may be a useful biomarker for APS (Andreoli et al., 2015). An additional study evaluating aCL and/or aB2GPI-positive patients suggests that the addition of anti-B2GPI-DI positivity increases the likelihood of APS by three to five times. Positivity for IgG, IgA, or IgM anti-B2GPI-DI antibodies increased the strength of association between aCL and/or anti-B2GPI antibodies and thrombotic manifestations in APS (Pericleous et al., 2016). Recent studies have found that patients with multiple aPL have a higher prevalence and higher titers of anti-B2GPI-DI antibodies (Pengo et al., 2015a). Significantly higher levels of IgG aB2GP1-DI were found in patients with triple aPL positivity, compared with patients with double and single aPL positivity (Zhang et al., 2016).

Specific autoantibodies directed at other domains of B2GPI were less extensively studied. Nonetheless, the presence of an antibody directed at a peptide derived from domain III of B2GPI was found to be a significant predictor of recurrent spontaneous abortions (Shoenfeld et al., 2003).

### **Antiphosphatidylethanolamine Antibodies**

Antiphosphatidylethanolamine (aPE) antibodies were found to be associated with fetal loss and venous thrombosis (Pierangeli et al., 2011). In a different cohort, it has been reported that aPE antibodies were found in 19% of

the patients with unexplained recurrent early or mid-to-late pregnancy losses, suggesting an association between these antibodies and pregnancy losses (Sugi et al., 2004). The pathogenic role of aPE in pregnancy complications was assessed in a mice model, and it was found that passive immunization with aPE antibodies significantly induced thrombosis and hemorrhage in the placenta (Velayuthaprabhu et al., 2011).

In contrast, several studies failed to find an association between aPE and PM and thrombosis in SLE patients (Bertolaccini et al., 2012). The role of aPE in patients with seronegative APS remains a field of broad and current interest that requires additional investigation. The diagnostic value of aPE is still not established and aPE assays are not yet standardized. Similarly, there are no definitive therapeutic recommendations for patients with thrombotic or obstetric events and isolated aPE.

### **Antiphosphatidylserine Antibodies**

Antiphosphatidylserine (aPS) positivity was documented in women with recurrent pregnancy losses who were negative for aCL (Sater et al., 2012). In addition, aPS can inhibit trophoblast development and invasion and impede syncytiotrophoblast formation further supporting their pathogenic role (Blank and Shoenfeld, 2004).

The diagnostic value of aPS antibodies in APS has been recently assessed in a prospective observational study consisting of 212 patients with thrombosis and recurrent pregnancy failure. In this study, aPS antibodies were detected in 47.6% of the patients with thrombosis and in 52% of the patients with pregnancy failure. This prevalence of aPS antibodies in these two groups was similar to the prevalence of LAC (57% and 53%), anti-B2GPI antibodies (45.7% and 56%), and aCL (52% and 56%). In this study, 75% of the patients with confirmed primary APS had aPS antibodies. Thus aPS may be used as a diagnostic tool in clinical cases when other aPL are absent (Khogeer et al., 2015).

### **Antiprothrombin Antibodies**

Antiprothrombin antibodies (aPT) similarly to anti-B2GPI are phospholipid-binding proteins. The coexistence of IgG aPT and LACs was found to be an essential risk factor for venous thromboembolism in patients with SLE (Nojima et al., 2001) and to play a role in the pathogenesis of thrombosis in APS (de Groot et al., 1998; Von Landenberg et al., 2003; Haj-Yahia et al., 2003). Besides, aPT was linked to thrombosis and disease progression in other conditions such as acute ischemic STs in young women (Cojocaru et al., 2008), fetal death in women with previous uneventful pregnancies and seronegative aPL (Marozio et al., 2011), and more advanced primary biliary cirrhosis (Agmon-Levin et al., 2010). A recent systematic review of 38 studies on aPT has shown that the presence of aPT is linked to a higher risk of thrombosis (OR 1.82, 95% CI 1.44–2.75) (Sciascia et al., 2014). aPT may be detected by directly coating prothrombin on irradiated ELISA plates (aPT) (Bertolaccini et al., 2013).

### **Antiphosphatidylserine/Prothrombin Antibodies**

Antibodies directed at the complex phosphatidylserine/prothrombin (aPS/PT) were reported to be markers of APS with a high degree of concordance with LAC activity (Hoxha et al., 2012; Vlagea et al., 2013; Fabris et al., 2014). In a recent study that included 62 patients with inconclusive LAC analysis, the prevalence of aPS/PT antibodies was found to be 48% and allowed to discover a significant number of previously unrecognized aPL-positive cases with negative aCL and aB2GPI. Therefore, testing for aPS/PT antibodies may enhance the diagnostic performance for APS (Fabris et al., 2014).

In a cohort of 295 individuals that included primary and secondary APS and APS-related diseases, aPS/PT correlated with particular expressions of APS, namely venous thrombosis (OR 7.44; 95% CI 3.97–13.92) and obstetric abnormalities (OR 2.37; 95% CI 1.04–5.43), but not with arterial thrombosis (Vlagea et al., 2013). According to the systematic review of the literature, aPS/PT antibodies were found to be a strong risk factor for arterial (more significant) or venous thrombosis (less significant) (Sciascia et al., 2014). In line with this, a recent study has demonstrated that aPS/PT antibodies were found in 63% of 108 APS patients and were significantly associated with thrombosis (OR 3.4), especially arterial thrombosis (OR 4.8), independently of aCL and anti-B2GPI (Zhu et al., 2017).

Controversial data have been published regarding the connection between aPS/PT and PM. In one earlier study that included 208 women with history of pregnancy complications relevant to APS, the prevalence of aPS/PT was 13.0%. Moreover, 6.5% of these patients had isolated aPS/PT positivity (Žigon et al., 2015). In contrast, according to another study, no association has been found between aPS/PT positivity and history of PM (Zhu et al., 2017). The presence of aPS/PT antibodies may be a risk factor for more severe APS. Thus

aPS/PT antibodies, especially in high titers, were correlated with severe thrombosis, severe pregnancy complications inducing prematurity, and vascular microangiopathy (Hoxha et al., 2017). In addition, the inclusion of aPS/PT as a second-level assay to confirm APS classification was recommended in one study (Vlagea et al., 2013).

A recent report presented at the 14th International Congress on aPL antibodies concluded that testing for aPS/PT can contribute to a better identification of patients with APS and to the assessment of the risk of thrombosis (Bertolaccini et al., 2014).

### **Antiannexin A5 Antibodies**

Annexin A5 is one of the most important proteins in the annexin A group. It has an anticoagulant activity that prevents the binding and activation of clotting factors by the phospholipid shell that covers cells. aPL disturb this shield and expose phospholipids, thereby accelerating blood coagulation reactions. A significantly high correlation has been reported between annexin A5 resistance measured by flow cytometric assay (FCA) and the diagnosis of APS (Rodríguez-García et al., 2015). In a different recent report, positive FCA results were correlated with the presence of aCL and anti-B2GPI and were associated with APS features among patients with SLE (Avriel et al., 2016). A possible mechanism of annexin A5 resistance is linked to neutralization of annexin A5 by antiannexin A5 antibodies, which exposes the phospholipids on cell membranes for the accessibility of phospholipid-dependent coagulation enzymes.

In one recent study conducted on primary and secondary APS patients and disease and healthy controls, the levels of both IgG and IgM antiannexin A5 antibodies were significantly increased in patients with APS, compared with controls. Significant correlations were found between IgG antiannexin A5 antibodies and arterial thrombotic events (OR 2.60; 95% CI 1.44–4.71) and between IgG antiannexin A5 antibodies and venous thrombotic events (OR 2.80; 95% CI 1.55–5.06). In contrast, obstetric complications and IgG or IgM antiannexin A5 antibodies were not correlated. It has been suggested that antiannexin A5 antibodies could serve as a diagnostic biomarker for patients with APS (Zhang et al., 2017).

### **Metaanalysis: Prevalence of Different Noncriteria Antiphospholipid Antibodies**

Several additional investigations have addressed themselves to identify the prevalence of different noncriteria aPL in patients with APS. A recent metaanalysis of 16 such retrospective studies was conducted, incorporating 1404 APS patients, 1839 disease control patients, and 797 healthy patients. This analysis was based on studies published before June 2014 and reviewed the following noncriteria antibodies: IgA aCL, IgA anti-B2GPI, aPS, aPE, antiphosphatidylinositol, anti-B2GPI-DI, aPT, antiphosphatidylcholine, antivimentin/cardiolipin complex, and antiphosphatidic acid. Studies that evaluated the resistance to annexin A5 in APS patients were also included.

It has been shown that the prevalence of all noncriteria aPL was significantly increased in APS patients compared with controls. The most common laboratory characteristics were IgA anti-B2GPI antibodies (56.3%), resistance to annexin A5 (53.4%), and IgG anti-B2GPI-DI antibodies (44.0%) (Rodríguez-García et al., 2015).

---

## **SERONEGATIVE ANTIPHOSPHOLIPID SYNDROME**

---

The seronegative APS definition has been suggested for patients with clinical manifestations indicative of APS but with persistently negative results utilizing assays to detect criteria aPL (Rodríguez-García et al., 2012). Apparently these patients exhibit similar frequencies of thrombotic events and obstetric morbidity. Transient or false-negative aPL tests may explain some of these cases, as even today anti-B2GPI is routinely tested in only a small number of laboratories, and standardization of other criteria aPL is yet to be accomplished. In addition, noncriterion aPL are currently tested in only a few research laboratories (Cervera et al., 2012).

Therefore, new antigenic targets and different methodological approaches have been investigated in order to discover aPL in seronegative APS. One study analyzed the sera from 24 seronegative APS patients utilizing several methods: thin layer chromatography (TLC immunostaining) for all aPL, ELISA for antivimentin/cardiolipin, antiannexin A5 and aPT antibodies, and dot blot that was also used for antiannexin A5 and aPT antibodies (Conti et al., 2014).

This study has found that 54.2% of the cohort were positive for aCL antibodies according to the TLC immunostaining assay. In addition, 45.8% of them had IgG antibodies against vimentin/cardiolipin, 12.5% against prothrombin, and 4.2% against annexin A5. At least one aPL/cofactor antibody was detected using these assays in 79.2% of the patients. By combining TLC immunostaining for aCL and ELISA for antivimentin/cardiolipin

antibodies, aPL/cofactors were detected in two-thirds of the seronegative APS patients. Furthermore, recent evidence suggests that anti-B2GPI-DI, IgA aCL, or IgA anti-B2GPI may be used to identify seronegative APS patients (Meroni et al., 2014).

## RISK ASSESSMENT IN ANTIOPHOSPHOLIPID SYNDROME

APS manifestations may vary greatly between different patients. Some patients with aPL remain healthy, while others develop PM and/or thrombosis.

The value of different aPL profiles in the stratification of risks for thrombosis or obstetric events is under current investigation. Among aPL, LAC, triple positivity, and isolated persistently positive aCL at medium-high titers have been shown to be associated with a high risk for thrombosis (reviewed in Khamashta et al., 2016). In line with this, LAC and triple positivity were also correlated with worse pregnancy outcome (Alijotas-Reig et al., 2015).

While the presence of aPL is a risk factor for APS, additional risk factors have been incorporated in the global APS score (GAPSS) that was developed in 2013 (Sciascia et al., 2013). The GAPPS combines independent risk factors for thrombosis and pregnancy loss, including aPL profiles (criteria aPL and noncriteria aPL), and conventional cardiovascular risk factors and autoimmune antibody profiles, including anti-nuclear antibodies (ANA), extractable nuclear antigens antibodies (ENA), and anti-double stranded DNA antibodies (dsDNA), among others.

It has been demonstrated that arterial hypertension, hyperlipidemia, LAC, and IgG/IgM isotypes of aCL, anti-B2GPI, and aPS/PT were independent risk factors for thrombosis and/or PM.

Each risk factor was assigned a number of points within the GAPSS, as follows: IgG/IgM aCL (5 points), IgG/IgM anti-B2GPI (4 points), LAC (4 points), IgG/IgM aPS/PT (3 points), hyperlipidemia (3 points), and arterial hypertension (1 point).

The GAPSS model was initially developed in patients with SLE, and higher GAPSS scores were associated with thrombosis and/or pregnancy loss (Sciascia et al., 2013). Later, the GAPSS scoring system was evaluated in a cohort 62 patients with primary APS (Sciascia et al., 2015). Higher values of GAPSS were found in APS patients who had thrombosis alone, in comparison with patients who had previous pregnancy loss alone. In addition, patients with GAPSS values higher or equal to 11 had a higher risk of recurrent thrombotic events. Furthermore, a different study has shown that GAPSS correlated with a history of APS manifestations, particularly with thrombosis, suggesting that it may be used as a quantitative marker for APS (Oku et al., 2015).

Recently, GAPSS above 16 was reported as a predictor of thrombosis in a study that included APS and SLE patients (Zuily et al., 2015).

## GENETICS

The role of various genetic factors in the pathogenesis of APS was evaluated in several studies, including animal model studies, family studies, and population studies.

The current data suggest the existence of a genetic predisposition to APS, both as a primary condition or in association with SLE. This genetic predisposition is partly associated with the HLA system, and several family studies have shown that specific haplotypes, especially those containing DR4 and DRw53, may be correlated with aPL production or APS itself (reviewed in Sebastiani et al., 2016).

According to different population studies, the HLA loci relevant to the pathogenesis of primary APS appeared to be DRB1\*04, DR7, DRw53, DQB1\*0301/4, DQB1\*0604/5/6/7/9, DQA1\*0102, and DQA1\*0301/2.

With regard to aPL in SLE patients, the majority of the reports indicate that these antibodies are associated with DR4, DR7, the closely linked antigen DRw53, and DQB1\*0302 (Sebastiani et al., 2016). Several other genes unrelated to the HLA system may also increase the susceptibility to APS, including STAT 4 (Yin et al., 2009), 12q24.12 (Ochoa et al., 2013), and PTPN22 (Bottini et al., 2006). In addition, in a recent metaanalysis including 1507 APS patients, a strong association was found between valine/leucine (247) polymorphism of B2GPI and APS, thrombosis, and anti-B2GPI positivity (Lee et al., 2012).

In addition to genetic factors, epigenetic processes such as DNA methylation, histone modification, noncoding RNA, and nucleosome remodeling may be the topics of future research and provide additional insights regarding APS (Zhang and Zhang, 2015).

## CLASSIFICATION CRITERIA VERSUS DIAGNOSTIC CRITERIA

To date, there are no diagnostic criteria available for APS and therefore physicians should consider this diagnosis in the presence of minor features, even when major manifestations are absent. As mentioned earlier, there are minor clinical features and several noncriteria antibodies that may be potentially included in the disease's classification criteria.

Recently, it has been suggested to classify APS as definite, probable/possible, or uncertain. According to this suggestion, if the patient satisfies the 2006 Sydney APS Classification Criteria and has triple positivity, the diagnosis is considered definite. These patients may not require repeat testing after 12 weeks and have a high risk for recurrence of thrombosis and pregnancy loss. The diagnosis of APS is considered as probable in patients with double positivity (mostly LAC negative but with aCL IgG or IgM >99th percentile and anti-B2GPI IgG or IgM of the same isotype >99th percentile) and proven venous/arterial thrombosis and/or pregnancy loss. The diagnosis is "uncertain" if only one of the tests turns positive. Low titer single test positivity may be significant in obstetric cases only ([Pengo et al., 2015b](#)).

## DIAGNOSTIC PROCEDURES

Great efforts have been made to standardize the tests evaluating the presence of aPL. Several committees published guidelines regarding different coagulation and immunological tests. In 2009, the subcommittee on LAC/aPL antibodies of the International Society of Thrombosis and Haemostasis (ISTH) initiated the new guidelines for the detection of LAC ([Pengo et al., 2009](#)). Generally, two tests are used for the detection of LAC: dilute Russell venom time (dRVVT) and a sensitive activated thromboplastin time (aPTT).

The test for the detection of LAC consists of three steps: screening for prolongation in a phospholipid-sensitive test, mixing with normal plasma to discriminate between the presence of an inhibitor and coagulation factor deficiencies, and confirmation through result shortening in a phospholipid-rich test screening, mixing, and confirmatory studies. It has been found that the mixing test is essential to avoid false-positives in patients with prolonged dRVVT ([Devreese and de Laat, 2015](#)). In addition, the Scientific and Standardization Committee of the ISTH initiated new recommendations regarding aCL and anti-B2GPI ELISAs. In particular, the aCL ELISA cutoff should be calculated by the 99th percentile based on a population of healthy volunteers, a value that is quite different from the usually adopted cutoff of 40 GPL ([Devreese et al., 2014](#)).

Novel assay techniques have been proposed for aPL testing, such as chemiluminescence-based methods, fluorescence enzyme immunoassays, or line immunoassays (LIAs). A comparison of the LIA and ELISA techniques in 56 APS patients, 24 aPL carriers, and 73 aPL-positive patients with infectious diseases revealed a good inter-method agreement for the detection of IgG/IgM anti-B2GPI and aCL in APS patients. Unlike ELISA, according to LIA, the prevalence of aCL and anti-B2GPI IgG in aPL carriers and in aPL-positive patients with infectious diseases was significantly reduced in comparison with APS patients. This indicates that LIA discriminates patients with APS from aPL-positive asymptomatic carriers and infectious patients ([Roggenbuck et al., 2016](#)).

Confirmation of aPL positivity in order to avoid the detection of transient antibodies is a mandatory part of the classification criteria for APS. However, it may delay the diagnosis of APS and influence the treatment decisions. It has been demonstrated that initial aPL profiles may predict aPL persistence after 12 weeks. For example, repeated testing of 161 aPL-positive individuals who initially had one or more aPL showed that in 98% of subjects with triple positivity at initial testing, aPL profile was confirmed after 12 weeks. The aPL profile confirmation rates in double-positive and single-positive groups were 84% and 40%, respectively. These results have raised the possibility that triple positivity at initial screening may help in the early identification of APS patients ([Pengo et al., 2013](#)).

## THE MECHANISMS OF ANTIPHOSPHOLIPID ANTIBODIES-MEDIATED DISEASE EXPRESSIONS: CLINICAL TRIALS AND ANIMAL MODELS

The pathogenic effects of these antibodies are exerted through binding to receptor on target cells, including monocytes, endothelial cells, and trophoblasts, leading to the recruitment of cell surface receptors and subsequent perturbation of intracellular signaling pathways ([Blank et al., 1991; Giannakopoulos and Krilis, 2013](#)).

In the last three decades, much effort has been devoted to clarify the pathogenic potential of aPL (Bakimer et al., 1992). Both vascular thrombosis and pregnancy loss are the classical clinical expressions of the APS, therefore aPL pathogenicity was studied focusing on these clinical aspects. Notably, aPL-related vascular thrombosis can occur both on the arterial and the venous side, making this acquired procoagulant condition very peculiar in human disease. The first evidence of the aPL-related pathogenic potential was obtained through animals that carried aPL as part of their disease (i.e., lupus-like-prone mice), or alternatively naive mice that were infused with antibodies or stimulated to produce their own aPL (Ziporen et al., 1997; Katzav et al., 2010). In a long series of studies, different polyclonal and monoclonal aPL with various specificities were utilized inducing pregnancy losses and enhancing the coagulation process. Probably in no other autoimmune disorders has there been so much evidence produced to show the pathogenicity *in vivo* of these autoantibodies. This body of evidence was pivotal in proving autoantibody-mediated damage and at the same time prompted further *in vitro* studies aiming to define the cellular pathogenic effects of aPL. Originally both pregnancy loss and vascular occlusions were ascribed to the thrombogenic effect of aPL. Nowadays, it is clear that placental thrombosis can be responsible for pregnancy failures, but at the same time it is accepted that aPL can exert a direct nonthrombotic effect on trophoblast cells (Di Simone et al., 2000) and other cells (Del Papa et al., 1995). Over the years, the concept of aPL itself has also been redefined. In fact, starting from the hypothesis that these autoantibodies were directed to phospholipids, we now know that in most cases they are directed to phospholipid-binding proteins (Giannopoulos et al., 2011). Even if these antibodies are detected with different assays, the main target of the so-called aPL was identified as B2GPI, a phospholipid-binding protein. Almost all pathogenic effects of aPL have been shown using highly purified anti-B2GPI antibodies (Meroni et al., 2011). However, at that time, antibodies that bind to phospholipids in a cofactor-independent manner were generally considered irrelevant for the pathogenesis of APS. In recent years, there is direct evidence that cofactor-independent aPL presented in the blood of APS patients may contribute to the pathogenesis of the APS.

Thus two human monoclonal cofactor-independent aPL that had been obtained from patients with APS stimulated proinflammatory and procoagulant responses in monocytes and endothelial cells (Müller-Calleja et al., 2015). Endosomal NADPH-oxidase 2 (NOX2) activation was mediated by cofactor-independent aPL with subsequent induction of cytokines, inflammasome components, and tissue factor (TF). All effects induced by the monoclonal aPL were reproduced with IgG fractions of APS patients suggesting that effects of the monoclonal aPL are relevant for the APS. In a different study, two monoclonal human aPL-induced thrombus formation *in vivo* mouse model (Manukyan et al., 2016). Rapid induction of thrombus formation within 3 hours after infusion of the aPL was observed, and this thrombogenic effect of aPL was not reintroduced in NOX2-deficient mice. It has been found that thrombus formation depends on TF induction in monocytes. These accumulating data suggest that cofactor-independent aPL play an important role in pathogenesis of APS (Lackner and Müller-Calleja, 2016).

Several noncriteria autoantibodies such as aPS/PT, aPT, and anti-B2GPI-DI have been proposed to be relevant to the pathogenesis of APS. The prothrombotic property of aPS-PT antibodies has been demonstrated *in vitro* (Oku et al., 2013) and *in vivo* (Yamada et al., 2017). Both purified IgG fractions obtained from the sera of aPS/PT positive patients with APS and murine monoclonal aPS/PT antibodies induced TF expression and shortening of coagulation time in cells in the presence of prothrombin in procoagulant cells via p38 mitogen-activated protein kinase (MAPK) phosphorylation pathway.

The pathogenicity of aPS-PT antibodies *in vivo* has also been demonstrated in rat model of thrombosis induced by intravenous injection of aPS-PT antibodies (Yamada et al., 2017).

A direct demonstration of the pathogenic effect of anti-B2GPI-DI antibodies has been recently observed in animal model, in which infusion of human monoclonal anti-B2GPI-DI antibodies resulted in fetal losses in pregnant mice and blood clots in rat mesenteric microcirculation following priming with LPS. A variant of this antibody, lacking the CH2 domain, is effective in preventing blood clot formation and fetal loss induced by aPL (Agostinis et al., 2014). In a different work, intraperitoneal injection of two polyclonal IgG fractions (anti-B2GPI-DI rich and anti-B2GPI-DI poor IgG) isolated from APS patients *in vivo* mouse model demonstrated that anti-B2GPI-DI-rich IgG induced significantly larger thrombi compared with anti-B2GPI-DI poor IgG. Similarly, anti-B2GPI-DI-rich IgG significantly increased the procoagulant activity of the carotid artery endothelium and peritoneal macrophages isolated from the experimental animals (Pericleous et al., 2015).

## Thrombotic Manifestations

Many factors are involved in the pathogenesis of thrombotic manifestations. Several mechanisms have been proposed regarding the development of thrombosis, including the activation of endothelial cells, monocytes, platelets, coagulation, and complement pathways, along with the inhibition of fibrinolytic and anticoagulation pathways (Merashli et al., 2015). Consequently, it has been recently indicated that vasculopathy, related mainly to severe intimal hyperplasia, may also play a role in arterial vascular occlusion secondary to stenotic lesions and in PM. In this regard, the vascular endothelium of proliferating intrarenal vessels from patients with APS nephropathy demonstrated signs of mTOR activation, which is the mammalian target of rapamycin (Canaud et al., 2014). It has been shown that in cultured vascular endothelial cells, IgG antibodies from patients with APS stimulated mTOR through the phosphatidylinositol 3-kinase–AKT pathway. Treatment with sirolimus (rapamycin) led to the inhibition of mTOR in APS patients who underwent renal transplantation, which in turn inhibited the recurrence of vascular lesions and decreased vascular proliferation on biopsy, compared with APS patients who were not treated with sirolimus. Therefore, it was concluded that the activation of mTOR stimulates intimal hyperplasia, leading to the formation of the chronic vascular lesions seen in APS. It has also been found that mTOR is able to induce a prothrombogenic phenotype leading to thrombosis (Canaud and Terzi, 2014).

## **Antiphospholipid Antibodies and the Coagulation Cascade**

Several mechanisms have been described to explain the thrombophilic properties of aPL, generally related to their interaction with the coagulation and fibrinolysis systems or with cells involved in thrombus formation. These include B2GPI–anti-B2GPI complexes that were found to be localized to atherosclerotic plaques, mainly to oxidized low-density lipoprotein, to induce autoimmune thrombogenesis (Matsuura et al., 2003), and to amplify thrombus size (Arad et al., 2011).

Activated protein C (APC) is a natural anticoagulant that interacts with factors Va and VIIIa impairing their procoagulant activity. In the presence of B2GPI–anti-B2GPI complexes, APC cannot exert its action possibly because it is unable to bind Va/VIIIa or, alternatively, the formed APC/Va/VIIIa complex is sterically impaired in its binding to a phospholipid surface (Vlachoyiannopoulos and Routsias, 2010). aPL antibodies can also impair the anticoagulant function of antithrombin. This can occur because some of the targets such as thrombin or activated factor IX, when bound by aPL, are no longer available for antithrombin action (Chen et al., 2010). On the other hand, aPL can interfere with the fibrinolytic cascade.

Fibrin degradation, which allows thrombus remodeling and dissolution, is mediated by the active enzyme plasmin which is derived from the conversion of plasminogen. This conversion is mediated by tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator, and both of them are controlled by specific inhibitors -plasminogen activator inhibitors PAI-1 and PAI-2. In the presence of aPL, PAI-1 activity was reported as enhanced resulting in reduction of tPA and plasminogen activation. Apparently B2GPI protects tPA from the action of PAI-1, thereby promoting fibrinolysis; if B2GPI is bound by its specific antibodies, it cannot exert its protective action with the consequent prevalent action of the inhibitory effect of PAI-1 (Vlachoyiannopoulos and Routsias, 2010). Another impairment of fibrinolytic activity seems to be due to a possible direct binding of aPL to plasmin, followed by its inactivation (Yang et al., 2004). The data reported so far represent only some of the plausible mechanisms by which aPL interfere with the coagulation process, and recently another possible explanation has been formulated (Lambrianides et al., 2011). Many of the proteins involved in coagulation/fibrinolysis processes belong to the family of serine protease (SP) enzymes, such as APC, thrombin, plasmin, tPA, and others. These proteins share a high homology region at their catalytic domain. Most aPL recognize a conformational epitope that is shared by B2GPI molecule and the catalytic domain of SP. Therefore the presence of aPL can result in binding of SP molecules and impairment of their enzymatic activity, resulting in enhanced risk of thrombosis.

## **Antiphospholipid Antibodies Cellular Interactions**

One of the most studied pathogenic effects of aPL deals with the interaction of antibodies with the cells involved in the coagulation process. This basically occurs through the recognition of B2GPI that has adhered to cell membranes. It is known that anti-B2GPI antibodies can upregulate adhesion molecules such as endothelial leukocyte adhesion molecule-1, vascular cell adhesion molecule-1, intracellular adhesion molecule-1, and TF, conditioning their expression on the cell surface. This process was described in vitro on monolayers of human umbilical vein endothelial cells (HUVECs) (Meroni et al., 1996) and its consequences were shown in vivo on CD1 mice

infused with aPL: in fact in this model, leukocytes were seen to adhere to vascular endothelium favoring clotting (Pierangeli et al., 1995). In the presence of aPL, HUVECs also significantly increase the production of some proinflammatory cytokines such as IL-6 and IL-1B. Therefore the consequence of the aPL effect on endothelium is the shift toward a proadhesive/procoagulant as well as proinflammatory phenotype.

These profound modifications are basically due to the presence of B2GPI on the endothelial surface. A number of possible receptors for B2GPI have been described on the endothelial cell surface. Heparin sulfate, annexin 2 receptor, Toll-like receptors (TLR) 2 and 4, and apolipoprotein E receptor 2 were all shown to be involved in the thrombogenic mechanisms related to aPL using *in vitro* and *in vivo* models (Poulton et al., 2012). It was also observed that animals lacking one of these receptors are only partially resistant to the pathogenic potential of aPL, suggesting that they play a similar, probably redundant, role (Meroni et al., 2011). The binding of anti-B2GPI to its antigen on the endothelial surface should produce intracellular signaling, able to upregulate the cellular expression of adhesion molecules and TF. The signal can start from the receptors that are sensitive to the clustering of B2GPI that follows their specific antibody binding. Among receptors, those having a cytoplasmic tail, TLR 2 and 4 are most likely to be the favorite candidate. Several intracellular pathways have been described as activated, including nuclear factor  $\kappa$ B, p38 MAPK, myeloid differentiation primary response protein (MyD88), and tumor necrosis factor receptor-associated factor 6. The above-reported mechanisms are well defined in endothelial cells, but they are also at least partially described in monocytes, platelets, and in other cells serving as a possible target of aPL-mediated damage (Meroni et al., 2011; Poulton et al., 2012). The thrombophilic effect of aPL was also investigated at platelet level. In subjects with aPL, platelet activation was proven by the increase of thromboxane B2 and the decrease in vascular prostacyclin. Receptors of B2GPI at the platelet surface seem to be the apolipoprotein E receptor 2 and the platelet glycoprotein Ib alpha chain (Cognasse et al., 2005; Urbanus et al., 2008). In *vitro*, the pathogenic effect of affinity purified anti-B2GPI antibodies was shown as an increased aggregation and intracellular signaling activation of platelets in the presence of low doses of thrombin stimulation. In *vivo*, the B2GP1–anti-B2GP1 complex binds to platelets and activates thrombus-associated platelets. This enhanced platelet activation leads to increased activation of the endothelium and fibrin generation (Proulle et al., 2014). In this respect, a recent study (Vlachoyiannopoulos and Routsias, 2010) has underlined the importance of platelet factor 4, a protein derived from platelet alpha granules and belonging to the chemokine family. Platelet factor 4 is secreted by platelets but can also bind to the platelet surface as well as anionic molecules and B2GPI, both in solid phase and in solution. Platelet factor 4 is able to gather two B2GPI molecules, so favoring an efficient antibody binding. Complexes containing platelet factor 4, dimerized B2GPI, and anti-B2GPI antibodies can induce an activated procoagulant phenotype in platelets. Notably, platelet factor 4 is expressed in different cells such as endothelial cells, monocytes, T cells, and dendritic cells suggesting that its capacity to dimerize B2GPI could favor immune system sensitization and the production of pathogenic anti-B2GPI antibodies.

Neutrophil extracellular traps (NETs) represent an important activator of the coagulation cascade and an important component of arterial and venous thrombi. In one study, freshly isolated APS neutrophils demonstrated enhanced NET release in a spontaneous manner. Circulating aPL both purified IgG fractions and anti-B2GPI monoclonals can promote NET release from neutrophils. A positive correlation was found between circulating levels of NETs and IgG anti-B2GPI positivity, LAC positivity, and triple positivity in APS patients (Yalavarthi et al., 2015). A decreased degradation of NETs was found in a subgroup of patients with both primary and secondary APS and was associated with antibodies against NETs in patients with secondary APS (Leffler et al., 2014).

Cell-released vesicles and exosomes are important systems of intercellular communication. aPL may promote pathogenic effects on vascular cells (endothelial cells, platelets, monocytes) through the release of extracellular vesicles, which include exosomes and microparticles. In this regard, an increased number of monocyte and endothelial microparticles was found in APS patients, in comparison with healthy controls (Vikerfors et al., 2012). Notably, endothelial cells exposed to polyclonal IgG from APS patients produced significantly more endothelial microparticles than those exposed to polyclonal IgG from healthy subjects (Pericleous et al., 2013).

## Obstetric Manifestations

The pathogenesis of pregnancy failure in APS patients seems to be multifactorial, and it is well known that aPL are associated with reproductive failure (reviewed in Blank and Shoenfeld, 2010).

The mechanisms responsible for aPL-mediated obstetric manifestations include intraplacental thrombosis, inflammation, interference with annexin A5 function, inhibition of syncytium-trophoblast differentiation, defective placentation/placental apoptosis, and complement activation (reviewed in Arachchillage et al., 2017).

Although many different obstetric expressions of APS have been described, the most typical are midpregnancy losses, mainly related to defective placentation and intrauterine growth restriction. Therefore, the first pathogenic mechanism to be investigated was the presence of intraplacental thrombosis (Inbar et al., 1993; Levy et al., 1998). Indeed the above-described thrombophilic properties of aPL favor an increased thrombosis occurrence, particularly during pregnancy, that can work as a “second hit” since pregnancy per se is characterized by an increased thrombosis risk, even in the general population. A potent anticoagulant acting mainly, but not exclusively, on the trophoblast surface is annexin A5 that produces the so-called protective shield, by binding negatively charged phospholipids such as phosphatidylserine. The presence of annexin A5 at the intervillous surface was found to be significantly reduced in patients with APS, thus confirming that B2GPI–anti-B2GPI complexes are able to displace in vivo annexin A5 from the cell surface as shown in vitro (Hunt et al., 2011). Furthermore, it is recognized that aPL can also directly interact with trophoblast during syncytium formation (Di Simone et al., 2000) when it expresses phosphatidylserine at its outer surface. As shown by in vitro experiments, B2GPI can bind to negatively charged phospholipids such as phosphatidylserine on the cell surface and become a target of circulating anti-B2GPI antibodies.

Direct placental damage induced by aPL may be caused by several mechanisms including inhibition of trophoblast differentiation and syncytialization, induction of trophoblast apoptosis, impairment of trophoblast invasiveness and trophoblast expression of adhesion molecules, and also inhibition of the angiogenic factors production by trophoblasts (Tong et al., 2015). An additional mechanism for preeclampsia is related to the internalization of aPL by trophoblasts with the subsequent acceleration of cell death and release of debris that can activate maternal endothelial cells (Viall et al., 2013).

Inflammation has been described as one of the main mechanisms of aPL-induced PM, and it has recently gained additional support from an in vitro study, which showed that aPL can induce trophoblasts to produce interleukin-1 $\beta$  by inflammasome activation (Müller-Calleja et al., 2015).

A novel mechanism of trophoblast inflammation may be related to endothelial microparticles production upon exposure to aPL. MicroRNA released via exosomes may induce the trophoblast to secrete the proinflammatory cytokines IL-8 through activation of TLR 8 (Gysler et al., 2016).

Current research focuses on the identification of aPL targets on cell membranes and on the intracellular signaling pathways.

In particular, a recent study suggests that apolipoprotein E receptor 2 may be the key molecule mediating trophoblast dysfunction in a mouse model (Ulrich et al., 2016). In a different study, it was shown that TLR 4 mediated the inhibition of trophoblast invasion in vitro by purified aPL IgG from patients with OAPS, but this effect was not observed when aPL IgG from non-OAPS was used (Poulton et al., 2015).

## The Complement System in Antiphospholipid Syndrome

Complement is apparently involved in APS as antibodies cannot exert their pathogenic effect in animals that lack complement factors or receptors. This effect has been observed in both pregnancy loss (Holers et al., 2002) and in a thrombosis model (Fischetti et al., 2005). If the binding of aPL to their target cells (endothelial cells, trophoblasts) can activate complement, several activation molecules can be released. A recently described damage mechanism focused on C5a as a possible activator of neutrophils via its receptor on the cell surface (Girardi, 2010); according to this model, the consequence of C5a binding to neutrophils is TF production that can exert procoagulant and proinflammatory actions, and these can cause both thrombosis and fetal loss. Direct evidence that activation of the complement system is an important mechanism for aPL-mediated thrombosis was demonstrated in an APS mouse model of induced thrombosis (Romay-Penabad et al., 2014). In this study, the thrombosis was induced in a femoral vein pinch manner, and it was found that mice treated with IgG from APS patients with high levels of aPL developed larger thrombi and higher soluble TF activity than controls. Furthermore, the coadministration of rEV576 (coversin), a recombinant protein inhibitor of C5 activation, resulted in significantly smaller thrombi and reduced TF activity (Romay-Penabad et al., 2014). These data suggest that complement inhibition may significantly reduce aPL-mediated venous thrombosis and TF production. Hypocomplementemia was frequently observed in a cohort of 36 patients with primary APS, reflecting complement activation and consumption, and was also correlated with LAC activity but not with particular

clinical manifestations (Oku et al., 2009). In contrast, one large study that included 2399 aPL-positive SLE patients found that in aCL-positive patients, the presence of hypocomplementemia (both low C3 and C4) was strongly associated with DVT (Durcan et al., 2016).

The assumption that the complement system is involved in pregnancy morbidities in APS patients is supported by histopathological evaluation of the placentae in women with aPL (Viall and Chamley, 2015). While lower complement levels were observed in patients with OAPS, no correlation has been found between hypocomplementemia and obstetric complications in these patients (Reggia et al., 2012).

The reason of complement activation in APS has not been fully clarified yet. One recent study that included primary APS patients detected the presence of antibodies directed against C1q which is the initiator of the classical complement pathway. These antibodies bind to C1q on anionic phospholipids and accelerate complement activation. Thus autoantibodies against C1q were detected in 36% of APS patients and their titers were significantly higher compared to normal healthy controls. Neither the prevalence nor the titers of anti-C1q antibodies were correlated with a specific manifestation of APS (arterial thrombosis, venous thrombosis, PM) and no correlation was found between titers of anti-C1q and titers of aPL. In addition, patients with refractory APS tended to have higher serum titers of anti-C1q antibodies than patients with nonrefractory APS (Oku et al., 2016). It has been suggested that the presence of aPL alone is not enough to cause thrombus formation. Thus the activation of the complement pathway due to the existence of anti-C1q antibodies may play an additional role in the pathogenesis of APS.

## MORTALITY IN THE ANTIIPHOSPHOLIPID SYNDROME

The mortality rate in patients with APS is still relatively high despite the current treatment. One of the most prominent studies that investigated mortality in APS patients was performed within the Euro-Phospholipid project (Cervera et al., 2015). In this study, the mortality rate observed during a 10-year period (1999–2009) was 9.3% (5.3% in the first 5-year period and 4% in the second 5-year period), and the mean age of death was 59 years. No differences were detected in the mortality rate or the causes of death between patients with primary APS and patients with APS associated with SLE. Similarly, there were no differences in the causes of death between patients receiving different treatments (immunosuppressive or anticoagulant agents). The causes of death were severe thrombotic events including MI, STs, and PE (36.5%), followed by infections (26.9%) and hemorrhages (10.7%). In addition, among the nine patients who developed CAPS, five patients (55.6%) died. Despite the similar mortality rates in both the first and second 5-year periods of the study, there were some differences in the causes of death: fatal thrombotic events were more frequent in the first period, while malignancies were more frequent during the second period. According to this study, no clinical or immunological parameter with prognostic significance for mortality was identified.

## TREATMENT OF ANTIIPHOSPHOLIPID SYNDROME

In contrast to the large body of evidence on the pathogenesis, mechanisms, and diagnosis of APS, there is still a gap in our knowledge on appropriate therapy for patients affected by this disease. The management of patients with APS is currently directed to antithrombotic medications. Balancing an individual's risk of thrombosis against the benefits and risks of antithrombotic therapies is crucial for optimizing management and preventing morbidity in patients with APS or aPL-positive-asymptomatic ones.

Primary thromboprophylaxis in aPL carriers is mainly based on controlling any additional vascular risk factors that should be treated according to the cardiovascular disease prevention guidelines for the general population. All aPL carriers should receive thromboprophylaxis with usual doses of low molecular weight heparin (LMWH) in high-risk situations including surgery, prolonged immobilization, and puerperium period.

Estrogen-containing oral contraceptives are not recommended while progestin-only contraception is considered to be safe. Low-dose aspirin (LDA, 75–100 mg/day) is recommended in subjects with persistent positivity of multiple and/or high titer aPL (Ruiz-Iraistorza et al., 2010). In accordance with a recent metaanalysis, a lower rate of first thrombotic events was found in aPL-positive patients receiving aspirin in comparison with nontreated patients (7.8% vs 15.2%,  $P < .0001$ ). According to the subgroup analysis, aspirin had a significant protective effect in asymptomatic aPL-positive individuals (OR 0.50, 95% CI 0.25–0.99), in SLE patients (OR 0.55, 95% CI 0.31–0.98), and in OAPS patients (OR 0.25, 95% CI 0.10–0.62) (Arnaud et al., 2014, 2015).

No difference in the frequency of thrombosis was observed in aPL-positive patients treated with low-intensity anticoagulation target INR (1.5 and LDA) in comparison with those treated with LDA only ([Cuadrado et al., 2014](#)).

Definite APS patients with a first venous thrombosis event should receive oral anticoagulant therapy to a target of INR 2.0–3.0. Patients with definite APS and arterial thrombosis and/or recurrent events should be treated with oral anticoagulant therapy target with an INR of over 3.0, or receive anticoagulation therapy combined with antiaggregant agents, with an INR target between 2.0 and 3.0. In addition, indefinite antithrombotic therapy is recommended in patients with definite APS and thrombosis ([Sciascia et al., 2017](#)).

It has been recently demonstrated that persistent negative aPL profile is not an indication to stop oral anticoagulant therapy in APS patients. Thus in one study, thrombosis recurrence appeared in 46% of 24 primary APS patients with persistent negative aPL profile ([Medina et al., 2017](#)).

Oral anticoagulation therapies have been developed during the last years including direct anti-Xa inhibitors, including rivaroxaban, apixaban, and edoxaban, and a direct thrombin inhibitor named dabigatran etexilate. According to the rivaroxaban in antiphospholipid syndrome trial, rivaroxaban might be an effective alternative in patients with APS and previous venous thromboembolism ([Cohen et al., 2016](#)). The use of new oral anticoagulants in APS patients with arterial events and/or high-risk aPL profile requires further investigation. With regard to pregnancy management in women with APS, after pregnancy confirmation, the patient should discontinue oral anticoagulants because of teratogenicity and switch to LDA in combination with LMWH.

LMWH is commonly prescribed at prophylactic doses in women without previous thrombosis, or therapeutic doses in women with previous thrombotic episodes ([Erkan et al., 2014; Levy et al., 2015](#)).

Several clinical studies have examined the role of immunosuppressive therapy in APS patients and aPL-positive subjects. It has been previously shown that hydroxychloroquine (HCQ) has a beneficial effect on primary arterial and venous thromboses prevention in aPL-positive individuals and in SLE patients with or without aPL ([Tektonidou et al., 2009](#)). The use of HCQ as an additional treatment in refractory APS cases is also recommended ([Negrini et al., 2017](#)). Furthermore, an addition of HCQ to the current therapy may be considered in cases of OAPS when a standard treatment with aspirin and a heparin agent has failed, or in selected cases including women with previous thrombosis and/or ischemic placenta-mediated complications ([Sciascia et al., 2016](#)).

Rituximab, an anti-CD20 chimeric monoclonal antibody, may be considered in difficult-to-treat APS patients, possibly in those with hematologic and microthrombotic/microangiopathic manifestations ([Erkan et al., 2014](#)).

In cases of CAPS, an aggressive therapy is highly recommended using anticoagulation, glucocorticoids, and plasma exchange and/or intravenous immunoglobulins ([Puente et al., 2009](#)). This combination was retrospectively assessed and found to be advantageous ([Espinosa et al., 2011](#)), noting that APS has been revealed as a complex syndrome with multiple pathophysiological mechanisms previously unknown. In this context, new therapeutic approaches have been defended and empirically tested, with potentially promising results. For patients with refractory CAPS, rituximab has been reported to be safe and effective ([Sukara et al., 2015](#)). In addition, several reports have described the successful use of eculizumab, a humanized monoclonal antibody against complement protein C5, in CAPS and severe cases of APS, including APS and thrombotic microangiopathy (reviewed in [Sciascia et al., 2017](#)).

Peptide therapy and mTOR inhibition are new potential targets in APS that require additional investigation ([Andrade and Tektonidou, 2016](#)).

## CONCLUSIONS AND FUTURE ASPECTS

APS is a systemic autoimmune disease, mediated by autoantibodies directed at phospholipids and phospholipid-binding proteins. Since its definition some 40 years ago, our understanding of the mechanisms underlining this disease has greatly improved. Nonetheless, much is yet to be accomplished regarding the definition of subgroups of APS patients, the accurate diagnosis and interpretation of criteria and noncriteria aPL, and the appropriate treatments for APS- and aPL-affected patients. These goals may be achieved by conducting well-designed, large-scale, multicenter clinical trials to explore and address the unmet needs of better, safer, and targeted management of APS.

## GENERAL INTRODUCTION

Sjogren's syndrome (SS) is one of the most common autoimmune diseases. It may exist as either a primary syndrome or as a secondary syndrome in association with other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus (SLE), systemic sclerosis, and primary biliary cirrhosis (Brito-Zerón et al., 2016; Delaleu et al., 2005; Fox, 2005; Mavragani and Moutsopoulos, 2014). As with all autoimmune diseases, there is a great deal of clinical variability such that some patients may only have dry eyes and/or dry mouth, while others may have systemic manifestations including lung disease, kidney disease, and lymphoma. The 2016 American College of Rheumatology (ACR)—European League Against Rheumatism (EULAR) criteria for SS include symptoms of oral and/or ocular dryness or one extraglandular manifestation along with object indicators including a minor salivary gland biopsy showing lymphocytic infiltration, anti-Ro antibodies, positive ocular staining score, reduced Schirmer's test, and/or reduced unstimulated salivary flow (Shiboski et al., 2017). These criteria have undergone and will continue to undergo revision as more is learned about the disease and its protean manifestations. Because of its often-subtle presentation, SS may not be identified in patients until they have had the disease for several years (Akpek et al., 2015; Beckman et al., 2017).

Treatment of reversible manifestations, however, requires early identification. Animal models and genetic studies have provided novel insights that may lead to early identification of the disease and improved forms of therapy (Burbelo et al., 2014; Delaleu et al., 2011). I will highlight in this chapter the current understanding of SS and introduce some of the areas where current and future research is directed.

## HISTORICAL ASPECTS

Dr. Johann von Mikulicz-Rdeck, a surgeon from Cernowitz, Austria, is credited with identifying the first patient with SS in 1892 based on round-cell infiltrate and acinar atrophy of the parotid and lacrimal glands (Fox, 2005; Parke and Buchanan, 1998). The syndrome is named after an ophthalmologist from Jonkoping, Sweden, Dr. Henrik Sjogren, who noted a patient with low secretions from the salivary and lacrimal glands in 1930. He subsequently published series of patients with "keratoconjunctivitis sicca" in 1933 and 1951 that brought the syndrome to worldwide medical attention (Parke and Buchanan, 1998; Sjogren, 1951). He importantly distinguished the primary disease from other causes of keratoconjunctivitis sicca, such as vitamin A deficiency and tuberculosis. In the 1950s and 1960s SS was felt to be a relatively rare disorder and the appreciation of its association with other autoimmune diseases was just starting (Bloch et al., 1965). In the 1970s immunological abnormalities associated with SS, especially hypergammaglobulinemia, monoclonal gammopathy, and various lymphoid abnormalities, were just being elucidated. The association between SS and lymphomas was noted. Minor salivary gland biopsies were used for diagnosis. Immunological therapies, such as the use of corticosteroids, were attempted. The association of SS with HLA-B8 and DR3 was made. Animal models for SS were first examined (Anderson and Talal, 1972; Keyes et al., 1977; Strand and Talal, 1979). In the 1980s came the association of SS with anti-Sjogren's syndrome A (SSA) and anti-Sjogren's syndrome B (SSB) antibodies (Eisenberg, 1985). SS was noted to have a strong correlation with chronic fatigue. Cholinergic agents were used to increase salivary gland flow (Fox, 1987). Immunological studies focused on the hypothesis that SS involves abnormal B cells and T cells of the adaptive immune system producing autoreactive antibodies and direct cytotoxicity (Moutsopoulos, 1988). Genetic studies identified particular human leukocyte antigen (HLA) associations with SS (Harley et al., 1986). The 21st century has seen a blossoming of research in SS that has led to improved understanding of clinical manifestations, greater appreciation of disease pathophysiology including the involvement of the innate immune system, role of epithelial cells and other cell types, determination of contributory genetic factors, development of improved animal models, and therapeutic trials with encouraging outcomes. These will be discussed in the remainder of this chapter.

## EPIDEMIOLOGY

The true prevalence of SS is very hard to determine because of the frequent changes in diagnostic criteria, variation in the method of diagnosis based on the training of the clinician making the diagnosis (i.e., ophthalmologist vs oral surgeon vs rheumatologist vs internist), and novel diagnostic markers that are potentially more sensitive. While SS was once considered a rare disease, it is now considered the second most common autoimmune disease, after rheumatoid arthritis. Its prevalence is estimated at 1% (0.1%–4.8%) with an incidence of 7 per 100,000 in the United States. It is felt that roughly 4 million Americans have SS with 90% of them being women and 50% of them having SS in association with another autoimmune disease (Helmick et al., 2008; Reksten and Jonsson, 2014; Thomas et al., 1998). The incidence of SS is felt to be lower in China and higher in Japan (Qin et al., 2015). While SS is felt to be a disease predominantly of women, with a female-to-male ratio of 9:1, the incidence of SS is likely higher in males than is currently estimated, because males tend to make a different pattern of autoantibodies than females and are often missed with the current diagnostic criteria (Beckman et al., 2017; Gondran et al., 2008). The reason for the difference in the estimated prevalence of SS in various countries is likely due to many factors, but certainly different genetic backgrounds and environmental influences could explain some of these variations. SS, depending upon how it is defined, may in fact turn out to be more common than rheumatoid arthritis.

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

As with all autoimmune diseases, the expression of SS is due to combinations of various genetic and environmental factors that result in wide variability in phenotype in different patients. The clinical manifestations that define the disease are dry eyes and dry mouth. There are patients with predominantly dry eyes without dry mouth, patient with predominantly dry mouth with minimal dry eyes, and patients with both. Some of these patients will go on to have extraglandular manifestations, but some will not. It is also possible that some patients have bouts of autoimmune salivary and/or lacrimal gland injury with recovery before permanent damage to the salivary and/or lacrimal glands is noted. It is estimated that the average SS patient has had disease for 3 years before they are diagnosed (Akpek et al., 2015).

### Eyes

Involvement of the eyes is one of the defining features of SS. Dry eye disease is one of the most common diseases seen by ophthalmologists and can be due to environmental toxins, drugs, various infections, genetic factors accelerated by aging, various diseases including sarcoidosis, radiation therapy, malignancies, and SS (Abelson et al., 2009; Akpek et al., 2015; Basak et al., 2012; Gayton, 2009; Li et al., 2015a). It has been estimated in the United States that as many as 25% of the dry eye patients have SS. In China, one study estimated that only 1.9% of the dry eye patients had SS (Akpek et al., 2015; Li et al., 2015b). Both primary and secondary SS are included in these numbers.

Patients note dryness, a feeling of gravel in their eyes, and often associated pain in their eyes. These symptoms are often responsible for life alterations (Akpek et al., 2015). Patients can have problems with both aqueous and lipid secretions as well as meibomian gland dysfunction. Complications in the eye can include corneal ulceration and perforation, conjunctivitis, uveitis, scleritis and episcleritis, optic neuritis, and orbital inflammation all of which can be infectious and/or “autoimmune” (Akpek et al., 2015).

### Oral Cavity

Involvement of the salivary glands is the second defining feature of SS. There are three major salivary glands, the submandibular gland, the parotid gland, and the sublingual gland. The submandibular gland, which secretes both serous and mucous secretions, tends to be involved first and is responsible for the majority of the symptoms in the oral cavity. The parotid gland produces predominantly serous secretions and tends to be involved second. The sublingual glands, which also secrete serous secretions, may or may not be involved but cannot compensate for the loss of submandibular gland function (Chen et al., 2016; Dugonjic et al., 2014; Pijpe et al., 2007). Similarly, there are numerous minor salivary glands that cannot compensate for loss of submandibular and parotid function. As with dry eyes, dry mouth can occur for many reasons including mouth breathing, genetic factors accelerated by aging, environmental toxins, drugs, radiation, infections, chronic diseases such as sarcoidosis, malignancies, and SS. It is unclear what percentage of patients with dry mouth has SS. This has never been carefully studied.

Patients with SS experience dry mouth; burning sensation in their mouth; loss of sense of taste and smell; inability to eat, chew, and swallow food; speaking difficulty; and weight loss. Complications of SS in the oral cavity include dental caries, gingivitis, dry and cracked lips, depapillation of the tongue, oral ulcers, and infections especially with fungi (Napenas and Rouleau, 2014).

### Lungs

Lung involvement occurs in 9%–75% of the patients with SS, depending upon what criteria are utilized to define pulmonary disease and whether primary and/or secondary causes of lung disease are being considered (Parke, 2008; Quismorio, 1996). The most common lung finding in SS patients, which occurs in roughly 1% of the patients, is lymphocytic interstitial pneumonia (LIP) (Parambil et al., 2006). LIP that is indistinguishable from what is seen in SS can be seen in SLE, systemic sclerosis, polymyositis, and other autoimmune diseases. In one

study of patients with LIP, 25% had SS (Koss et al., 1987). Patients with LIP are often asymptomatic but may have chronic cough and dyspnea on exertion (Swigris et al., 2002). In SS, cough can also be secondary to dryness in the upper airway and trachea.

Other less frequent airway manifestations in SS include other forms of interstitial pneumonitis (usual interstitial pneumonia (UIP), nodular interstitial pneumonia (NIP), and bronchiolitis obliterans with organizing pneumonia (BOOP)), lymphocytic bronchitis, pleuritis with or without pleural effusions, pulmonary vasculitis usually in the setting of systemic vasculitis, pseudo-lymphoma, and lymphoma (Parke, 2008). Especially in SS with secondary antiphospholipid antibody syndrome, one can see transient and/or permanent pulmonary hypertension as well as thrombosis and pulmonary embolism (Ostrowski and Robinson, 2008; Paran et al., 2007). In secondary SS, it may be hard to distinguish whether the lung disease is secondary to the primary disorder (i.e., rheumatoid arthritis and systemic sclerosis) or SS. Furthermore, patients with SS are more likely than normal individuals to get various infections in both the upper and lower airways because of the deficiency in protective mucous secretions.

## Kidney

Kidney involvement occurs in approximately 5% of the patients with primary SS (Evans et al., 2015; Francois and Mariette, 2016; Ren et al., 2008). The majority of SS patients have lymphocyte predominant tubulointerstitial nephritis (TIN), although some patients have glomerular disease. Variability is seen in studies done in different locations. In one study of 130 patients with SS, 80% had TIN and 20% had glomerular disease while another study of 33 patients with SS found 35% with TIN, 52% with glomerular disease, and 12% with both (Kaufman et al., 2008; Ren et al., 2008).

TIN frequently leads to distal renal tubular acidosis that results in hypokalemia, nephrolithiasis, and nephrocalcinosis. In some patients, antibodies to carbonic anhydrase II are demonstrated. One may also see diabetes insipidus and hypomagnesemia. Patients may notice polydipsia, polyuria, pain from kidney stones, muscle cramps, and rarely paralysis (Both et al., 2015; Evans et al., 2015; Francois and Mariette, 2016; Pertovaara et al., 2011).

Glomerular disease is generally immune complex-mediated and may occur in the setting of systemic, often cryoglobulinemic, vasculitis. It is generally asymptomatic until renal failure occurs, at which point patients note oliguria, fatigue, and problems with hypertension (Evans et al., 2015; Francois and Mariette, 2016; Ren et al., 2008).

## Gastrointestinal Tract

Almost all patients with SS will have some issues with the gastrointestinal tract, as the mouth is a part of the gastrointestinal tract (discussed previously) (Ebert, 2012). Beyond the mouth, however, various problems can be seen. In the esophagus, dysphagia may be seen because of the lack of saliva. Dysmotility with associated dysphagia and gastroesophageal reflux disease may occur because of muscarinic receptor 3 antibodies, acetylcholine receptor antibodies, other forms of nerve injury, and/or secondary metabolic muscle problems (Bengtsson et al., 2011; Ebert, 2012; Park et al., 2013; Pierce et al., 2016).

In the stomach, chronic inflammation and glandular atrophy may be noted. Secondary *Helicobacter pylori* infections may be seen. This may lead to lymphoma. Some patients have antiparietal cell antibodies, but not all of these develop pernicious anemia (Fox et al., 1984).

With regards to small and large bowel disease, abdominal bloating, constipation, diarrhea, nausea, and malabsorption of various nutrients including vitamin D and iron may be seen. Celiac disease has been noted in up to 15% of the patients with SS as well as other food hypersensitivities (Barton and Murray, 2008; Kim-Lee et al., 2015; Pittman and Holub, 1965). Many of these patients were initially labeled as having irritable bowel syndrome. Several patients with SS have been described to have inflammatory bowel disease (Gainey et al., 1985). In patients with vasculitis, the small and large bowel are frequently involved (Scofield, 2011; Tsokos et al., 1987). The neurological and muscular problems affecting the esophagus and stomach are likely to involve the small and large bowel in a similar manner. Furthermore, lymphoma in patients with SS is frequently seen in the small and large bowel in the presence or absence of lymphoma in the salivary glands (Thieblemont et al., 1995).

Involvement of the pancreas in SS can occur for many reasons. There can be autoimmune attack of the pancreatic cells, injury to the biliary tract from sclerosing cholangitis or biliary cirrhosis, inspissation of biliary secretions

because of poor glandular function, ischemic injury because of vasculitis or vasculopathy (commonly associated with antiphospholipid antibodies), and toxic injury because of medications (Ebert, 2012; Lin et al., 2010). Disorders in pancreatic exocrine function have been seen in 18%–37% of the patients with primary SS. However, acute or chronic pancreatitis is identified in 0%–7% of the patients with SS. Rarely neoplasms of the pancreas have been seen, probably not more commonly than in the general population. Patients notice abdominal pain and sometimes diarrhea associated with eating.

The liver is generally not a target organ in primary SS. However, secondary SS can be seen in association with various autoimmune liver diseases including primary sclerosing cholangitis, primary biliary cirrhosis, and autoimmune hepatitis (Floreani et al., 2014; Sun et al., 2015). Furthermore, hepatitis C infection is associated not only with keratoconjunctivitis sicca but also many of the autoantibodies described in patients with primary SS (Buskila, 2009; Ramos-Casals et al., 2001).

## Nervous System

Neurological involvement in SS can involve both the peripheral and central nervous system (CNS) and may be the presenting symptoms in several patients. In two large studies, peripheral nervous system (PNS) was seen in 16% and 10.4% of primary SS patients, respectively, while CNS involvement occurred in 3.6% and 2.7%, respectively. One study estimated CNS involvement to be as high as 8% of the patients with SS (Carvajal Alegria et al., 2016).

PNS manifestations included pure sensory neuropathy, sensorimotor neuropathy, cranial nerve involvement, mononeuritis multiplex, and polyradiculoneuropathy (Mellgren et al., 2007). CNS manifestations included meningitis, encephalitis, transverse myelitis, seizure, stroke, multiple sclerosis-like disease, vasculitis, and various cognitive and psychiatric disorders (Massara et al., 2010). Some degree of autonomic dysfunction was noted in 37.5% of the patients with SS and most strongly associated with the presence of Raynaud's and fatigue (Koh et al., 2017). It was noted that SS patients with one form of neurological disease are likely to develop other neurologic manifestations as their disease progresses.

The mechanisms by which the nervous system is injured in SS are poorly understood but may involve several overlapping pathophysiological processes. There may be autoantibodies affecting nerve function, such as aquaporin 4 antibodies that have been associated with the multiple sclerosis-like disease involving the optic nerve, cerebrum, brainstem, and spinal cord (Dellavance et al., 2012). Cell-mediated injury may occur. The presence of predominantly CD4<sup>+</sup> T lymphocytes has been noted in some peripheral nerve biopsies in patients with primary SS (Mellgren et al., 2007). Immune complex–mediated vasculitis is frequently associated with mononeuritis multiplex and seen more commonly in SS than in most other autoimmune diseases (Cacoub et al., 2015; Jamilloux et al., 2014). Certainly, other forms of nerve ischemia can occur with the vasculopathy of antiphospholipid antibody syndrome seen in association with SS (Acheson and Sanders, 1994). Cytokines produced in the course of the disease can have variable influences on neurological function. Tumor necrosis factor (TNF) at high levels, for example, can induce depression and fatigue (Hermann et al., 2005; Patejdl et al., 2016). Metabolic dysfunction occurring as part of the disease initiating process or as a result of the inflammation seen in SS may certainly contribute to various forms of neurological dysfunction, including autonomic dysfunction and fatigue (Morris et al., 2015; Pagano et al., 2013; Suresh et al., 2014). Not to be forgotten are neural toxicities that can occur because of medications and/or infections (that may occur secondarily to particular medications or to the disease itself) in patients with SS. As with other autoimmune diseases that are treated with immunosuppressive medication, it is not always clear what is a primary disease manifestation and what manifestations occur as secondary processes.

Patients with neurological manifestations of SS are as likely to be seen first by a neurologist as they are to be seen by an ophthalmologist or rheumatologist. It is important that the care of these patients involves a multidisciplinary approach.

## Genitourinary

The involvement of the genitourinary tract is one of the most disabling manifestations of SS for women. Vaginal xerosis has been identified in 53% of SS patients and is often associated with dyspareunia and sexual dysfunction (Priori et al., 2015; van Nimwegen et al., 2015). These problems contribute to the social isolation that is exacerbated by fatigue and depression. The cause for the vaginal xerosis is unknown but is felt to be secondary

to similar processes that cause the loss of secretory function in the salivary and lacrimal glands. No studies have evaluated the effects of SS on male sexual function.

A disorder of bladder inflammation, interstitial cystitis, has been reported in several patients with SS (Darrieutort-Laffite et al., 2015). This disorder can result from many different causes, which were not investigated in these studies (Patnaik et al., 2017). The true incidence of interstitial cystitis in SS is unclear. It is also unclear whether it is actually a manifestation of SS.

Patients with SS also have a higher risk of spontaneous abortion than normal controls (Ballester et al., 2017; De Carolis et al., 2014; Upala et al., 2016). The contribution of secondary antiphospholipid antibodies to this problem has not been adequately studied. Furthermore, because many patients with SS have anti-Ro antibodies, their children may be subject to neonatal lupus, which consists of skin rash and/or heart block (Ballester et al., 2017; Cimaz et al., 2003; Luo et al., 2015).

## Vascular System

The vascular system is commonly involved in patients with SS. The most common manifestation is Raynaud's, which occurs in 30%–50% of the patients (GarciaCarrasco et al., 2002; Kraus et al., 1992; Vivino et al., 2016). Besides causing transient color changes noticed in the hands and feet, Raynaud's can cause reversible CNS vasospasm, causing migraine headaches and transient ischemic attacks, reversible pulmonary hypoxemia, Prinzmetal's angina, and abdominal angina (Gupta et al., 2014; Herrick, 2016; Wigley, 2002). Raynaud's may or may not be associated with the presence of antiphospholipid antibodies (Cervera et al., 2002). The true incidence of antiphospholipid antibodies in SS is not known, but it is probably lower than in SLE, as the incidence of thrombosis is significantly lower in SS than in SLE (Ungprasert et al., 2015). Nonetheless, the presence of antiphospholipid antibodies in SS, as in other autoimmune diseases, is associated with an increased incidence of stroke (Pasoto et al., 2012).

Vasculitis was noted in 10.5% of 152 patients followed over a 25-year period. In another study, 6% of the 1115 patients with SS developed vasculitis (Abrol et al., 2014; Baldini et al., 2014; Retamozo et al., 2016). The vasculitis frequently involved the skin and bowel but can involve other organs such as peripheral nerves, kidney, and muscle. Patients will notice palpable purpura on their skin and crampy abdominal pain, with or without bloody diarrhea. Vasculitis is commonly associated with hypergammaglobulinemia (often predominantly IgM), high titers of autoantibodies and rheumatoid factor (RF), hypocomplementemia, and cryoglobulinemia (Scofield, 2011; Tsokos et al., 1987). While some vasculitis in SS is limited to the skin, as in most other autoimmune diseases, a systemic vasculitis with organ involvement similar to polyarteritis nodosa is more commonly seen in SS than in other autoimmune diseases (Scofield, 2011).

Atherosclerotic cardiovascular disease is increased in patients with SS as well as in patients with SLE (Bartoloni et al., 2015; Birt et al., 2017; Valim et al., 2016). How much this is due to SS and how much to medications, especially corticosteroids used to treat SS, are unclear. Evaluation of potential atherosclerotic disease should be a part of the care of all patients with SS.

## Musculoskeletal and Constitutional Symptoms

Musculoskeletal complaints occur in most patients with SS. The most common complaints are arthralgias without frank arthritis although synovitis can occur in 15%–35% of the patients (Fauchais et al., 2010; Malladi et al., 2012). The most typical joint involvement is the knees and the small joints of the hands and wrists. The arthritis tends to be nondeforming and not associated with erosions. It is important to remember, however, that inflammation in the gastrointestinal tract from either food hypersensitivities or inflammatory bowel disease can lead to an arthritis involving predominantly the hands, wrists, and knees (Holden et al., 2003). Furthermore, SS is frequently seen secondary to rheumatoid arthritis (Anaya et al., 2016).

One of the most debilitating complaints of patients with SS is fatigue. Fatigue is a complex symptom that can occur for many reasons, including sleep disorders, metabolic disorders, cytokines released as part of chronic inflammation, and psychiatric disorders such as anxiety and depression (Norheim et al., 2011). Any or all of these may be relevant to particular patients with SS. It is estimated that 30% of the patients with SS have fatigue (Segal et al., 2009; Vivino et al., 2016). Several studies have identified sleep disorders in patients with SS, although none indicated the true incidence of sleep disorders in this population. It was observed that patients with SS and

obstructive sleep apnea demonstrated improvement in their fatigue when appropriately treated with continuous positive airway pressure (CPAP) (Hackett et al., 2016; Priori et al., 2016; Usmani et al., 2012).

The role of metabolic disorders in various autoimmune diseases has become a recent topic of investigation. Metabolic disorders have been observed in patients with SLE and systemic sclerosis (Fernandez and Perl, 2009; Marra et al., 2015). In SS, decreased antioxidant molecules have been observed in the sera and saliva of patients, evidence of oxidative stress has been observed in the salivary glands and mutations in a mitochondrial carrier protein SLC24A40 have been found in a number of SS patients with fatigue (Morris et al., 2015; Norheim et al., 2014; Ryo et al., 2006). Preliminary studies have observed frequent disorders of aerobic and anaerobic metabolism in patients with SS and fatigue. Treatment of these disorders resulted in symptomatic improvement of fatigue (Ambrus et al., 2015; Kim-Lee et al., 2015).

Various cytokines, especially TNF, are associated with symptoms of fatigue and depression (Norheim et al., 2011). These symptoms are improved with the use of various medications blocking TNF. This effect has been observed in rheumatoid arthritis but has not been systematically studied in SS.

The presence of anxiety and depression in patients with SS has been observed in several studies. The true incidence in SS is unclear, but it is more common than what was observed in normal controls (Epstein et al., 2014; Kocer et al., 2016). Furthermore, the cause for the anxiety and depression is likely to be multifactorial and could involve distress over life changes that occur because of the disease, metabolic disorders, and cytokine effects. It is noted that attention to anxiety or depression in patients with SS is an important part of their care.

## Lymphoma and Other Hematological Manifestations

The incidence of lymphoma is increased in many autoimmune diseases, but most notably in SS. The incidence of lymphoma in patients with primary SS has been estimated to be between 5% and 10% (Voulgarelis et al., 2012; Zintzaras et al., 2005). The malignancies of patients with SS are generally non-Hodgkin's B-cell lymphomas that may be various histological subtypes including follicular lymphoma, large B-cell lymphoma (LBCL), and marginal zone lymphoma (Smedby et al., 2008). Interestingly, the tumors may start not only in the salivary glands but also in other mucosal lymphoid tissues, such as the Peyer's patches, suggesting that there is systemic dysregulations of the B cells. Little is known regarding the evolution of the chronic inflammation of SS into lymphoma, but one hypothesis is that the rapid proliferation of autoreactive cells leads to accumulation of mutations that ultimately allow the malignant state to prevail. Another hypothesis is that there are intrinsic abnormalities in the B cells of SS patients that allow malignancy to develop after further environmental insults (Mackay and Rose, 2001). Malignancy generally requires the dysregulation of at least three genes, one putting the cells into the cell cycle, one inducing proliferation, and one inhibiting apoptosis (BernalMizrachi et al., 2006). It has been observed clinically that SS patients with hypergammaglobulinemia, monoclonal gammopathy, and low C4 are most likely to go on to develop lymphoma. Some of these patients may develop multiple myeloma instead (Giannouli and Voulgarelis, 2014). Studies evaluating LBCL have shown that LBCL from patients with autoimmune diseases is more aggressive and harder to treat than LBCL from patients with no predisposing factors. The LBCL from patients with autoimmune diseases is more commonly the activated B-cell type (ABC) than the germinal center type and is associated with NF- $\kappa$ B activation and a poorer prognosis (Smedby et al., 2008; Song et al., 2009).

Other hematological manifestations of SS include hemolytic anemia, autoimmune thrombocytopenia, and leukopenia (Brito-Zeron et al., 2009; Manganelli et al., 2006). Both hemolytic anemia and thrombocytopenia can be related to the presence of antiphospholipid antibodies (de Groot et al., 2012). Alternatively, they can occur as part of a primary disorder such as SLE. Patients with SS can also have hematological manifestations related to drug reactions, gastrointestinal blood loss, and malabsorption of nutrients, renal failure, and secondary infections.

## PATHOLOGICAL FEATURES

Several issues complicate understanding the histopathology of SS. First, as with all autoimmune disease, SS is a heterogeneous disease determined by different genetic and environmental factors. Different immunological events may contribute to injury of the salivary and lacrimal glands in different patients. Second, SS is a disease that is often not diagnosed until it has been present for several years. Analysis of patients with SS frequently

misses the immunological events involved with the initiation of the disease. In addition, some of the observed changes in patients with SS may be related to attempts of the immune system to correct the problems at hand, rather than being causative for the disease. And third, SS inevitably transitions through various stages, and not all patients are at the same stage of the disease when they are being evaluated. In this section, I will discuss the observations that have been made in patients with SS. In a later section, I will discuss how animal models have been used to put these observations into perspective and to provide new insights into disease pathogenesis, especially initiating factors and disease progression.

When SS was first described, the diagnosis involved the presence of clinical symptoms of dry eyes and/or dry mouth along with the presence of a mononuclear cell infiltrate in the glands that presumably was responsible for these symptoms and ultimately led to the total destruction of the glands (Parke and Buchanan, 1998). Among the current criteria for the diagnosis of SS is the demonstration of  $>1$  mononuclear cell/ $4\text{ mm}^2$  surface area of a minor salivary gland biopsy, called the focus score (Shiboski et al., 2017). Much work has gone into the characterization of these cells and the products that they produce. Lymphocytic foci in the interlobular and intralobular ducts are initially predominantly CD4 $^+$  T cells. These cells have been shown to produce interferon- $\gamma$ , interleukin (IL)-17, IL-21, and IL-22 (Ciccia et al., 2012; Furuzawa-Carballeda et al., 2014; Katsifis et al., 2007). Patients with long-standing SS sometimes have CD4 $^-$ , CD8 $^-$  "double negative" T cells in their salivary glands. These cells were first described in the peripheral blood of patients with SLE (Alunno et al., 2014; Crispin et al., 2008). B cells are commonly found in these lesions and have the phenotype of transitional type 2 B cells (marginal zone B-cell precursors) and marginal zone B cells (Ambrus et al., 2016; Bohnhorst et al., 2002; Daridon et al., 2006; Jonsson et al., 2007; Mariette, 2008; Pers and Youinou, 2014). These B cells have been shown to produce lymphotoxin, which has been implicated in direct injury to the salivary glands (Pillai et al., 2005; Shen et al., 2016, 2010). Plasma cells are identified and are felt to be the distinguishing feature between SS and other forms of salivary gland inflammation (Llamas-Gutierrez et al., 2014). Production of anti-Ro antibodies has been described by plasma cells in the salivary glands of patients with SS (Maier-Moore et al., 2014). Approximately 25% of SS patients have ectopic germinal center-like structures in their salivary glands. The presence of these germinal centers correlates with a higher likelihood of developing lymphoma (Delaleu et al., 2016).

Much work has focused on determining the signals that attract lymphocytes to the salivary and lacrimal glands. Current hypotheses emphasize a role for injury to salivary gland epithelial cells (SGEC) by a viral or other environmental trigger causing them to release CCL17, CCL19, CCL22, CXCL10, CXCL12, and CXCL13 that attract various populations of lymphocytes and dendritic cells to the glands (Amft and Bowman, 2001; Barone et al., 2008). B-cell activating factor (BAFF) produced by SGEC contributes to the abnormal activation of B cells (Mariette, 2008; Pers and Youinou, 2014). Salivary gland epithelial cells also produce IL-7 and have reduced levels of thymic stromal lymphopoietin that influence the activity and survival of T cells (Bikker et al., 2012; Hillen et al., 2016). Local plasmacytoid dendritic cells produce type 1 interferons, which are responsible for the "interferon signature" seen in patients with SS (Bave et al., 2005; Gottenberg et al., 2006). The stimulus for production of type 1 interferons, the timing of type 1 interferon production in the course of the disease, and the roles of type 1 interferon in the pathophysiology of the disease at different stages of the disease are poorly understood (Maria et al., 2015; Mitsias et al., 2002; Nezos et al., 2015; Shen et al., 2013).

Additional studies have emphasized abnormalities in glandular structure and function that may be observed in the presence or absence of cellular infiltrate. These changes may be induced by infections or environmental toxins and/or by cytokines and other mediators released by local cells in response to these toxins. Normal luminal localization of aquaporin 5 is lost in the glands of patients with SS (Gresz et al., 2015). This causes some of the fluid that should be part of the secretions to leak into the interstitium. Furthermore, increased production of cholinesterase and muscarinic receptor antibodies prevents normal production of salivary and lacrimal gland secretions (Dawson et al., 2006; Sumida et al., 2012). Normal signaling through the muscarinic receptors involves import of calcium, release of intracellular calcium, and activation of protein kinase C. Abnormalities in calcium loading via stromal interaction molecules 1 and 2 and calcium signaling have been observed in the cells of the patients with SS that can be mimicked by treating normal salivary glands with lymphotoxin (Cheng et al., 2012; Sneyd et al., 2014; Teos et al., 2015). Finally, the remodeling of the basement membrane of the glands that occurs every 200 days in normal individuals is defective in patients with SS (Konttinen et al., 2006). Extensive acinar cell atrophy and loss are seen in conjunction with ductal cell hypertrophy. Increased production of matrix metalloproteinase 9, which can degrade collagen type IV, and trypsin-2 in patients with SS have been implicated in these changes (Molina et al., 2006).

## AUTOIMMUNE FEATURES

SS is an autoimmune disease because organ damage is demonstrated in the presence of autoantibodies, in the absence of other explanations for the organ damage. Infections that are known to cause disease similar to SS are excluded from the diagnosis, including hepatitis B and C, HTLV-1 mumps, and CMV. Other causes of glandular dysfunction, such as anticholinergic drugs, radiation therapy, aging, and other systemic inflammatory diseases, such as sarcoidosis, must also be excluded before a diagnosis can be made (Cornec et al., 2015). What is unclear, however, is the mechanism(s) by which the actual organ injury occurs.

As with other autoimmune diseases, such as type 1 diabetes (T1D) and rheumatoid arthritis, evaluation of patients with very early disease often reveals damaged tissue with some associated macrophages, but not lymphocytes (McNelis and Olefsky, 2014; Tapinos et al., 1999). Furthermore, as discussed below, several animal models for SS have demonstrated loss of salivary and lacrimal gland function before any lymphocytes are seen in the glandular tissue. This suggests that lymphocyte-directed killing of the target organ is not a major factor in the early course of the disease, at least in some patients. Whether it is a feature in later stages of the disease is unclear as well.

Autoantibodies, such as anti-Ro, which are used to define SS as a disease entity, may have many functions as well. Studies in various autoimmune diseases have suggested that some autoantibodies, especially IgM autoantibodies, may be utilized by the immune system to recognize damaged tissues and bring in cells that can participate in tissue repair (Gronwall and Silverman, 2014; Nguyen et al., 2015). If the tissue is repaired and inflammation is stopped, the individual can return to a normal state. Perhaps what defines the development of this as well as other autoimmune diseases is the inability to turn the immune system off once it has initiated a response—normal low-affinity autoreactivity is converted to a high-affinity autoimmune response that is (1) capable of injuring self—for example, IgG autoantibodies can induce antibody-mediated cytotoxicity while IgM autoantibodies cannot and (2) memory B and T cells are formed which are not as susceptible to growth inhibitory and apoptotic signals as primary B and T lymphocytes (Kurosaki et al., 2015; Sallusto et al., 2004). Studies have demonstrated autoantibodies in some patients with SS and SLE years before clinical disease was evident (Arbuckle et al., 2003; Theander et al., 2015). Did this merely demonstrate that they were responding to an environmental challenge that they were able to confine without leading to overt disease? Overt disease occurred later when more potent environmental challenges occurred that could not be contained. And/Or, did it demonstrate that they had a genetic predisposition to have difficulty turning off their immune systems once the wrong kind of environmental trigger occurred. All autoantibodies can be seen in normal individuals, but not in the titers, isotypes, and affinities seen in patients with autoimmune diseases.

Once more is learned about the pathophysiology of SS, the environmental triggers, the predisposing genes, the sequence of events leading to organ malfunction, and the sequence of events leading to the progression from a localized disease of the salivary and lacrimal glands to a systemic disease involving multiple other organs and ultimately lymphoma, a greater understanding will be available of what it means that SS is an “autoimmune” disease.

## GENETICS

SS, like all other autoimmune diseases, has a strong genetic component. All centers studying patients with SS have patients whose family members have SS as well as other related autoimmune diseases (Reksten et al., 2016). However, in contrast to SLE and T1D, twin studies have never been done in this disorder to document a definitive genetic contribution. Attempts to understand the genetic components of SS have largely been done by genome-wide association studies (GWAS). These studies are hampered by the fact that large numbers of patients and controls are needed to get statistically significant data and the patients being studied have variable ethnic backgrounds and distinct clinical phenotypes. Even in patients with the same clinical phenotype, the genetic factors contributing to the development of disease may be variable. These factors are likely responsible for differences in the results of the GWAS studies with SS patients in the United States and China (Lessard et al., 2013; Li et al., 2013). Furthermore, genetic association studies done in various other locations with smaller numbers of patients identify potential genetic associations not appreciated in the larger GWAS studies (Bolstad and Jonsson, 2002; Miceli-Richard and Criswell, 2014).

The first genetic studies done on patients with SS at the National Institutes of Health in Bethesda, Maryland (United States) evaluated HLA genes because of their importance in antigen presentation. These studies revealed a strong association of SS with HLA-Dw3, HLA-B8, HLA-DRw3, HLA-DR3, and HLA-Dw52. Later studies revealed a strong association of North American SS patients with HLA-DRB1\*0301-DRB3\*0101-DQA1\*0501-DQB1\*0201. Japanese SS patients were associated with HLA DRB1\*0405-DRB4\*0101-DQA1\*0301-DQB1\*0401 and Chinese SS patients with DRB1\*0803-DQA1\*0103-DQB1\*0601 (Kang et al., 1993). In Finland, the association of SS was with HLA-DRB1\*0301-DQA1\*0501-DQB1\*0201 (Kerttula et al., 1996). Some variability has been seen in all different SS patient populations, depending upon their ethnic background and location.

Besides the HLA genes, GWAS studies have identified statistically significant polymorphisms involved with various cellular functions (Reksten et al., 2016). These include IRF5 (interferon regulatory factor 5), a transcription factor induced by type 1 interferon that induces production of IL-6, IL-12, type 1 interferon, and tumor necrosis factor alpha (TNF- $\alpha$ ). IRF5 also induces the production of BLIMP-1, which is important for the differentiation and function of plasma cells and B1 cells (Reksten et al., 2016; Salloum and Niewold, 2011). Genetic associations with SS were also found with several gene polymorphisms relevant to IL-12 function, the IL-12 receptor subunit B, signal transducer and activation of transcription 4, and interferon regulatory factor 8 (Korman et al., 2008; Low and Witte, 2011; Reksten et al., 2016). IL-12 is important for various aspects of innate and cell-mediated immunity. With regards to B-cell function, polymorphisms increased in patients with SS were found in the B lymphocyte tyrosine kinase, Ras guanyl-releasing protein 3, diacylglycerol kinase theta, and cytoplasmic polyadenylation element binding protein 4 all of which are involved with intracellular signaling in B cells (Reksten et al., 2016). In addition, polymorphisms were found in CXCR5, the chemokine receptor for CXCL13 that is involved with bringing B and T cells into germinal centers (Kramer et al., 2013). In other studies, polymorphisms were seen in the genes for lymphotoxin- $\alpha$  and its receptor tumor necrosis factor receptor 1, tumor necrosis factor super family 4, and the TNF- $\alpha$ -induced protein 3 (Bolstad et al., 2012; Fletes-Rayas et al., 2016; Nocturne et al., 2016; Nordmark et al., 2011). These proteins may all be involved with induction of cellular cytotoxicity and inflammation.

The significance of these genetic polymorphisms in the pathophysiology of SS is poorly understood, but they do suggest areas of cellular function that deserve further attention. They also emphasize the importance of studying genetic of SS in patients with the same form and stage of disease. This is currently a problem in the study of all autoimmune diseases.

## ANIMAL MODELS INCLUDING RELEVANCE

The use of animal models in the study of SS has several caveats. On the plus side, spontaneous animal models of SS allow study of the time course of various physiological changes in the disease, they allow introducing genetic changes to see how they influence the disease process and they allow the investigation of particular therapeutic strategies. Animals can be autopsied to make complete assessment of the status of each organ at any particular stage of disease. The initiation of disease can be investigated, which can almost never be appreciated in patients with SS. On the negative side, since SS is a heterogeneous disease, each animal model likely represents a form of disease that may be present in some but not all patients. Second, depending upon how the animal model is established, the cure of the disease may involve reversing the mechanism by which the disease was induced rather than doing something that would be relevant to treating the human disease. And, finally animals may have different ways of dealing with particular immunological challenges than people, so all observations made in animals may not be directly referable to human disease. Any observations made in animal models of SS need to be reassessed in SS patients, when possible (Delaleu et al., 2011; Lee et al., 2012).

The first murine models used to study SS were in fact animal models already being utilized to study SLE (Keyes et al., 1977). The (NZB × NZW) F1 mouse develops many of the features of SLE and has been used to identify genes involved in the pathogenesis of the disease (Wakeland et al., 1999). These mice do not develop sicca symptoms but can be induced to develop them with agonists for Toll-like receptor 3 which induced production of type 1 interferons (Deshmukh et al., 2008). The MRL/lpr mouse has also been used to study SLE, although its disease is largely due to a mutation in fas, which make them a model for the human lymphoproliferative syndrome (Turbyville and Rao, 2010). These mice develop lymphocytic infiltration of salivary glands and in some cases anti-Ro antibodies, but they do not develop either keratoconjunctivitis sicca or loss of salivation (Jabs and Prendergast, 1988).

The first animal model that developed salivary and lacrimal gland dysfunction more consistent with SS was the NOD mouse (Gao et al., 2006). These mice develop both T1D and SS, although these two autoimmune diseases developed by different mechanisms. >20 chromosomal regions contribute to the development of T1D. Deleting Toll 2 from the NOD genome eliminates the T1D but does not influence the development of SS (Kim et al., 2011). Blocking intercellular adhesion molecule-1 (ICAM-1) early in the course of the disease prevents the salivary gland inflammation without affecting the T1D (Roescher et al., 2011). Two genetic loci of the NOD strain, *Idd3* (also known as *Aec1*—autoimmune exocrinopathy 1) and *Idd5* (*Aec2*) were noted to be critical for the development of SS. A new strain of mice expressing these genetic loci on a C57Bl/6 background was developed, the C57BL/6.NOD-Aec1Aec2 mouse. This mouse does not develop T1D but demonstrates loss of salivary gland function before lymphocytic infiltration of the salivary glands, activated B and T lymphocytes, autoantibodies, and inflammatory cytokines (Nguyen et al., 2006; Peck et al., 2011). Another derivative of the NOD mouse is the NOD.B10Sn-H2<sup>b</sup>/J (NOD.B10) mouse that was generated by replacing the MHC locus of the NOD mouse with the MHC of the C57BL/6 strain. These mice also develop SS without developing T1D. They develop lymphocytic infiltration of the salivary and lacrimal glands as well as pulmonary disease, renal disease, and autoantibodies (Coursey et al., 2016).

Various animal models for SS have been developed based on mediators felt to be important in the development of human disease. One of the hypotheses for the development of SS is that viral infection of the salivary and lacrimal glands leads to the initial tissue injury that sets off the disease process in a person with the appropriate genetic background (Igoe and Scofield, 2013). Murine cytomegalovirus was used to infect C57BL/6 lpr-deficient mice (C57BL/6.lpr/lpr). The mice developed sialadenitis that persisted after the infection was cleared. Chronic inflammation with T cells and high titers of anti-Ro antibodies were noted (Ohyama et al., 2006).

In patients with SS, increased expression of BAFF was noted in epithelial cells and was felt to be responsible for the abnormal activation of B cells and survival of autoreactive B cells (Kalled, 2005). BAFF transgenic mice develop a disease very similar to human SS except they develop a proliferative glomerulonephritis and fail to develop lymphoma (Mackay et al., 1999). BAFF transgenic mice lacking the TNF- $\alpha$  gene do develop lymphoma (Sutherland et al., 2006). BAFF transgenic mice lacking marginal zone B cells fail to develop features of SS, although they still develop glomerulonephritis (Fletcher et al., 2006). Marginal zone B cells produce lymphotoxin, which was felt to be critical for the development of SS (Pillai et al., 2005; Shen et al., 2016).

Similarly, patients with SS, as well as MRL/lpr, (NZB × NZW) F1 and C57BL/6.NOD-Aec1Aec2 produce IL-14 at high levels, a cytokine felt to be important for the development and survival of memory B cells (Shen et al., 2006). One hypothesis is that the development of autoimmune disease occurs when normal low-affinity autoreactivity is converted to a high-affinity memory response. IL-14 could drive this abnormal memory B-cell function. IL-14 transgenic mice were demonstrated to develop features of SS seen in the patients with SS in the same relative time frame: hypergammaglobulinemia, autoantibodies, loss of salivary gland function before infiltration of the salivary glands with lymphocytes, lymphocytic infiltration of the submandibular and lacrimal glands before the parotid glands, lymphocytic interstitial lung disease, mild renal disease, and in old age LBCLs (Shen et al., 2009). Features of SS could be eliminated from IL-14 transgenic mice by deletion of either marginal zone B cells or lymphotoxin (Shen et al., 2010, 2016). Deletion of the type 1 interferon receptor gene from IL-14 transgenic mice prevented late manifestations of the disease (parotid gland, lung and kidney disease as well as lymphoma) but not the early manifestations of the disease (loss of salivary gland function and lymphocytic infiltration of the submandibular and lacrimal glands) (Shen et al., 2013). Autoantibodies to the salivary and lacrimal gland antigens, salivary gland protein 1, carbonic anhydrase 6, and parotid secretory protein were demonstrated to occur in the mice before antibodies to Ro (Shen et al., 2012). These observations have been confirmed in other animal models for SS as well as in patients (Everett et al., 2017; Shen et al., 2014; Suresh et al., 2015).

Anti-Ro antibodies are commonly seen in SS, and in fact part of the diagnostic criteria for SS (Shiboski et al., 2017). BALB/c mice were immunized with Ro peptides to generate these autoantibodies. Decreased salivary gland flow and infiltration of the salivary glands with lymphocytes were noted. Neither lacrimal gland disease nor disease of the lungs, kidneys, or lymph nodes were noted (Scofield et al., 2005). Similarly, antimuscarinic receptor 3 antibodies are seen in a subgroup of patients with SS (Zuo et al., 2016). T cells from C57Bl/6-M3R  $-/-$  mice immunized with M3R peptides transferred into C57BL/6-Rag-1  $-/-$  mice caused decrease in salivary flow and infiltration of the salivary glands with lymphocytes (Sumida et al., 2012).

Other proteins that are aberrantly expressed in SS have also been investigated in animal models of SS. Bone morphogenic protein 6 (BMP6) was noted on microarray studies to be selectively increased in the salivary glands

of patients with SS compared to normal controls. Increased expression of BMP6 in the salivary gland cells of C57BL/6 mice led to loss of salivary gland function in the absence of infiltrating lymphocytes (Lai et al., 2016). Protein kinase C-delta expression is reduced in lymphocytes of patients with SS (Varin et al., 2012). Deletion of protein kinase C-delta gene from C57BL/6 mice led to lymphocytic infiltration of multiple organs including the salivary glands with resulting hyposalivation (Miyamoto et al., 2002). Phosphatidylinositol-3-kinase (PI3K) is critical for downstream signaling of the T-cell receptor as well as other receptor molecules on T cells (Garcon et al., 2008). Deletion of PI3K from T cells of C57BL/6 mice led to lacrimal gland selective loss of secretory function (Oak et al., 2006). Another molecule important for signaling through the T-cell receptor, inhibitor of differentiation 3, was also deleted from C57BL/6 mice (Yokota, 2001). These mice showed loss of both lacrimal gland and salivary gland function without infiltration of the glands with lymphocytes or production of either anti-Ro or anti-La antibodies (Pan et al., 1999).

Overall, these animal models for SS raise several important issues that were largely missed in studies looking exclusively at patients with SS. First, loss of salivary and lacrimal gland function may occur before or even without identifiable lymphocytic infiltration of the glands. This does not mean, however, that lymphocytes do not participate in the pathophysiology of the disorder. Second, the innate immune system is important in the pathophysiology of the disease and this is not simply a disorder of the adaptive immune system in which self-tolerance has been lost. Third, salivary and lacrimal gland injury may occur via multiple different mechanism that may not be the same in all patients. In some cases, marginal zone B cells and the lymphotoxin they produce are important in the pathophysiology of the disorder in its early stages. SS progresses through many stages of disease that may occur over a course of many years in patients. The significance of particular cytokines, such as type 1 interferons and IL-17, may be variable at different stages of the disease. In chronic viral infections, type 1 interferon has very different effects at the onset of the infection compared to the state in which a chronic infection has been established (Muller et al., 1994; Taleb et al., 2017). Finally, events necessary for the progression of SS through its various stages including the development of lymphoma will have to be studied further in animal models before headway will be made in understanding what patients with SS undergo. Animal models will help to delineate parameters that will allow SS to be divided into its various subtypes.

## DIAGNOSTIC PROCEDURES

The ACR/EULAR 2016 criteria for the diagnosis of SS require a positive response to at least one of the following questions (Shiboski et al., 2017):

1. Have you had daily, persistent, troublesome dry eyes for >3 months?
2. Do you have a recurrent sensation of sand or gravel in the eyes?
3. Do you use tear substitutes >3 times a day?
4. Have you had a daily feeling of dry mouth for >3 months?
5. Do you frequently drink liquids to aid in swallowing dry food?

Exclusion of the following entities:

1. History of head and neck radiation treatment
2. Active hepatitis C infection (with confirmation by polymerase chain reaction)
3. AIDS
4. Sarcoidosis
5. Amyloidosis
6. Graft-versus-host disease
7. IgG4-related disease

And a score of >4 on the following weighted tests:

1. Labial salivary gland with focal lymphocytic sialadenitis and focus score >1 foci/4 mm<sup>2</sup> (weight = 3)
2. Anti-Ro positive (weight = 3)
3. Ocular staining score >5 in at least one eye (weight = 1)
4. Schirmer's test <5 mm/5 minutes in at least one eye (weight = 1)
5. Unstimulated whole saliva flow rate <0.1 mL/min (weight = 1)

The questions for the diagnosis of SS are straightforward and usually not a challenge for the patients. Some may feel, however, the mild dry eye is normal however. The exclusion criteria require a thorough history and physical as well as potentially laboratory and radiographic studies for further analysis. An oral surgeon or other trained physician can do the lip biopsy. Rheumatologists in specialized SS clinics often do them. However, the key is to have the labial biopsy read by a pathologist who has experience with them. There are many mistakes that can be made in interpreting them (Caporali et al., 2008). Similarly an experienced lab should do the identification of anti-Ro antibodies in sera. There is no national standard for this test, so variability may be seen in the test results among different labs. Furthermore, the titers of anti-Ro antibodies in sera may vary over time in individual patients. An experienced ophthalmologist should do the ocular staining score and Schirmer's test. Variability in the results of these studies depends on not only the experience of the person doing the study but also day-to-day fluctuation in individual patients (Valim et al., 2015). The collection of saliva requires appropriate cooperation of the patient and may show day-to-day variability but is generally not technically challenging.

These diagnostic criteria will certainly undergo further modification in the next several years.

Other studies used to establish abnormalities in the salivary and lacrimal glands, although not part of the diagnostic criteria, can also be helpful. Some investigators have utilized ultrasound including ultrasound-guided biopsies, but this is not routinely done at most centers (Astori et al., 2016; Delli et al., 2015). Technetium 99m Tc-sodium pertechnetate scintigraphy can be used to evaluate saliva formation as well as resting and stimulated function. The utility of this study is dependent upon the experience and expertise of the center doing the study. Magnetic resonance imaging (MRI) including MR sialography, computed tomography, and 18F-FDG PET/CT are utilized to evaluate swelling in the salivary glands, especially when a diagnosis of lymphoma is being considered (Cohen et al., 2013).

The investigation of the extraglandular manifestations is done according to the organ system being studied. All patients should have a complete blood count to look for hematological abnormalities, basic metabolic profile to look for liver or kidney abnormalities, urinalysis to look for kidney abnormalities, especially renal tubular acidosis, quantitative IgG, IgA, and IgM levels to look for hypergammaglobulinemia, and serum protein electrophoresis to look for monoclonal gammopathy. If breathing abnormalities are suggested, a high-resolution chest CT may be indicated to look for interstitial lung disease. Gastrointestinal problems may indicate a workup for celiac sprue, food hypersensitivities, inflammatory bowel disease, and/or motility disorders. Neurological abnormalities may indicate nerve conduction studies, MRI studies of the brain and spinal cord as well as additional serological studies. The presence of Raynaud's should trigger a workup for antiphospholipid antibodies. The presence of profound fatigue may indicate the need for a sleep study as well as a workup for metabolic abnormalities. If vasculitis is likely based on skin findings, appropriate angiograms and/or biopsies may be necessary before therapy is initiated.

The complete workup for each SS patient is individualized based on the initial history and physical examination. It is important to remember the types of organ involvement that can occur with SS so each patient gets the appropriate workup and therapy as their disease evolves.

## TREATMENT

Rheumatologists and internists have ignored SS historically for several reasons. First, they believed that it was a very rare disease. We now know that this is not true. Second, they thought that it was a benign disease, since no one dies from dry eyes and dry mouth. We now know that dry eye, dry mouth, fatigue, and dyspareunia can be very debilitating and socially isolating for patients. And, we understand that of all the autoimmune diseases, SS has the highest incidence of systemic vasculitis and lymphoma, both of which can be fatal (Singh et al., 2016). And finally, studies done in the 1980s and 1990s suggested that there were really no therapies for SS. We now know that various symptomatic therapies can be beneficial for the day-to-day lives of SS patients. More importantly, as we learn more about SS, various therapies are emerging that show promise to control the underlying disease. Beyond the specific treatment of SS itself, however, each patient is managed according to their organ involvement. For example, if a SS patient has LIP, they are treated with rituximab, cyclophosphamide, or a similar immunosuppressive therapy that has been shown to work in LIP in patients not only with SS but also with SLE, scleroderma, polymyositis, and other autoimmune diseases.

Recent treatment recommendations have been published by the Sjogren's Foundation for the management of patients with SS ([Vivino et al., 2016](#)):

1. Management of oral problems is recommended that a topical fluoride be used. Attempts should be made to increase salivary flow and these include masticatory stimulation, sugar free lozenges or gums, mannitol, xylitol, and either Pilocarpine or Cevimeline. Chlorhexidine mouthwash is used to reduce dental caries. Nonfluoride remineralizing agents are encouraged.
2. Management of eye problems includes artificial tears, gels, and ointments. For more severe disease, topical steroids, topical cyclosporine, punctal plugs, and secretagogues (Pilocarpine and Cevimeline) are recommended. For the next level of disease severity, contact lenses, topical autologous serum, and permanent punctal occlusion are recommended. For the most severe patients, eyelid surgery and systemic antiinflammatory therapy are recommended.
3. Regarding musculoskeletal pain, hydroxychloroquine is recommended as a first-line agent with the addition of methotrexate if hydroxychloroquine alone is not adequate. Short and long term (>1 month), corticosteroids are recommended in the worst cases. The use of other disease-modifying agents, such as leflunomide, sulfasalazine, azathioprine, and cyclosporine, are only weakly recommended.
4. Regarding fatigue, exercise and dehydroepiandrosterone received strong recommendations. A strong recommendation against the use of TNF- $\alpha$  inhibitors is included.
5. The only biological agent to be given a positive recommendation is rituximab, which is recommended moderately for cryoglobulinemia, vasculitis, severe parotid swelling, inflammatory arthritis, pulmonary disease, and peripheral neuropathy. Only weak recommendation is given for the use of rituximab for keratoconjunctivitis sicca and xerostomia.

A new treatment for eye disease, lifitegrast ophthalmic solution 5%, which works by blocking the interaction between lymphocyte function-associated antigen (LFA-1) and ICAM-1, was not considered in this publication because it is new and has no long-term studies. It has been shown in three trials to improve inferior corneal staining score and eye dryness score ([Keating, 2017](#)).

The use of hydroxychloroquine for musculoskeletal disease is accepted. The use of hydroxychloroquine to help symptoms of dry eyes is debated. Both positive and negative studies have reported its use in this indication ([Gottenberg et al., 2014](#); [Yavuz et al., 2011](#)). Interestingly, in SLE patients with antiphospholipid antibodies, the use of hydroxychloroquine has been associated with a lower incidence of thrombosis ([Belizna, 2015](#)).

With regards to the use of biological agents in SS, rituximab is the only agent that has received a positive recommendation. Interestingly, several trials using rituximab in SS have been done. The trials that utilized patients with early SS showed more positive results than the trials done in patients with more advanced disease ([Carubbi et al., 2013](#); [Devauchelle-Pensec et al., 2014](#); [Pijpe et al., 2005](#); [Souza et al., 2016](#)). The issue of patient selection and the timing of drug administration plays an important role in all the ongoing trials with other biological agents, which to date have not seen significant positive results to warrant their use: Belimumab, a monoclonal antibody that blocks BAFF ([Ginzler et al., 2014](#)); Abatacept, a soluble CTLA-4-Ig that interferes with T-cell activation ([Meiners et al., 2013](#)); and Baminercept, a soluble lymphotoxin beta receptor IgG fusion protein that blocks the actions of lymphotoxin beta ([St Clair et al., 2015](#)). Additional biological agents are in the early phases of the study. These include a monoclonal antibody that blocks CD 40, to inhibit B-cell activation, a monoclonal antibody to inducible T cell costimulator-ligand (ICOS-L) to block the formation of T follicular helper cells and production of high-affinity autoantibodies, a PI3K inhibitor, to block B- and T-cell activation, and a monoclonal antibody to the IL-6 receptor, to block the formation of plasma cells ([Vivino et al., 2016](#)).

Management of extraglandular manifestations of SS often involves therapies that have been studied in other related disease entities, but not necessarily specifically in SS. As mentioned previously, the LIP can be managed with rituximab, but other immunosuppressive agents, including cyclophosphamide and mycophenolate mofetil (MMF), have been used successfully in patients with SS and other autoimmune disease ([Parambil et al., 2006](#); [Wells and Denton, 2014](#)).

Renal disease is managed according to the nature of the problem ([Francois and Mariette, 2016](#); [Ren et al., 2008](#)). TIN has generally been treated with corticosteroids alone, although MMF has been proposed as a "steroid-sparing" agent in patients who require long-term therapy. With renal tubular acidosis, the acidification is corrected with sodium bicarbonate and secondary hypokalemia is corrected with potassium. Glomerular disease is treated according to the nature of the abnormality. If an immune complex glomerulonephritis occurs because of cryoglobulinemia, rituximab can be utilized, as can other immunosuppressive drugs including cyclophosphamide and MMF.

Treatment of the gastrointestinal manifestations in SS depends upon the nature of the gastrointestinal problem. If the patient has celiac sprue or another food hypersensitivity, an elimination diet of the offending food is warranted (Aziz et al., 2016; Farrell and Kelly, 2002; Kim-Lee et al., 2015). In some cases, antiinflammatory agents targeting the gastrointestinal tract are indicated. Similarly, with inflammatory bowel disease, various immunosuppressive agents can be utilized, including budesonide, mesalamine, and TNF- $\alpha$  inhibitors, depending upon the nature and severity of the disease (Abraham et al., 2017). Other biological agents, such as an inhibitor of the integrin  $\alpha 4\beta 7$ , are used in special cases (Perez et al., 2017). Motility disorders can be treated with various agents stimulating motility, including erythromycin, loperamide, and metoclopramide. However, an endocrine and/or metabolic workup may be indicated to look for an underlying treatable cause (Gidwaney et al., 2016; Sanger and Pasricha, 2017). Vascular disease of the gastrointestinal tract may require specific therapy, as does vascular disease anywhere (see later).

Treatment of nervous system problems depends upon the nature of the underlying problem. Rituximab is shown to improve peripheral neuropathy related to either vascular disease or autoantibody-mediated injury (Mekinian et al., 2012; Tracy and Dyck, 2010). Corticosteroids and other immunosuppressive agents have also been used in this setting. Other neurological problems are treated according to the pathophysiology of the disorder (Carvajal Alegria et al., 2016; Jayaramaiah et al., 2014; Massara et al., 2010; Zhong et al., 2017).

Raynaud's is treated with the appropriate vasodilators (Bakst et al., 2008; Hughes and Herrick, 2016). Calcium channel blockers, such as nifedipine and verapamil; alpha-blockers, such as Doxazosin; nitrates, such as isosorbide mononitrate; and phosphodiesterase inhibitors, such as Cilostazol, can all be utilized. If Raynaud's occurs in the CNS, something called reversible CNS vasospasm, the calcium channel blockers nimodipine and nicardipine are most effective (Gupta et al., 2014; Rao and Muthuchellappan, 2016; Singhal et al., 2011). Raynaud's uncontrollable with oral agents, which rarely occurs in SS, can be treated with intravenous prostaglandin E1 (Hauptman et al., 1991). If antiphospholipid antibodies are present, patients should be on an antiplatelet drug, preferably aspirin. If thrombosis has occurred, systemic anticoagulation is indicated (Scoble et al., 2011).

The vasculitis of SS can be restricted to the skin. This can be managed with hydroxychloroquine and in rare cases rituximab (Chen and Carlson, 2008). If patients with SS have vasculitis involving major organs or larger blood vessels, however, rituximab or an immunosuppressive agent, such as cyclophosphamide, is utilized (Scofield, 2011; Tsokos et al., 1987).

Treatment of fatigue in SS is dependent upon the cause of the fatigue. If sleep apnea is present, this should be treated with CPAP, bilevel positive airway pressure (BiPAP), or a dental appliance (Usmani et al., 2012). If a metabolic disorder is present, this should be treated according to the underlying problem. Patients with mitochondrial problems may respond to a combination of CoQ10, creatine, carnitine, folic acid, and alpha lipoic acid (Abdullah et al., 2012; Finsterer and Bindu, 2015; Nicolson, 2014; Tarnopolsky, 2008). Patients with glycogen storage diseases eliminate complex carbohydrates from their diets and substitute them with simple sugars (Adler and Shieh, 2015; Weinstein and Wolfsdorf, 2002). Patients with myoadenylate deaminase deficiency use a protein-restricted diet along with ribose (Goebel and Bardosi, 1987; Teijeira et al., 2009). If SS patients have significant anxiety and/or depression, counseling is indicated and in some cases appropriate pharmacological intervention as well (Kotsis et al., 2014; Milin et al., 2016).

The lymphomas associated with SS are treated according to their histology and genetic make-up. The most common lymphoma seen in SS is diffuse LBCLs of the ABC type (Blenk et al., 2007; Theander et al., 2006). This is a difficult lymphoma to treat. Recent therapies have utilized a combination of rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone (Fu et al., 2008; Zhou et al., 2017). New forms of therapy are being developed as more is learned about the characteristics of these tumors.

Overall, the treatment of patients with SS must be individualized to the particular manifestations that are present. Attention to each of the existing abnormalities is necessary to provide the SS patient with needed symptomatic relief. Appreciation of the genetic variability contributing to SS in different patients may also demand different approaches to similar disease manifestations in individual patients. Improved therapies are being developed as more is learned about the pathophysiology of SS as well as its variability.

## PERSPECTIVES

SS is an interesting disorder to look at from a historical perspective. It has gone from being considered a rare disorder to being recognized as one of the most common autoimmune diseases. It has gone from being considered an inconsequential and untreatable disorder to one that causes significant patient morbidity and mortality.

Various treatment options exist and are being developed. The research in SS has blossomed in the last decade and will hopefully continue at a similar pace.

The research in SS using both patients and animal models has focused attention on several paradigm shifts in the field of autoimmunity, which have been observed in other autoimmune diseases as well. For a disease that was once considered due to a lack of self-tolerance in the adaptive immune system, we now recognize the importance of the innate immune system in the initiation and perpetuation of the disease (Kramer, 2014; Low and Witte, 2011; Shikhagaie et al., 2017). We recognize that autoreactivity is often part of the normal immune system and not equivalent to autoimmune disease (Tiller et al., 2007). We recognize that some autoantibodies, especially IgM autoantibodies, may be part of the immune system's attempt to regulate itself as well as to repair tissue injury. All autoantibodies are not necessarily pathological (Bayry et al., 2004; Carselli et al., 2005; Gronwall and Silverman, 2014; Panda and Ding, 2015). We have begun to appreciate the complexity of SS as it evolves through various stages (Delaleu et al., 2011; Haldorsen et al., 2008; Jonsson et al., 2006; Roescher et al., 2012; Shen et al., 2013; Xuan et al., 2013). Particular mediators and cytokines may play various pathophysiological roles in different stages of the disease. We appreciate the phenotypic and genetic variability of the disease. We understand the overlapping nature of the genes predisposing to SS and other autoimmune diseases (Bolstad and Jonsson, 2002; Lessard et al., 2013; Reksten et al., 2016; Teruel and Alarcon-Riquelme, 2016). Many patients will have clinical features that overlap what is expected in the textbook definitions of particular autoimmune diseases including SS, SLE, celiac sprue, inflammatory bowel disease, and many others. Improved care of patients with SS requires more in-depth understanding of the genetic and environmental factors involved, the dysfunction that has occurred in various tissues, the dysregulation that has occurred in the immune system, and the way that these changes evolve over time. For example, understanding that all autoimmune diseases involve the inability to turn off the immune system once activated provides insights into the causes of flares in these diseases. One must look for and eliminate the agent that activated the immune system, be it an infection, drug reaction, or other environmental trigger, before using immunosuppression to quiet down the over reactive cells.

## INTRODUCTION

The joints are a target organ of many systemic autoimmune diseases, but in rheumatoid arthritis (RA), they are the preponderant and mostly sole evident focus of attack, with a large propensity to become destroyed. The pain and damage it elicits underlie the significant disability that can strike the patients and may lead to a wheelchair- or bed-ridden state. Thus RA impairs all aspects of quality of life, including the ability to work, and the consequences of the burden of the disease to the individual and society are enormous. For all these reasons, a better understanding of the pathogenesis of RA to develop new therapeutic agents interfering ideally with all pivotal events in all patients, or finding and abrogating the cause (or causes) of the disease, constitutes a major task.

## CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

The *epidemiology* of RA is quite well characterized. RA is the most common chronic inflammatory joint disease, affecting 0.5%–1% of the populations in the industrialized world and women more frequently than men (2–3:1) (Silman and Pearson, 2002; Helmick et al., 2008; Eriksson et al., 2013). However, in certain Native American (Eriksson et al., 2013) populations, the prevalence is much higher (Helmick et al., 2008). The causes of the disease are unknown; however, several pieces of indirect evidence suggest that both environmental as well as genetic factors play an important role. Several environmental risk factors have been identified: (1) RA has already at the time of its description been regarded as a disease of the poor (Landre-Beauvais, 1800) and lower levels of education and upbringing under adverse socioeconomic conditions are afflicted with a more severe course of RA and/or a higher baseline inflammatory state (Callahan and Pincus, 1997; Uhlig et al., 1999; Packard et al., 2011); (2) smoking may increase the risk and possibly also the severity of RA and is associated with increased tumor necrosis factor (TNF) and autoantibody production which in turn is related to genetic factors characteristic of RA (Silman et al., 1996; Symmons et al., 1997; Uhlig et al., 1999; Mattey et al., 2002; Glossop et al., 2006), although

these associations have not been confirmed in all populations (Klareskog et al., 2011; Vesperini et al., 2013); (3) the microbiome, especially in the gastrointestinal tract, has been identified as an important regulator of autoimmunity and appears to play a major role in experimental forms of arthritis (Yoshitomi et al., 2005; Abdollahi-Roodsaz et al., 2008; Wu et al., 2010). In human RA, an association with particular bacteria, such as *Porphyromonas gingivalis*, a bacterium that produces peptidyl-arginine deiminase (PAD1), the enzyme responsible for citrullination (see below), has been found (Wegner et al., 2010; Scher et al., 2012). Recently, *Prevotella copri* has been linked to the pathogenesis of RA, as this bacterium is overexpanded in patients with RA and both humoral and cellular immune responses to this bacteria have been observed (Scher et al. 2013; Pianta et al. 2017). Beyond these aspects, hormonal factors may also play a role in the development of RA (Silman and Pearson, 2002).

The main clinical characteristics of RA are pain and swelling of the joints. The 2010 ACR/EULAR classification criteria (Aletaha et al., 2010), which are mainly used for clinical trial purposes but can also support the diagnostic process, require the presence of clinical synovitis (i.e., swelling due to synovial involvement) in at least one joint. The more joints that are affected (swollen or painful), the easier the patient can fulfill the criteria. Joints involved are primarily those of the wrists, fingers, toes, and knees (Smolen et al., 1995) but also many other joints can be affected, although some joints, such as the distal interphalangeal joints, are usually spared. Affected joints are not only painful upon motion and visibly swollen (Fig. 34.1A) or upon clinical examination but also tender to mild

**FIGURE 34.1** A. Hands of patients with RA. In the upper left image showing early RA, swelling is visible especially at the level of the proximal interphalangeal joints (arrow); in the upper right image, showing more established RA, swelling is visible at the level of the wrist, but also metacarpophalangeal joints (arrows). In the lower left image showing long-standing RA, joint damage has led to subluxation of the metacarpophalangeal joints and one can also find massive carpal joint damage (arrows). The lower right image shows a case of mutilation in virtually all joints of the hand. B. Evolution of X-ray changes from early arthritis without visible changes to severely destructive disease (bony erosions and cartilage damage seen indirectly as narrowed joint space, arrows) and ultimately mutilating disease.

pressure and stiff for many hours after rest, such as in the morning. RA synovitis leads to subchondral bone erosions and damage to cartilage and thus to the totality of the pathology of RA which can culminate in completely destroyed joints, as seen clinically (Fig. 34.1A, lower photographs) and upon imaging, especially by radiography (Fig. 34.1B).

## AUTOIMMUNE FEATURES

The immunologic hallmark of RA is the presence of autoantibodies in the circulation (and also in the synovial fluid). Indeed, the presence of autoantibodies constitutes an important aspect of the new ACR–EULAR classification criteria of RA and contributes 2 points out of a maximum of 10 if detectable and even 3 points if at high levels (Aletaha et al., 2010).

The first autoantibody ever described in RA was rheumatoid factor (RF) (Waaler, 1939), subsequently recognized to be a family of autoantibodies directed against the Fc portion of immunoglobulin (Ig)G. In clinical routine, IgM-RF is most commonly determined, but RFs can be of any isotype, and next to IgM-RF, IgG-RF and IgA-RF are frequently seen. The latter has been found to be predictive for the development of RA and is associated with worse prognosis (Houssien et al., 1997; Rantapaa-Dahlqvist et al., 2003; Nell et al., 2005). Also, IgM-RF precedes the occurrence of RA and, especially at high levels ( $>50$  IU/mL), it is associated with significant joint damage (Nielen et al., 2004; Nell et al., 2005; Aletaha et al., 2012). Moreover, the risk of developing RA for RF-positive individuals in the general population may be up to 26-fold increased (Nielsen et al., 2012). This suggests an involvement of RF in the pathways to inflammation and especially joint destruction which could be a consequence of immune complex formation and subsequent Fc receptor binding, complement activation, and consequential increase in levels of inflammatory cytokines (Winchester et al., 1970; Schur et al., 1975; Mallya et al., 2016). RFs are not specific for RA but can occur in other disorders, such as systemic autoimmune rheumatic diseases or chronic infections (Elagib et al., 1999; Bassyouni et al., 2009; Lima et al., 2013); when occurring in the course of acute infections, such as Epstein–Barr virus infection, they are usually of low level and transient (Halbert and Anken 1982). RF occurs in up to 5% of healthy individuals, with the highest frequency in elderly people, although this has recently been disputed (Nielsen et al., 2012). The physiologic role of RFs may be to enhance immune complex clearance by amplifying complement binding and increasing immune complex size and to eliminate modified IgG (Grabar, 1975; van Snick et al., 1978). RFs are found in up to 80% of RA patients and, as indicated before, a pathogenic role of RF must be assumed. Indeed, RF-positive patients exhibit the highest disease activity among all RA subsets, irrespective of the presence or absence of anti citrullinated protein antibodies (ACPA) (Aletaha et al. 2015). RF can be produced locally by B cells infiltrating the synovial membrane (Jasin, 1985; Wernick et al., 1985; Kraan et al., 1999). The fact that IgG and IgA RFs exist and the observation that they have undergone somatic mutations (Williams et al., 1999) suggest T-cell help. On the other hand, some RFs, and especially IgM-RF, may be highly conserved and coming from a B-cell population producing natural autoantibodies, so-called B1–B cells (Chen et al., 1986; Hardy et al. 1987; Martin et al., 1992; Hayakawa et al., 1999), suggesting that IgM-RF may not be derived from long-lived plasma cells. In line with the latter, RF levels change quite rapidly with changes in disease activity and decrease with effective therapy (Bohler et al., 2013).

Another very important autoantibody in RA is directed against citrullinated peptides. Originally described as antikeratin antibodies and antiperinuclear factor (Nienhuis and Mandema, 1964; Young et al., 1979; Aho et al., 1993b), the autoantibody was subsequently characterized as reactive with citrullinated peptides (Schellekens et al., 1998; Girbal-Neuhauser et al., 1999). Citrulline is an amino acid derived from deimination of arginine by PADI. A large number of proteins can undergo this posttranslational modification, including fibrin, vimentin, alpha enolase, and collagen; some of these are used in ELISAs for the purposes of autoantibody testing, including a synthetic, not naturally occurring cyclic citrullinated peptide. The anticitrullinated-protein antibodies (ACPAs) have been suggested to be more predictive of RA, associated with a bad outcome and more specific for RA than RF. However, with increasing numbers of studies, an increasing number of diseases in which ACPAs are present are reported, including chronic infections and other rheumatic diseases (Takasaki et al., 2004; Vossenaar et al., 2004; Candia et al., 2006; Bassyouni et al., 2009; Lima and Santiago, 2010; Du Toit et al., 2011; Singh et al., 2011; Lima et al., 2013). Thus while ACPAs are somewhat more specific for RA than RF, they are neither pathognomonic nor of truly high specificity; this has also been accounted for in the ACR–EULAR classification criteria for RA (Aletaha et al., 2010), where both specificities are regarded as equivalent. Importantly, ACPA and RF overlap in over 90% of the patients and it has been suggested that RA is particularly severe when both specificities are present especially with regard to erosive joint destruction (Rantapaa-Dahlqvist et al., 2003; Hecht et al. 2015).

Also *in vitro*, the proinflammatory properties of immune complexes on macrophages are potentiated when RF and ACPA are present (Anquetil et al. 2015).

In contrast to RF, ACPA levels do not rapidly change with changes of disease activity or effective therapy (De Rycke et al., 2005; Bohler et al., 2013). While ACPA positivity has been reported to be associated with the shared epitope (see below) and suggested to be elicited by smoking by virtue of activation of PADI in the respiratory tract (Klareskog et al., 2006), these data stem from particular European sites and have not been uniformly confirmed in other cohorts of patients (Lee et al., 2007; Xue et al., 2008). Overall, determining ACPA is a valuable addition to the diagnostic armamentarium, but it may be sufficient to do this primarily in RF-negative patients (National Collaborating Centre for Chronic Conditions, 2009). In general, autoantibody testing for RA should only be done when clinical synovitis is present in at least one joint. Interestingly, ACPAs appear to precede RA for even longer periods of time than RF (Nielen et al., 2004; Brink et al., 2013); this indicates that once pre-RA becomes a recognized entity due to evidence for the efficacy of preventive therapy, ACPA testing may be an important screening method. At present, however, it appears that a significant proportion (3%) of healthy individuals are ACPA or RF positive and, therefore, further studies to define “pre-RA” are needed (Jimenez-Boj et al., 2012).

As citrullination constitutes a posttranslational protein modification, the potential autoantigenic nature of other posttranslationally modified proteins was tested and, indeed, antibodies targeting carbamylated proteins and acetylated proteins have been identified, whose significance in RA is currently under investigation (Shi et al., 2013; Juarez et al. 2016).

A variety of other autoantibodies can also be found in RA, confirming the broad autoimmune nature of the disease. Among these are autoantibodies to nuclear antigens, especially the heterogeneous nuclear ribonucleoprotein (hnRNP) A2 (anti-RA33) which occurs in 30%–40% of RA patients, has some differential-diagnostic potential especially in RF/ACPA-negative patients, and appears to be associated with a more benign form of RA (Steiner et al., 1992; Nell et al., 2003). Moreover, anti-RA33 can also precede the development of RA (Aho et al., 1993a), although this occurs closer to the time of disease onset than ACPA and RF. Anticollagen antibodies are yet another interesting autoantibody subset, but their role appears more important in experimental models of RA (Trentham et al., 1977) than in the human disease (Steffen, 1970), although collagen might play some autoantigenic role in the context of its citrullination (Burkhardt et al., 2005).

The observation of the appearance of various autoantibodies prior to the onset of RA is similar to findings in other autoimmune diseases, such as type 1 diabetes and systemic lupus erythematosus (Arbuckle et al., 2003; Pietropaolo et al., 2012). This suggests that the activation of the autoimmune response occurs long before clinical manifestations become apparent and that the evolution of disease is a multistep process which initially involves a trigger eliciting autoimmunity and a second trigger activating the disease pathology in the presence of a particular autoreactivity (Smolen et al., 2006). Recently, the identification of posttranslational modifications (primarily glycosylation) of antibodies that are able to modify their effector functions has been described (Albert et al. 2008). In RA, especially ACPAs have been described to be glycosylated, and it has been shown that ACPA glycosylation shifts toward a more proinflammatory profile (Pfeifle et al. 2017; Rombouts et al. 2015). These observations allow the development of a two-step scenario in RA, with an initial breach of (self)tolerance and the occurrence of autoantibodies, which in a second step become pathogenic by acquiring a proinflammatory glycosylation pattern, leading to clinical disease.

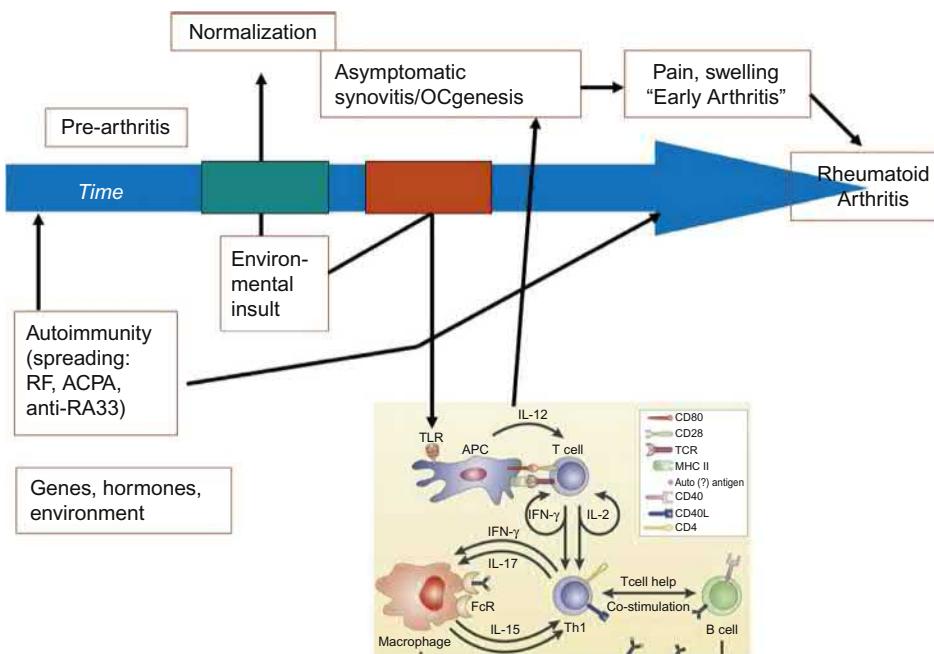

A depiction of a possible pathway from prearthritis to full-blown RA is shown in Fig. 34.2.

T cell-mediated autoimmunity in RA has been described for collagen and hnRNPA2 (Trentham et al., 1978; Fritsch et al., 2002) but not for IgG-Fc or citrullinated peptides. Whether cellular immunity to autoantigens is of pathogenetic importance is hitherto unknown. Clearly, the presence of autoantibodies is the major autoimmune characteristic of RA.

## GENETIC CHARACTERISTICS

One of the major indications for a genetic predisposition to a disease is its increased familial occurrence. While in RA the prevalence in the general population is 0.5%–1%, it rises to 2%–4% in siblings and about 15% in identical twins (Silman et al., 1993; Seldin et al., 1999); however, a quantitative genetic analysis of two European populations showed a consistent heritability of RA in the order of 60% (MacGregor et al., 2000).

The earliest observation that a particular gene may predispose to RA came from Stastny's seminal work describing the presence of human leucocyte antigen (HLA)-DRw4 in 70% of RA patients compared with 28% of controls (Stastny, 1978). The association with this major histocompatibility complex (MHC) class II gene, located

**FIGURE 34.2** A Putative Concept of Pre-arthritis and Its Evolution to Full-blown Rheumatoid Arthritis. A hostenvironment interaction (with the microbiome?) could trigger the evolution of a nonpathogenic autoimmune response which, in contrast to many similar reactions, in a genetically predisposed host may persist. Another environmental insult leads to expansion (spreading) of the autoimmune response without any clinical consequence. At some point, one of such recurring environmental insults with a potentially arthrotropic agent could trigger an asymptomatic synovitis which, in the presence of autoantibodies, could ultimately become clinically manifest and due to an overwhelming cytokine response also trigger osteoclastogenesis (OCgenesis) and thus the full RA picture.

on chromosome 6p21, was subsequently numerously confirmed to constitute the most important genetic contribution to susceptibility for the disease. It was ultimately observed that in RA patients of various ethnic backgrounds, the HLA-DRB1 alleles are frequently different, but each encodes a common sequence of amino acids at position 70–74 of the HLA-DR $\beta$  chain (QKRRA or similar, such as QRRAA or RRRAA) within the third hyper-variable region of the HLA-DRB1 molecule (Gregersen et al., 1987), a region pivotally important for peptide binding. Thus the risk contribution apparently comes from the presentation of potentially arthritogenic antigens. The respective alleles include HLA-DRB1\*0401, \*0404, \*0405, \*0408; HLA-DRB1\*0101, \*0102; HLA-DRB1\*1001; and HLA-DRB1\*1402 which occur at different frequencies in different populations but together are present in about 80% of RA patients. The overall odds ratio (OR) is about 3 with the biggest risk conveyed by HLA-DRB1\*0401 and \*0404, and especially strongly with homozygosity of the shared epitope (OR of 30). There are also protective alleles, such as HLA-DRB1\*0402. However, since HLA accounts for only about one-third of the total genetic risk in RA (Deighton et al., 1989), non-MHC genes must also contribute to susceptibility.

One of the non-MHC genes found to be associated with RA is protein tyrosine phosphatase, nonreceptor type 22 (lymphoid) gene (PTPN22) on chromosome 1p13. A single nucleotide polymorphism (SNP) in this gene is the culprit, occurring in 14% of RA patients and 9% of controls (OR B1.7) (Begovich et al., 2004). This phosphatase, which is expressed in hematopoietic cells, inhibits T-cell receptor (TCR) signal transduction and the 620W variant is associated with reduced CD4 T-cell activation.

SNPs in the complement component 5/TNF receptor-associated factor 1 (TRAF1) region at chromosome 9q33 have likewise been found to be associated with RA (Plenge et al., 2007). Complement genes, indeed, are interesting candidates given the potential involvement of complement activation in RA pathogenesis discussed previously and below. TRAF1, on the other hand, codes for a protein which acts as a negative regulator of signaling via TNF receptors 1 and 2, and in light of the apparent pivotal involvement of TNF in the pathogenesis of RA (see below), there is some logic behind this association. However, it is not clear at present which of these genes is primarily associated with RA or if the association may not even be with an adjacent gene. The OR is about 1.3.

Other proteins involved in signaling are the signal transducers and activators of transcription (STATs). STATs are activated by Janus kinases (Jaks) and recently the first Jak inhibitor was approved for the treatment of RA in the United States (Burmeister et al., 2013). Indeed, a variant allele of STAT4, located on chromosome 2q, was found associated with RA (Remmers et al., 2007). STAT4 protein mediates signaling of various cytokines, such as IL-12, IL-23, and type I interferons. The variant allele was found in 27% of patients and 22% of controls, OR B1.3. Homozygosity of the allele was associated with a 60% increased risk of RA.

Other genetic risk factors include polymorphisms in the CD40 and the TNF, alpha-induced protein 3 genes (Li and Begovich, 2009).

Thus a variety of genetic associations have been found in RA, many of them in or near genes involved in the regulation of the immune system (cytokines and their receptors, costimulatory molecules, signal transduction molecules), supporting the concept of RA being an immunologically driven disease (reviewed in Viatte et al. 2013). However, and this is the case for many genetic association studies, the functional consequences of a given single nucleotide polymorphism (SNP) are mostly not known yet (increased/decreased expression of the target gene? altered gene function?), and therefore the exact contributions to disease pathogenesis still have to be determined.

Importantly, most of these genes are primarily related to autoantibody-positive RA, indicating that immune response genes contribute their effects indeed via particular immune responses (Mattey et al., 2002; van der Helm-van Mil et al., 2006). The only genetic associations with seronegative RA that have been identified are SNPs in the DCIR gene (a C-type lectin) and IRF5 (Lorentzen et al. 2007; Sigurdsson et al. 2007). Gene–environment interactions have been postulated in terms of genetic susceptibility in smokers to develop ACPA and RA (Klareskog et al., 2011) but have not been generally confirmed (Lee et al., 2007); thus more information is clearly needed.

Apart from genetic factors, epigenetic regulators of gene expression have been identified as possible important regulators of RA pathology. Epigenetic mechanisms include DNA methylation, modification of histones (phosphorylation, acetylation), and expression of noncoding RNAs (especially microRNAs but also long noncoding RNAs) (Ospelt et al. 2017).

## IN VIVO MODELS

Based on Koch's postulate that a causal agent must be sufficient and necessary to cause infectious disease (Koch 1890; Witebsky et al., 1957) formulated postulates for autoimmune diseases: an autoantigen should be necessary and sufficient to cause an autoimmune disease in experimental models; in other words, the demonstration of an autoimmune nature of a disease requires the recognition of a particular autoantigen to which antibodies or cells are autoreactive and which elicits a similar disease in an experimental model. To date, the only such autoantigen in RA is collagen, hypothesized to be the culprit several decades ago by Steffen (1970); collagen-specific autoantibodies and autoreactive cells exist (Menzel et al., 1975; Trentham et al., 1978; Smolen et al., 1980) and type II collagen (CII) elicits a chronic, destructive arthritis (Trentham et al., 1977). This collagen-induced arthritis (CIA) meanwhile, one of the classic RA models, depends on both the activation of T cells and the production of arthritogenic autoantibodies, but the disease itself can also only be transferred with anti-CII antibodies (Holmdahl et al., 2002). However, current views do not suggest a major role for this reactivity in eliciting human RA, and interestingly, this model responds better to IL-1 than TNF-blockade, contrasting human RA (Joosten et al., 2008). Not only CII but also other cartilage antigens, such as proteoglycan, can be used to induce experimental arthritis (Glant et al., 1987, 1998), but their role in human RA is not established.

Other autoantigens used to develop experimental models, to which autoantibodies and partly cellular immune responses exist in RA, and which are even widely used diagnostically, are IgG (targeted by RFs), several citrullinated proteins including fibrinogen, vimentin, alpha enolase, and collagen (targeted by ACPA), and heterogeneous nuclear ribonucleoprotein A2 (hnRNP)-A2; targeted by anti-RA33 antibodies (Steiner et al., 1992). However, none of them elicit a chronic destructive arthritis upon immunization. At most, ACPA can be detected in occasional experimental approaches, such as a study on CIA (Kuhn et al., 2006), although other studies reported negative observations in this respect. Further, immunization with hnRNP-A2 can aggravate arthritis in TNF overexpressing mice (Hayer et al., 2005).

Several adjuvants can induce arthritis, in particular Freund's adjuvant ("adjuvant arthritis") and pristane, a mineral oil ("pristane-induced arthritis"); while they allow one to study certain aspects of the pathways to arthritis, they do not appear to be appropriate models for human RA (Holmdahl et al., 2001), although being free of known autoantigens, they support the involvement of environmental factors in the generation of arthritis.

That any type of immune complexes can induce arthritis has been shown by Dumonde and Glynn (1962). A particular form of an immune complex arthritis has been more recently described in the form of the KRN mouse model, originally developed to study diabetes; these mice express a transgenic TCR recognizing glucose-6-phosphoisomerase (G6PI), a ubiquitous cytoplasmic protein which is also present on the surface of articular cartilage. The ensuing autoantibodies, which by themselves can induce disease upon serum transfer, form intraarticular immune complexes followed by a severe inflammatory and destructive response, and expectedly the system is complement and mast cell dependent (Matsumoto et al., 2002). Interestingly, G6PI is not

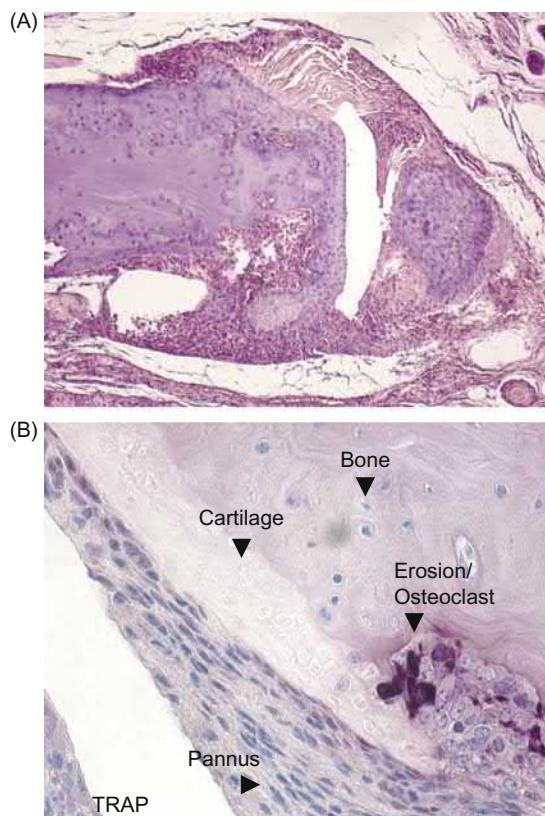

recognized as being an important autoantigen in man but nonetheless this model confirms the role of immune complexes in chronic arthritis and especially the serum transfer model can be used to investigate the role of the innate immune system selectively.

Apart from the inducible models, also spontaneous models exist. In the SKG model, which is based on a spontaneous mutation of ZAP70, an important TCR signaling adaptor molecule, mice develop a severe arthritis over the course of months with histopathological features resembling human RA. Interestingly, also high titers of RF can be found in those mice.

Another widely used model is a model in which a human TNF transgene is expressed in mice. These develop a severe inflammatory and highly destructive polyarthritis (Fig. 34.3A) (Keffer et al., 1991). This model has served particularly well in studies devoted to the development of bone and cartilage damage in arthritis (Redlich et al., 2002; Korb-Pap et al., 2012). Yet another example of the role of cytokine hyperactivity and consequential joint inflammation and damage is provided upon the deficiency of IL-1 receptor antagonist (IL-1ra) (Horai et al., 2000), although as mentioned before, IL-1 inhibition has little effect in human RA.

Thus a variety of experimental models exist which can mimic parts of the spectrum of RA allowing studies of many aspects of pathways to arthritis and joint destruction. It is interesting to note that both overactivation of the innate immune system (hTNFtg, IL-1ra deficient mice) as well as of the adaptive immune system (SKG mice) result in destructive arthritis with similar histopathological features in mice. Some of these models even appear to fulfill Witebsky's postulate; alas, the role of the respective autoantigen(s) in human RA is not confirmed.

Of note, many of these animal models do not occur under germ-free conditions and different commensal agents can activate individual forms of experimental arthritis in hosts with particular genetic backgrounds (Wu et al. 2010), further suggesting the important involvement of the environment in the induction and maintenance of chronic arthritis (Scheinecker and Smolen 2011; Scher and Abramson 2011).

**FIGURE 34.3** A. Arthritis in mice overexpressing human TNF. Note the significant inflammatory response and the dramatic destruction due to subchondral invasion of the bone by the pannus tissue. B. Bone damage is elicited by osteoclasts differentiating within the synovial membrane. The small dark blue (tartrate-resistant acid phosphatase [TRAP] positive) cells are osteoclast precursors.

## PATHOLOGIC EFFECTOR MECHANISMS

The detailed mechanisms leading to the expression of the disease are still insufficiently known. Fig. 34.4 depicts current views on the pathways to synovitis and joint damage in RA, showing a schematic representation of the events (Smolen et al., 2007) as well as histologic and immunohistochemical characteristics of the RA synovial membrane. It is assumed that an autoantigen or hitherto unrecognized foreign antigen is taken up by antigen presenting cells, prototypically dendritic cells, leading to activation of the innate immune system as well as to that of T cells (and thus also the adaptive immune response) via respective antigen presentation and costimulation. The involvement of the shared epitope (see above) suggests that either particularly arthritogenic peptides bind with high affinity to these but not other MHC molecules or that an arthritogenic T-cell repertoire is selected via the shared epitope. These activated T cells, possibly because of insufficient control by regulatory T cells (Chavele and Ehrenstein, 2011), in turn activate macrophages and provide B-cell help. However, the type of T cells involved remains enigmatic. Many have suggested that Th17 cells are pivotal in inducing autoimmunity and especially chronic inflammation, since they not only produce IL-17 which activates macrophages as well as other cells and is proosteoclastogenic but also secrete TNF (Miossec 2004). Alas, IL-17 or IL-17 receptor inhibition has been rather disappointing with respect to efficacy, especially in patients who have failed prior biologic disease modifying anti-rheumatic drug therapies (Tahir et al. 2017). Moreover, inhibition of IL-23, the major cytokine involved in Th17 differentiation, also failed to show efficacy (Smolen et al. 2017). However, also IL-12 inhibition using the anti-p40 antibody ustekinumab is not efficacious (Smolen et al., 2017). Nevertheless, as alluded to above, T cells must be involved in RA by virtue of the significant MHC association and class switch as well as affinity maturation of the autoantibodies involved. Thus one can only explain the current findings by assuming that Th1 or Th17 cells only play a role very early in the disease process and recede themselves long before signs and symptoms appear, or that a hitherto unknown T-cell population exists, that ought to be CD4 negative, since anti-CD4 is not effective in RA (van der Lubbe et al., 1995).

These events presumably occur partly centrally and partly within the synovial membrane into which the cells have migrated. Activated macrophages secrete proinflammatory cytokines. Activated RA B cells and their progeny produce autoantibodies which, after forming immune complexes, bind to Fc and complement receptors and thus increase macrophage cytokine production (Aringer and Smolen, 2012). In parallel, fibroblast-like synovial cells become activated and also produce inflammatory mediators (Lee and Firestein, 2003).

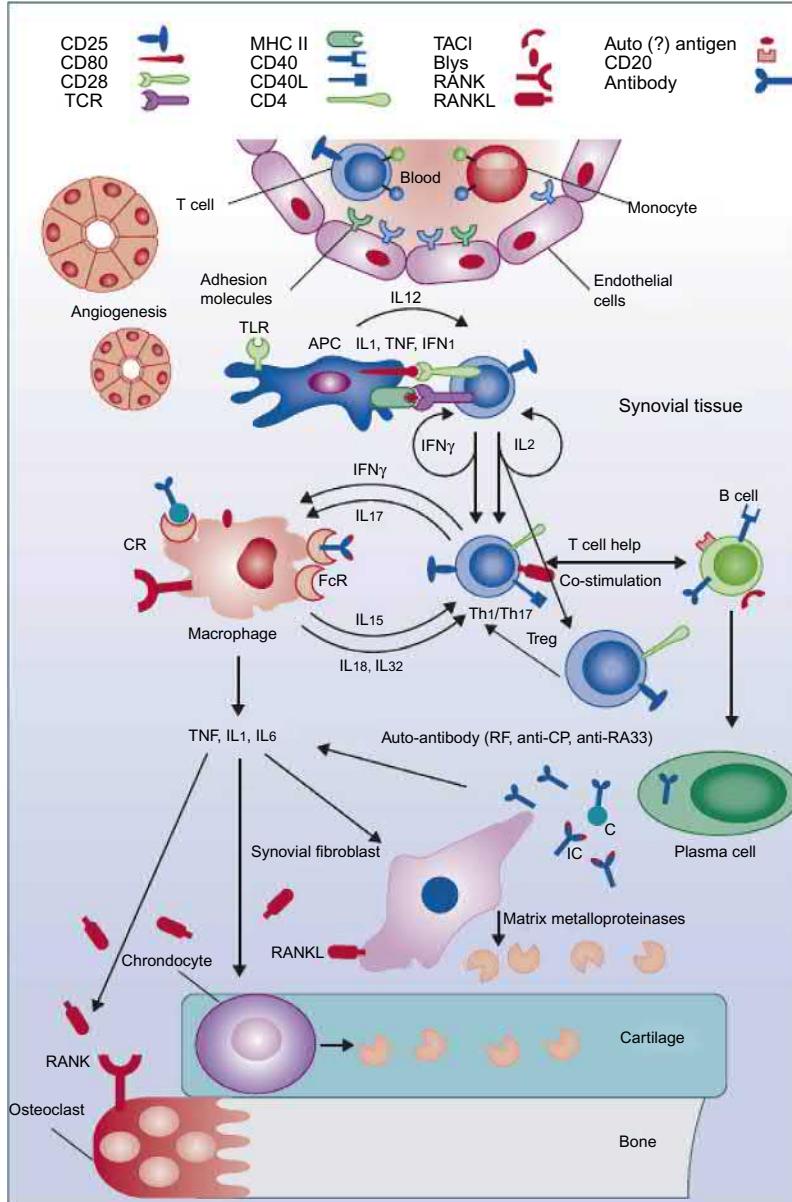

By whichever way the detailed events evolve (i.e., whether the innate immune reactivity, T or B-cell activations are dominant), the mechanisms ultimately lead to an influx of inflammatory cells into the synovial membrane; the inflamed synovial membrane transforms into an autonomous “semimalignant” tissue (pannus) leading to destruction of bone (erosions) and cartilage. Indeed, the major feature distinguishing RA from other inflammatory joint diseases is the high propensity for joint destruction.

Cartilage damage appears to arise primarily via direct action of metalloproteinases secreted within the joint on cartilage matrix and/or via the activation of chondrocytes by cytokines and subsequent matrix degradation; attachment of the synovial membrane to the cartilage appears to play an important role in these respects (Korb-Pap et al., 2012).

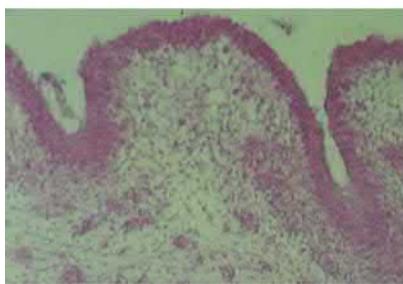

Bone destruction is mediated by osteoclasts activated within the synovial membrane at sites adjacent to bone (Fig. 34.3B) (Gravallese et al., 1998; Redlich et al., 2002). While osteoclast differentiation and activation are pivotally dependent on receptor activator of NF $\kappa$ B and its ligand, proinflammatory cytokines enhance the generation and activity of osteoclasts (Lam et al., 2000; Teitelbaum, 2000). The much stronger destructive nature of RA compared with other inflammatory joint diseases may be explained by the higher load of cytokines like TNF and IL-6 (Partsch et al., 1997) which in turn are likely to be a consequence of the presence of autoantibodies and immune complexes in the joint (Zvaifler, 1974). Indeed, the presence of RF is related to the joint damage via association with higher disease activity and also independently of disease activity (Aletaha et al., 2012).

With all due recognition of deliberations on pathogenetic pathways based on experimental models or ex vivo and in vitro studies of patient cells, tissues, or body fluids, ultimately the validation of the involvement of specific pathways must come from the efficacy of therapies targeting a presumed pathogenetic principle (sort of reverse Witebsky postulate). Due to the wealth of clinical trials in RA, both from successful ones but also (maybe even more so) from the unsuccessful ones, it is possible to redraw the concepts on the pathophysiology of human RA. The important role of TNF, IL-6, costimulatory molecules, the JAK/STAT pathway, and CD20-positive B lymphocytes has been convincingly demonstrated in clinical trials interfering with these molecules, thus validating these targets as importantly involved (although also eliciting new questions; see below). In contrast, the

(D)

**FIGURE 34.4** A. A schematic representation of the pathogenesis of RA (Smolen et al., 2007). B. Hematoxylin-eosin stain of an RA synovial membrane section showing hyperplasia of the lining layer, hypercellularity in the sublining and hypervascularity. C. TNF expression (brown) in type A (monocyte-like, blue) and type B (fibroblast-like, unstained) synovial lining cells. D. Activated T cells in synovial membrane (CD3 in brown, HLADR in blue).

cytokines IL-12/23, IL-17, the protein kinases p38 mitogen-activated protein kinase, and spleen tyrosine kinase (Syk) all have been shown not to be important targets for the treatment of human RA and therefore very likely are not involved in its pathogenesis.

However, the fact that all currently approved, efficacious agents lead to similar clinical results, that their efficacy is not increased in patients who have failed one of the other targeted therapies, and combinations of these biological hitherto do not apparently increase efficacy although they do mostly increase serious adverse event rates suggest that all these cells and molecules have a single major final pathway in common; this bottleneck appears to be the proinflammatory cytokine system (Smolen and Aletaha, 2013).

Still some questions arise in this respect: (1) if T cells do play a major role as suggested by the efficacy of costimulation inhibition, why is anti-CD4 therapy not effective (van der Lubbe et al., 1995)? (2) If B cells play a major role, why are several B cell-directed therapies ineffective (Blumel et al., 2013)? (3) With so many similarities regarding the effects of the three major proinflammatory cytokines: TNF, IL-1, and IL-6, why is IL-1 inhibition so much less efficacious than TNF and IL-6 inhibition (Singh et al., 2009)? And, most importantly, (4) what determines the arthrotropism of the disease? Do particular antigens of the joint (cartilage components?) elicit the disease? Is it influx into the joint, with its permissive anatomical structures lacking efficient basement membranes, of nonspecific bacterial products that are of decisive nature (Toivanen, 2001)? Resolving these questions will allow better insights into the pathways leading to RA, but they simply attest that proof of concept can only come from the clinic and not from theoretical considerations or experimental models.

## AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

As discussed in the section on autoimmunity, the most prevalent autoantibodies in RA are RF and ACPA. They are both important components in classification criteria and therefore of diagnostic help (Aletaha et al., 2010). Their sensitivity and specificity for the diagnosis of RA are similar (sensitivity about 50%–60%, specificity about 85%–95%) (Mjaavatten et al., 2010; Neogi et al., 2010; Nicaise-Roland et al., 2013). Both of these autoantibodies fluctuate with disease activity and effective therapy, although RF appears to do so to a much greater extent (Bohler et al., 2013); indeed, RF can become negative (seroconversion) with long-standing remission which is not known for ACPA. ACPA can be tested for using several different citrullinated antigens: fibrinogen, vimentin, filaggrin, CII, enolase, or a cyclic peptide. These autoantibodies differ only slightly in terms of time of appearance and frequency (Brink et al., 2013; Nicaise-Roland et al., 2013).

Another autoantibody specificity which can be of diagnostic help is anti-RA33, especially if RF and ACPA are negative (Nell et al., 2005).

All these autoantibodies can also be present in a variety of other diseases, especially other autoimmune disorders and infectious diseases, and also notably so for ACPA (Abdel Fattah et al., 2009; Bassyouni et al., 2009; Lima and Santiago, 2010; Singh et al., 2011; Gokhan et al., 2013). They can also be present in healthy people and it has previously been suggested that RF positivity increases with age, but this was not seen in more recent series (Nielsen et al., 2012). Therefore, only in the right clinical setting, RF and ACPA can be regarded as marker autoantibodies of the disease and as having a high weighting in the classification criteria for RA (Aletaha et al., 2010).

Of particular importance, the presence of autoantibodies can partly inform in advance on response to therapy. Thus B cell-targeted therapy with rituximab is more efficacious in RF and/or ACPA positive than negative patients (Chatzidionysiou et al., 2011). This is conceptually sound since rituximab eliminates CD20-positive B cells and levels of these autoantibodies decrease with effective therapy. This observation appears to be specific for rituximab since therapies targeted against cytokines do not appear to be differently effective in seropositive and seronegative patients.

## CONCLUDING REMARKS—FUTURE PROSPECTS

RA is the prototypic autoimmune joint disease. Autoreactivity, in association with a genetic predisposition and an environmental trigger, appears to play a major role in pathways to RA and the presence of autoantibodies is associated with joint damage and thus of prognostic in addition to diagnostic value. The observations that autoimmunity precedes clinical disease onset by many years and that the presence of ACPA or RF in otherwise healthy individuals may increase the risk for developing RA more than 20-fold imply that there is a prearthritic phase. This suggests that in the future, long before the onset of disease, preventive measures might be taken for

people at risk (see Chapters 77–79). Thus the autoimmune response may at some early point in time serves as guidance toward novel therapeutic approaches. Further, the causes of RA are still unknown: which (environmental?) provocation elicits RA? And how then does the autoimmune reaction ensue?

Systemic Juvenile Idiopathic Arthritis	680		

Juvenile idiopathic arthritis (JIA) is not a single disease, but an exclusion diagnosis that gathers together all forms of arthritis of unknown origin, with onset prior to the age of 16 years and lasting more than 6 weeks (Ravelli and Martini, 2007; Prakken et al., 2011). This heterogeneous group of chronic arthritides, we call JIA, is unified by the presence of a chronic inflammatory process, primarily targeting the synovial membrane. The persistence of synovial inflammation may lead to an increased risk of osteocartilaginous damage with subsequent physical functional disability. The etiology of JIA is still unknown. The heterogeneity of these conditions indicates that different factors are likely to contribute to the pathogenesis of the various forms of childhood chronic arthritis. According to the current classification, proposed by the International League of Associations for Rheumatology (ILAR) (Petty et al., 2004) (Table 35.1), patients are classified into mutually exclusive categories based on clinical features and laboratory results during the first 6 months of the disease. This ILAR classification, which was conceived as “work in progress,” has however been recently challenged since there is evidence that while some categories represent quite definite disease entities, others still include heterogeneous disorders (Martini, 2003; Martini, 2012a,b).

Genetic and immunological studies, as we will discuss, provide an opportunity to address this heterogeneity through classifying patients into more homogeneous subtypes based on the genetic pathways that drive disease.

**TABLE 35.1** Frequency, Age at Onset, and Sex Distribution of the International League of Associations for Rheumatology Categories of Juvenile Idiopathic Arthritis

	Frequency <sup>a</sup> (%)	Onset age	Sex ratio
Systemic arthritis	4–17	Throughout childhood	F = M
Exclusions: a, b, c, d			
Oligoarthritis	27–56	Early childhood; peak at 2–3 years	F>>>M
Exclusions: a, b, c, d, e			
Rheumatoid factor–positive polyarthritis	2–7	Late childhood or adolescence	F>>M
Exclusions: a, b, c, e			
Rheumatoid factor–negative polyarthritis	11–28	Biphasic distribution, early at 2–4 years and later peak at 6–12 years	F>>M
Exclusions: a, b, c, d, e			
Enthesitis-related arthritis	3–11	Late childhood or adolescence	M>>F
Exclusions: a, d, e			
Psoriatic arthritis	2–11	Biphasic distribution; early peak at 2–4 years and later peak at 9–11 years	F>M
Exclusions: b, c, d, e			
Undifferentiated arthritis	11–21		

<sup>a</sup>Percentage of all juvenile idiopathic arthritis cases.

Exclusion criteria: (a) Psoriasis or a history of psoriasis in the patient or first-degree relative. (b) Arthritis in an HLA-B27 positive male beginning after the sixth birthday. (c) Ankylosing spondylitis, enthesitis-related arthritis, sacroileitis with inflammatory bowel disease, Reiter's syndrome, or acute anterior uveitis, or a history of one of these disorders in a first-degree relative. (d) The presence of IgM rheumatoid factor on at least two occasions at least 3 months apart. (e) The presence of systemic JIA in the patient. The different categories are defined according to the symptoms presented during the first 6 months of disease. JIA, Juvenile idiopathic arthritis.

## EPIDEMIOLOGY

JIA as a whole is the most common chronic rheumatic condition in childhood and an important cause of short- and long-term disability. Although present across the world, its incidence and prevalence vary considerably throughout. Studies in Western populations have reported an incidence and a prevalence varying from 2 to 20 and from 16 to 150 per 100,000, respectively, with higher occurrence in northern Europe (Ravelli and Martini, 2007). The rate of occurrence of the various JIA subtypes alters considerably according with geographic and ethnic differences: oligoarthritis, which is the most widespread category in the Western countries, is, in fact, quite rare in areas such as India, South Africa, Costa Rica, and New Zealand where polyarthritis outnumbers oligoarthritis and systemic-onset disease. Although JIA is more frequent in females than in males, the proportion may vary according to JIA onset categories and geographic or racial groups.

## CLINICAL FEATURES

The group of diseases gathered under the umbrella term of JIA encompasses several different forms of chronic arthritis that, in the absence of etiologic clues, have been classified according to clinical criteria.

### Systemic Arthritis

Systemic JIA (sJIA) accounts for 10%–15% of the children with JIA, and it is among the most severe childhood inflammatory diseases. First described by Sir George Frederic Still over a century ago, sJIA is characterized by arthritis and prominent systemic features, such as high-spiking fever, an evanescent salmon pink skin rash that characteristically occurs with fever peaks, hepatosplenomegaly, generalized lymphadenopathy, and serositis. Myalgias and abdominal pain may be intense during fever peaks. Arthritis is more often symmetrical and polyarticular. It may be absent at onset but could develop during disease course. Laboratory investigations show

leukocytosis (with neutrophilia), thrombocytosis and very high erythrocyte sedimentation rate, and C-reactive protein concentration. A microcytic anemia is common.

About 5%–8% of the children with sJIA develop a life-threatening complication, named macrophage activation syndrome (MAS) (Ravelli et al., 2012). The hallmark of MAS is an uncontrolled and dysfunctional immune response involving the persistent activation and expansion of T lymphocytes and macrophages and leading to an actual cytokine storm. The syndrome is a form of reactive hemophagocytic lymphohistiocytosis (HLH) and is characterized by the sudden onset of sustained fever, pancytopenia, hepatosplenomegaly, liver insufficiency, coagulopathy with hemorrhagic manifestations, and neurological symptoms. Laboratory features include elevated triglycerides, low sodium levels, and markedly increased ferritin concentrations. Soluble CD163 and soluble interleukin (IL)-2 receptor are also greatly increased in active MAS. The demonstration of active phagocytosis of hematopoietic cells by macrophage in the bone marrow is common. The early recognition and treatment of MAS, before the development of severe multisystem involvement, is crucial for the prognosis. In this perspective, diagnostic guidelines for sJIA-associated MAS have been developed (Ravelli et al., 2016).

sJIA probably does not represent a disease but rather a syndrome, the common endpoint of several different diseases causing a marked and persistent activation of the innate immune system (Martini, 2012a,b). The potential heterogeneity of this condition is suggested by a dramatic sensitivity to IL-1 blockade occurring in a subset of patients (see below) and by differences in clinical course.

Indeed, in about half of the patients, the disease is mainly characterized by the systemic features while the arthritis usually remits when systemic features are controlled. In the other half of patients, the disease follows an unremitting course; systemic symptoms may eventually resolve, leaving chronic arthritis as the major long-term problem. There are, moreover, patients who present the same systemic features observed in sJIA but never develop arthritis and, therefore, cannot by definition be classified as sJIA. This subgroup of patients lacks nowadays any taxonomic definition. The superimposable systemic clinical and laboratory features suggest that they have a disease strongly related to sJIA despite the lack of arthritis. This type of patients is indeed included in the definition of adult-onset Still's disease, where the presence of arthritis is not required for diagnosis. It has been suggested to include these patients in the sJIA disease category (Martini, 2012a,b), but, given the absence of arthritis, the term sJIA should be changed.

## Rheumatoid Factor–Positive Polyarthritis

Rheumatoid factor (RF)–positive polyarthritis is defined as five or more joints affected during the first 6 months of the disease and by the presence of positive RF. This rare (5% of the patients with JIA) subgroup is the childhood equivalent of adult RF-positive rheumatoid arthritis (RA), both sharing similar clinical phenotype, serology, and immunogenetic profile. The shared epitope present in some HLA-DR4, DR1, and DR14 alleles is associated with an increased risk for both adult RA- and RF-positive JIA. The onset occurs usually in late childhood or adolescence with a female predominance and a symmetric polyarthritis affecting principally wrists and the small joints of the hands and feet. Rheumatoid nodules, typical of adult RA, have been also reported in about a third of RF-positive JIA. Low-grade fever, lymphadenopathy, and weight loss may occur with active disease. Acute phase reactants are usually increased, and a moderate normochromic and normocytic anemia is often associated. RF-positive polyarthritis is the only form of JIA with positive antibodies to cyclic citrullinated peptides. As in adults RA, it is a chronic erosive disease. Erosive changes, as detected by conventional radiography, occur earlier and more frequently in RF-positive polyarthritis than in the other JIA categories and are commonly detected in the hands and feet. The aggressive medical treatment of RF-positive polyarthritis is recommended due to its poor prognosis. Patients with RF-positive polyarthritis, in fact, have the lowest remission rate (5%) off-medication among children with chronic arthritis.

## Enthesitis-Related Arthritis

Enthesitis-related arthritis represents a form of undifferentiated spondyloarthropathy. It accounts for about 5%–10% of the JIA cases and usually starts after the age of 6, being more frequent in boys. Arthritis initially affects the larger joints of the lower limbs and is generally associated to enthesitis (inflammation of the point where a tendon, ligament, or fascia inserts into the bone). The most common sites of enthesitis are the calcaneal insertions of the Achilles tendon and of the plantar fascia and the tarsal area. Most patients are HLA-B27

positive. The disease course can be moderate and remitting, but a variable percentage of patients, most of whom cannot be identified at disease onset, will develop involvement of sacroiliac joints later on. Unlike other JIA categories, hip involvement is frequent at disease presentation. These patients may present a symptomatic acute uveitis characterized by red eyes, photophobia, and pain.

All the different forms of adult spondyloarthropathies can be observed in children, although a much higher proportion of undifferentiated spondyloarthropathies is present in childhood. The discrepancy in terminology between children and adults has been a source of confusion. It would be advisable to substitute the term "juvenile spondyloarthropathy" in the place of enthesitis-related arthritis, which could suggest the existence of a form peculiar to childhood, not observed in adults ([Martini, 2012a,b](#)).

## Oligoarthritis

It is defined by the involvement of four or less joints during the first 6 months of disease. In the Western countries the large majority of patients belongs to a quite well-defined disease entity observed only in children and characterized by an asymmetric arthritis, involving mainly large joints, an early onset (before 6 years of age), a female gender predilection, a high frequency of positive antinuclear antibodies (ANA), a high risk of developing chronic iridocyclitis, and consistent human leukocyte antigen (HLA) associations (HLA-DRB1\*08 in particular). The current ILAR classification distinguishes two categories of oligoarthritis based on the number of joints affected after the first 6 months of the disease: one, often with a good long-term prognosis, in which the disease remains confined to four or less joints (persistent oligoarthritis) and another in which arthritis extends to more than four joints after the first 6 months of disease (extended oligoarthritis). It has however been shown that ANA-positive patients regardless of whether they have persistent or extended oligoarthritis, share the same characteristics (e.g., age at onset, sex ratio, asymmetry of articular involvement, etc.), strongly suggesting that these two subcategories of oligoarthritis represent the same disease, varying only in the spread of arthritis ([Ravelli et al., 2005](#)). About one-third of the patients with oligoarticular JIA develop a chronic, non-granulomatous, anterior uveitis affecting the iris and the ciliary body (iritidocyclitis), which may cause severe visual impairment. The onset is usually insidious and very often entirely asymptomatic. Uveitis generally occurs at the time of diagnosis or shortly thereafter, although in less than 10% patients it precedes the onset of arthritis. Evidence of increased protein concentration and inflammatory cells in the anterior chamber of the eye suggests anterior uveitis. Though inflammatory cytokines [IL-1 $\beta$ , IL-2, IL-6, interferon- $\gamma$ , and tumor necrosis factor (TNF)- $\alpha$ ] have been reported in ocular fluids and tissues, the pathogenesis of uveitis and the link between inflammatory joint and ocular diseases is not yet clear. The course of uveitis may be relapsing or chronic and does not parallel the clinical course of arthritis. Early diagnosis and treatment are of the utmost importance in order to prevent the serious visually disabling complications such as posterior synechiae, band keratopathy, cataracts, glaucoma, and cystoid macular edema. Complications can result from uncontrolled intraocular inflammation as well as from its treatment, particularly prolonged use of high-dose topical corticosteroids ([Sen et al., 2015](#)). Since uveitis is asymptomatic at onset, children with ANA-positive JIA should be screened at least every 3 months by slit-lamp examination. ANA positivity represents a strong risk factor for developing uveitis. ANA have been found to react against different chromatin constituents and against the DEK nuclear protein, a putative oncprotein; however, none of these molecular targets have been found to be specific for oligoarticular JIA. Although uveitis is more frequent in ANA-positive oligoarticular JIA, it is also manifest in 14% of the RF-negative polyarthritis and in 10% of the psoriatic arthritis, while it is uncommon in sJIA or RF-positive polyarthritis.

## Rheumatoid Factor Negative Polyarthritis

It is defined by the involvement of 5 or more joints during the first 6 months of disease in the absence of immunoglobulin M (IgM) RF. It is probably the most heterogeneous JIA category, and at least two distinct clinical phenotypes can be identified: one, that is comparable to adult-onset RF-negative RA, is characterized by overt symmetric arthritis of large and small joints, onset at school age and negative ANA; the second resembles ANA-positive early-onset oligoarthritis in many respects but for the number of joint involved during the first 6 months of disease. The similarities between this second subset and early-onset oligoarthritis led to the hypothesis that they represent the same disease, the former being a more aggressive phenotype than the latter ([Martini, 2003](#)). This view has been confirmed by the demonstration that those features (early age at onset, positive tests for

ANA, asymmetric arthritis, female predominance, and increased risk of chronic iridocyclitis) that characterize ANA-positive oligoarthritis are also present in ANA-positive, RF-negative polyarthritis, but not in ANA-negative RF-negative polyarthritis or in ANA-negative oligoarthritis (Ravelli et al., 2005, 2011). Moreover, ANA-positive, RF-negative polyarthritis is seldom observed in those countries in which ANA-positive oligoarthritis is rare (Martini, 2003). This hypothesis has finally gained support from gene expression studies demonstrating B-cell signature (Barnes et al., 2010) and an association with HLA-DRB1 (Hollenbach et al., 2010) in both oligoarticular and polyarticular forms of diseases in patients with early-onset arthritis ( $\leq 6$  years).

## Psoriatic Arthritis

This is another inadequately defined JIA category. The diagnosis of juvenile psoriatic arthritis (JPsA) according to the ILAR criteria requires the simultaneous presence of arthritis and a typical psoriatic rash or, if the latter is absent, the presence of arthritis and two of the following: dactylitis (swelling of one or more digits/fingers that extends beyond the joint margins), nail pitting or onycholysis, and a family history of psoriasis in a first-degree relative.

JPsA does not represent a clearly defined entity and at least two subsets of patients can be identified (Martini, 2003; Stoll et al., 2006; Ravelli et al., 2011). Younger children (<5 years old), most usually female and with ANA-positive test, are likely to develop asymmetric oligoarthritis and show a greater risk of chronic iridocyclitis. This subgroup appears very similar to the early-onset oligoarticular JIA. By contrast, later onset JPsA patients exhibit a gender ratio closer to 1:1, with a propensity to enthesitis and to develop sacroiliitis during follow-up, similar to several adult patients with psoriatic arthritis, who share features with spondyloarthropathies. The ILAR classification, in which patients with enthesitis are by definition excluded, defers by default the latter group to the category of undifferentiated arthritis (Stoll et al., 2008).

## Undifferentiated Arthritis

It does not represent a separate subset, but a category in which by definition patients that do not fulfill the inclusion criteria of any of the categories, or fit criteria for more than one category, are included.

## Perspectives

Over the last 20 years, there have been substantial developments in the classification of chronic arthritis in children. However, the debate surrounding classification is far from resolved. In fact, while some JIA categories clearly identify distinct disease entities, others still include heterogeneous disorders. There is now enough evidence that some patients with ANA-positive, early-onset arthritis are in the current ILAR classification mistakenly included in the RF-negative polyarthritis and in the psoriatic arthritis categories. It would be, therefore, advisable to group all these patients together in a new category of ANA-positive, early-onset arthritis, independently from the number of joints involved or the presence of psoriasis (Martini, 2012a,b). Once these patients are removed, the RF-negative polyarthritis and the psoriatic arthritis categories would presumably mainly be represented by patients with the clinical characteristics similar to their adult counterpart. Aligning JIA classification to adult nomenclature would alter the misleading concept that JIA is a single disease and that the various categories represent just phenotypic variants.

Further advances in classification will come from immunologic, genomic, and proteomic studies in the various JIA categories, as well as from differences in the response to biological agents that, by targeting specific molecules, represent a precious opportunity of “reverse translation” (from the bed to the bench side), as it has been with the inhibition of IL-1 in sjIA. As anticipated, sjIA appears to be a syndrome which includes a group of disorders characterized by an autoinflammatory hallmark. This group should include patients with systemic features without arthritis as in adults and switching to the nomenclature used by the adult physicians (Still’s disease) could be taken into consideration. Of note, gene-expression analysis of adult-onset Still’s disease and sjIA has suggested that these two clinical phenotypes are part of the same disease continuum, with different ages of onset (Nirmala et al., 2015; Jamilloux et al., 2015).

## ETIOLOGY AND PATHOGENESIS

As discussed above, it is now clear that in children, as in adults, there are several completely different diseases which are all responsible for chronic arthritis and that are gathered under the umbrella term of JIA. With the exception of early-onset, ANA-positive arthritis, which is a well-defined entity observed only in childhood, they appear to represent the childhood counterpart of diseases observed also in adults. Therefore, in order to avoid overlaps with other chapters, only those immunological aspects that belong to sJIA, which is far more common in children, and to early-onset ANA-positive arthritis, which occurs only in children, will be discussed in detail. For the other diseases, there are not relevant, specific immunological findings, and characteristic of childhood-onset forms.

### Systemic Juvenile Idiopathic Arthritis

sJIA is etiopathogenically different from all the other forms of JIA (Mellins et al., 2011). The systemic features, the marked inflammatory response, which has been associated with dysregulation of the innate immune system, and the lack of sex bias have suggested that it may be part of the spectrum of autoinflammatory disorders. The disease is in fact unique with regard to the other JIA categories, in terms of clinical manifestations, prognosis, and response to conventional immunosuppressant therapies. Indeed, methotrexate (MTX) or anti-TNF agents are less effective than in the other JIA categories, while anti-IL-6 or anti-IL-1 drugs are of impressive efficacy.

### Genetics

sJIA is much more frequent in children than in adults (adult-onset Still's disease). This can suggest a role for some widely diffused infectious agents that are encountered early in life or represent the effect of a strong genetic predisposing background. The disease is considered multifactorial and multigenic, although it is not known if genetic predisposition is due to the combinations of common genetic variants, each providing a small contribution to inherited susceptibility, or to high-penetrance rare mutations that only account for a few cases each. Of interest, a study from Saudi Arabia (Wakil et al., 2015) has recently reported a monogenic autosomal-recessive form of sJIA. Whole-exome sequencing of 13 patients with a phenotype of sJIA from five consanguineous families identified a homoallelic missense mutation in laccase domain containing 1 (LACC1), which encodes the enzyme laccase. It is a nonspecific enzyme that catalyzes the oxidation of polyphenols, aromatic amines, and inorganic ions; however, its specific biologic function is not yet fully understood.

Consistent with the supposed autoinflammatory nature of sJIA, gene expression studies on peripheral blood mononuclear cells (PBMCs) have shown an upregulation of genes associated with the activation of monocyte/macrophage lineage and a downregulation of the gene networks involving natural killer (NK) cells, T cells, and MHC antigen-related biological processes (Pascual et al., 2005; Fall et al., 2007; Ogilvie et al., 2007; Allantaz et al., 2007; Barnes et al., 2009). Some genetic polymorphisms, particularly of cytokine genes, have been associated with sJIA (Table 35.2).

Of interest the potential role of NK in the pathogenesis of sJIA has been recently reviewed. Put et al. found that NK cells from the sJIA patients showed increased expression of innate pathways, such as Toll-like receptor (TLR) 4 (TLR-4) and S100 proteins. Although NK cells cytotoxic activity appeared intact, a decreased expression of immune-regulating genes such as granzyme K in CD56 bright NK cells and a defective IL-18-induced IFN- $\gamma$  production were demonstrated (Put et al., 2017). Of note, CD56 bright NK cells were found to be able to kill autologous-activated T cells in patients with multiple sclerosis via granzyme K. As a result, the hypothesis is that a decreased granzyme K expression in sJIA patients might influence the killing of activated autologous cells, thus supporting the concept of defective immune regulation in sJIA.

The modern notion that sJIA is more a disease of innate than adaptive immunity has been recently challenged by the results of a multicenter study that has examined the MHC locus in a large collection of patients (982 patients and 8010 healthy controls). Metaanalysis of imputed classic HLA-type associations in six study populations of Western European ancestry has identified HLA-DRB1\*11 alleles as the strongest single-risk factor for sJIA, with a pooled odds ratio (OR) of 2.3 (Ombrello et al., 2015). This study strengthens the relationship between the class II HLA region and sJIA, implicating adaptive immune molecules in the pathogenesis of sJIA.

Ombrello et al. (2017) also found that sJIA did not share heritable risk factors with the more common oligoarticular and polyarticular forms of JIA. Even within the class II MHC region, which harbors disease-associated

genetic variation in each of these categories of JIA, the subtype-specific risk factors (single-nucleotide polymorphisms (SNPs), HLA alleles, and HLA haplotypes) are not shared between the subtypes. sJIA bears a unique genetic architecture, indicating that its underlying pathophysiological mechanisms are significantly divergent from other forms of JIA and arguing for a different classification framework.

## PROINFLAMMATORY MEDIATORS

Laboratory observations as well as the therapeutic efficacy of cytokine inhibitors have provided clear evidence for a major pathogenic role of phagocyte-derived cytokines, in particular of IL-6 and IL-1.

### Interleukin-6

The role of IL-6 in the pathogenesis of sJIA appears to be pivotal. Macrophages and endothelial cells are the main sources of IL-6, a cytokine that is responsible not only for the production of acute-phase proteins by hepatocytes, but also for hyperferritinemia, characterized by the uptake of free iron and ferritin synthesis. Furthermore, IL-6 is also closely related to the development of arthritis in both sJIA and adult-onset Still's disease. Circulating levels of IL-6 are markedly elevated, increase during the peak of fever, and correlate with the extent and severity of joint involvement and with platelet counts (De Benedetti et al., 1991). Synovial fluid levels of IL-6 are also markedly increased and significantly higher than those observed in patients with polyarticular and oligoarticular JIA or in RA patients (De Benedetti et al., 1997a,b). Moreover, in sJIA patients, huge quantities of IL-6 circulate bound to the soluble receptor; this bound IL-6 seems biologically active since it correlates much better with the level of C-reactive protein than free-circulating IL-6 (De Benedetti et al., 1994). At variance with findings in adult RA, anemia in sJIA is microcytic and characterized by a marked defect in iron supply for erythropoiesis, while growth of erythroid colonies is normal, and erythropoietin production is appropriate (Cazzola et al., 1996). These finding are consistent with the effect of IL-6 on the bone marrow. Indeed, IL-6 stimulates both hypoxia-induced erythropoietin production and erythroid progenitor proliferation and, by increasing ferritin expression and hepatic uptake of serum iron, causes a reticuloendothelial iron block. Moreover, IL-6 dramatically induces the liver production of hepcidin, a peptide that inhibits iron absorption in the small intestine and the release of recycled iron from the macrophages (Nemeth et al., 2004). This can well explain the oral iron malabsorption that has been observed in patients with sJIA (Martini et al., 1994).

Growth impairment is a well-known feature of sJIA since its first description and IL-6-transgenic mice with high circulating levels of IL-6 show a decreased rate of growth, attaining 50%–60% of the size of their wild-type littermates (De Benedetti et al., 1997a,b). Moreover, similar to patients with sJIA, IL-6-transgenic mice have normal growth hormone production but low levels of insulin-like growth factor 1 (IGF-1) and IGF-binding protein 3 (De Benedetti et al., 2001). All these finding led to the hypothesis that sJIA is an IL-6 and not a TNF-driven disease (De Benedetti and Martini, 1998). This hypothesis was supported 10 years later by the double-blinded controlled study with a withdrawal design that showed the marked efficacy of tocilizumab, a monoclonal antibody against the IL-6 soluble receptor (sIL-6R), which is essential for signal transduction (Yokota et al., 2008). These brilliant therapeutic results have been subsequently confirmed by a double-blind, placebo-controlled study (De Benedetti et al., 2012). Of note, it has been recently demonstrated that during treatment with tocilizumab patients with sJIA experience significant catch-up growth, normalization of IGF-1 levels, and bone balance improvement favoring bone formation (De Benedetti et al., 2015).

### Interleukin-1

The most compelling evidence for the important role of IL-1 in the pathogenesis of sJIA came from the quite serendipitous finding of the marked therapeutic efficacy of anakinra, an IL-1 inhibitor which is the recombinant version of the naturally occurring soluble IL-1 receptor antagonist (Verbsky and White, 2004; Pascual et al., 2005). In vitro exposure of healthy donor PBMCs to sera from subjects with sJIA induces transcription of genes associated with the IL-1 signaling pathway and markedly increases IL-1 $\beta$  protein secretion (Pascual et al., 2005). The role of IL-1 is not in contrast with that of IL-6, since IL-1 is upstream to IL-6. Interestingly, serum levels of myeloid-related proteins (MRPs) 8 and 14 (which are secreted by activated neutrophils and monocytes) are very high during active disease, and MRP-14 in serum of patients with sJIA has been shown to be a strong inducer of

IL-1 expression in phagocytes (Frosch et al., 2009). Moreover, MRP8/14 serum concentrations have been reported to correlate closely with response to drug treatment and disease activity and might, therefore, be useful also in monitoring treatment of individual patients with sJIA (Holzinger et al., 2012).

Of note, it has been shown that the response to anakinra can identify two different populations of sJIA patients (Gattorno et al., 2008). One (accounting for about 40% of the patients) shows a dramatic response to IL-1 blockade (similar to that observed in cryopyrin-associated autoinflammatory syndromes) leading to complete normalization of clinical as well as laboratory features in a few days. The other is resistant to treatment or shows an intermediate response. These two groups differed only in the number of joints involved, with patients with fewer joints affected, having a much higher probability of responding to anti-IL-1 therapy. The group with positive response could represent a separate entity in which the autoinflammatory component has the leading pathogenic role and where monocytes and neutrophils, rather than lymphocytes, are the predominant effector cells. The other group, characterized by the presence of an important synovitis, seems to have in addition a relevant autoimmune component. Of note, also Shimizu et al. (2013) suggested that patients with sJIA could be stratified into two subgroups, characterized respectively by very high circulating levels of IL-18 or IL 6. Interestingly, those with high levels of IL-18 had a low number of joint involved. As previously mentioned, Ombrello et al. (2015) found a relationship between the class II HLA region and sJIA, implicating adaptive immune molecules in the pathogenesis of sJIA. Although not tested, it is intriguing to speculate that this association could be limited to the sJIA subset with autoimmune features characterized by high number of joint involved, limited response to IL-1 inhibitors and high levels circulating IL-6.

A controlled trial has further supported the efficacy of Anakinra in sJIA (Quartier et al., 2011). Of interest in this trial a “de novo” type I IFN signature (which is not a feature of untreated sJIA) was observed in the majority of anakinra-treated patients regardless of the clinical response.

In a retrospective study, it has been recently suggested that a precocious treatment with Anakinra could prevent the subsequent appearance of refractory arthritis in the large majority of patients (Nigrovic et al., 2011). This hypothesis however needs to be confirmed in prospective randomized trials. More recently a high-affinity human IL-1 $\beta$  monoclonal antibody (canakinumab) has been used in the treatment of sJIA. It selectively binds to human IL-1 $\beta$ , thereby inactivating IL-1 $\beta$  signaling pathways and neutralizing its downstream effects. Clinical evidence of the efficacy and safety of canakinumab in patients with sJIA was demonstrated in two international trials that served as the basis for the approval of canakinumab for the treatment of sJIA by the United States and European regulatory authorities (Ruperto et al., 2012a,b).

## Interleukin-18

sJIA, as well as adult-onset Still’s disease, are characterized by very high levels of circulating IL-18 (Kawashima et al., 2001; Maeno et al., 2002). Of note, IL-18 is a member of the IL-1 cytokine superfamily, is stored as precursor protein, and, upon activation, is cleaved by caspase 1 in a manner similar to that of IL-1 to yield the active cytokine. It seems that in sJIA during MAS (see below), IL-18, and other proinflammatory cytokines (IFN- $\gamma$ , IL-6, TNF) are mainly produced by resident macrophages (bone marrow and liver) (Maeno et al., 2004; Billiau et al., 2005). A reversible defect in phosphorylation of IL-18 receptor has been reported in patients with sJIA (de Jager et al., 2009).

## MACROPHAGE ACTIVATION SYNDROME

It remains substantially a mystery why sJIA is so strongly associated with MAS. Of note, MAS is seldom observed in autoinflammatory diseases. It is unclear if this complication characterizes a distinct subset of the disease. Interestingly, activated macrophages or frank hemophagocytic cells have been found in 53% of the patients with sJIA who underwent bone-marrow aspiration, suggesting that subclinical MAS may be present in half of the patients (Behrens et al., 2007).

As mentioned above, MAS bears strong resemblance to a group of histiocytic disorders collectively known as HLH (Janka, 2012). Two types of HLH are recognized. The primary or familial HLH, familial haemophagocytic lymphohistiocytosis (FHLH) forms are secondary to genetic deficiency in cytolytic pathway proteins. The secondary or reactive HLH forms are associated with an identifiable infectious episode or are secondary to an autoimmune condition or to a neoplastic or a metabolic disorder.

HLH symptoms can be explained by the high concentration of inflammatory cytokines and by organ infiltration by lymphocytes and histiocytes. Fever is induced by IL-1 and IL-6, and pancytopenia is the consequence of high levels of TNF and IFN- $\gamma$  rather than of hemophagocytosis. TNF inhibits lipoprotein lipase leading to elevated triglycerides. Activated macrophages secrete ferritin and plasminogen activator which results in high plasmin levels and hyperfibrinolysis. Hepatosplenomegaly, increased liver enzymes, neurological symptoms are the consequence of organ infiltration by activated lymphocytes and histiocytes. Activated lymphocytes and macrophages are respectively the source for high concentration of circulating sIL-2 Ra and sCD163.

To date, all the described genetic defects associated with HLH appear to be related to one another in the pathway of granule-mediated cytotoxicity, with the lack of perforin being the most common. These genetic defects interrupt the mechanisms responsible for triggered apoptosis (mediated by cytotoxic cells on the target cell) or activation-induced apoptosis (putative suicide of activated T cell).

The similarities between HLH and MAS are not limited to clinical features. Similarly to patients with FHLH, patients with MAS in association with sJIA also have profoundly decreased cytolytic function, although this impairment reverts to normal after treatment (Ravelli et al., 2012).

These observations suggest that background inflammation is at least partially responsible for this functional abnormality in MAS. Indeed, IL-6 has been found to induce defective expression of perforin and decreased NK cell cytotoxic activity.

It has been recently hypothesized that cytolytic dysfunction in sJIA with MAS might be also influenced by a genetic component. In fact, a study using whole-exome sequencing reported hypomorphic mutations in primary HLH-associated genes in nearly a third of patients with sJIA and MAS (Kaufman et al., 2014).

The best experimental model of HLH is perforin-deficient mouse in which CD8 T cells produce large amounts of IFN- $\gamma$ .

It has been shown that repeated stimulation of TLR-9 produces an HLH/MAS-like syndrome on a normal genetic background, without exogenous antigen (Behrens et al., 2011). Like in perforin-deficient mice, the syndrome depends on the presence of IFN- $\gamma$ ; however, IFN- $\gamma$  is arising from different sources than CD8 T cells, including dendritic cells and NK cells. This model shows that MAS can develop during persistent innate immune activation independently from defects in cytotoxic cell function. Treatment of IL-6-transgenic mice with TLR ligands led to elevated levels of IL-1 $\beta$ , TNF, IL-6, and IL-18 and an increased fatality rate with features similar to those observed in MAS (Strippoli et al., 2012).

Of note, two reports described patients with periodic fevers and MAS-like features linked to a gain-of-function mutation in *NLRC4*, which was in turn linked to an overproduction of IL-1 $\beta$  and IL-18, in addition to an increased pyroptosis (a peculiar form of cell death). This caspase 1-mediated process is characterized by quick plasma-membrane rupture and release of proinflammatory intracellular contents. In patients with *NLRC4* mutation, MAS-like symptoms seemed to be induced by a macrophage intrinsic defect in the absence of primary cytotoxic abnormalities (Canna et al., 2014; Romberg et al., 2014).

The pivotal role of IFN- $\gamma$  pathway in sJIA patients with MAS has been recently confirmed by Bracaglia et al. who found levels of IFN- $\gamma$  and of IFN- $\gamma$ -induced chemokines (CXCL9 and CXCL10) markedly elevated during active MAS. In addition, levels of IFN- $\gamma$ , CXCL9, and CXCL10 strongly correlate with laboratory parameters of MAS severity (Bracaglia et al., 2017).

These observations suggest IFN- $\gamma$  could be targeted therapeutically in HLH; of note when this cytokine is neutralized, survival improved substantially in HLH animal models. A study to investigate the safety and efficacy of an Anti-IFN- $\gamma$  mAb in children affected by primary HLH is underway (<https://clinicaltrials.gov/ct2/show/NCT01818492>).

## Oligoarticular Juvenile Idiopathic Arthritis

As mentioned above, in the Western countries, most children with oligoarthritis have a definite disease, peculiar of childhood and characterized by an asymmetric arthritis, involving mainly large joints, an early onset (before 6 years of age), a female predilection, a high frequency of positive ANA, a high risk of developing chronic iridocyclitis. The homogeneity of this form of arthritis is also witnessed by consistent associations with HLA antigens. Positive associations include HLA-A2, HLA-DRB1\*11 (a subtype of HLA-DR5), and HLA-DRB1\*08. On the contrary, HLA-DRB1\*04 and HLA-DRB1\*07 have been found to be significantly decreased (Prahala and Glass, 2008). Evidence of the crucial role played by genetic variants in the HLA region is provided by the recent genome-wide association study (GWAS) studies of JIA (Hinks et al., 2009, 2013). In particular, the ImmunoChip

study (2816 JIA patients and 13,056 controls) found that the SNP rs7775055, located in the class II HLA region (DQ), was associated with oligoarticular and polyarticular RF-negative JIA with an OR of 6.01 (95% CI 5.30–6.81). HLA associations support an autoimmune pathogenesis, and the early onset suggests that the disease could be elicited by a very common infectious agent that can be encountered early in life. In this respect, evidence has been provided that T cells from patients with early-onset ANA-positive oligoarticular JIA are sensitized against epitopes that are shared between the disease-associated HLA antigens and proteins present on Epstein–Barr virus and other herpes viruses (Massa et al., 2002); herpes viruses represent a group of infectious agents to which the vast majority of children have already been exposed by 6 years of age.

The HLA region is estimated to explain ~8%–13% of the total variation in JIA susceptibility, suggesting that there are still many non-HLA loci to be identified. The most significant association outside the MHC region has been found with the PTPN22 gene, located on chromosome 1p13.2, and with the PTPN2 gene (Hinks et al., 2013). Both genes encode proteins tyrosine phosphatase involved in T-cell regulation. It is thought that functional mutations in these genes might lead to T-cell activation and the subsequent promotion of autoimmune disease. Mutations in PTPN22 have also been associated with multiple autoimmune diseases such as RA, systemic lupus erythematosus, autoimmune thyroid disease, and Type 1 diabetes mellitus. The ImmunoChip study has dramatically increased our knowledge of JIA susceptibility loci from non-HLA regions (PTPN22, STAT4, PTPN2, ANKRD55, IL2-IL21, TYK2, IL2RA, SH2B3-ATXN2, ERAP2-LNPEP, UBE2L3, C5orf6-IRF1, RUNX1, IL2RB, ATP8B2-IL6R, FAS, ZFP36L1 (Hinks et al., 2013)). In addition, multiple gene regions such as IL2RA, IL2/IL21, and IL2RB were confirmed to be susceptibility loci for JIA, thus highlighting the important role of the IL-2 pathway in JIA pathogenesis. This pathway plays a pivotal role in T-cell activation and development, as well as a key role in maintenance of immune tolerance through the dependence of regulatory T cells (Tregs) on IL-2. *SH2B3*, an adaptor protein involved in T-cell activation, and *STAT4*, a transcription factor important in T-cell differentiation, were also found to be related to this pathway and were confirmed to be susceptibility loci for JIA (Hinks et al., 2013).

The inflammatory synovitis observed in JIA is similar to that of adult RA. The synovium shows hyperplasia of the lining layer and infiltration of the sublining layer with mononuclear cells, including T cells, B cells, macrophages, dendritic cells, and plasma cells. The T-cell infiltrates are composed predominantly of Th-1-skewed CD4+ cells, expressing an activated memory phenotype. The inflammatory process leads to pannus formation with cartilage and bone erosions mediated by degradative enzymes such as metalloproteinases (Ravelli and Martini, 2007).

As mentioned above, a B-cell signature has been shown to characterize patients with early-onset arthritis (Barnes et al., 2010). Moreover, lymphoid aggregates and plasma cell infiltration have been found more frequently in patients with circulating ANA (Gregorio et al., 2007). These observations suggest that B cells can play a role in early-onset ANA positive arthritis. Corcione et al. found an expansion of activated switch memory B cells and of IgG-secreting plasma blasts in the SF of oligoarticular JIA patients. Memory B cells belonged to either the CD27+ or the CD27− subsets and expressed CD86, suggesting their involvement in antigen presentation to T cells (Corcione et al., 2009). Another study (Morbach et al., 2011), involving mainly patients with oligoarticular disease, has also confirmed that activated immunoglobulin class-switched CD27− and CD27+ memory B cells accumulate in the joints and might be involved in the amplification of pathogenic T-cell activation. These findings suggest that B cells play an antibody-independent immunopathologic role in oligoarthritis.

Cosmi et al. (2011) have studied Th17 cells in children with oligoarticular JIA. They showed that synovial fluid T cells could switch easily from a Th17 phenotype to a mixed Th1/Th17 phenotype, and, then, to a Th1 phenotype; the switch was linked to the presence of IL-12 in the synovial fluid. This study is in line with the findings of another study performed in JIA patients which showed that synovial fluid Th17 cells “convert” to Th17/1 in the presence of low TGFβ and high IL-12 levels, whereas Th1 cells cannot convert to Th17 (Nistala et al., 2010).

Within the joint, an inverse relationship between IL-17+ T cells and FoxP3+ Treg cells has been found (Nistala et al., 2008). In JIA, Tregs from the peripheral blood as well as from the inflamed joints are fully functional. Nevertheless, Treg-mediated suppression of cell proliferation and cytokine production by effector cells from the site of inflammation have been shown to be severely impaired (Haufe et al., 2011; Wehrens et al., 2011). This resistance to suppression has been shown to be secondary to the activation of protein kinase B/c-akt in inflammatory effector cells, since inhibition of this kinase restores responsiveness to suppression (Wehrens et al., 2011).

The fact that in oligoarticular JIA joint involvement can remain limited to four or less joints (oligoarticular persistent) or can extend to affect five or more joints after the first 6 months of disease (oligoarticular extended) provides an opportunity to study factors that are associated with disease extension.

IL-17+ T-cell numbers were found to be higher in patients with extended oligoarthritis as compared with patients with persistent oligoarthritis (Nistala et al., 2008). The ratio between SF regulatory and activated effector

CD4 cells was found to be higher in patients with persistent oligoarticular disease with respect to those in whom the disease extended to affect five or more joints (Ruprecht et al., 2005). Hunter et al. sampled patients with recent-onset oligoarticular JIA and looked at potential differences in synovial fluid cells between patients with persistent or extended disease. Synovial CCL5 levels were higher and SF CD4:CD8 ratio was lower in children whose disease extended to a more severe phenotype. Gene expression profiling revealed increased levels of genes associated with inflammation and macrophage differentiation in patients with extended disease and of genes associated with immune regulation in patients with persistent oligoarticular disease (Hunter et al., 2010). Finnegan et al. studied the immunohistochemical features of the synovial membrane in early untreated, newly diagnosed JIA in relation with disease outcome at 2 years. CD4 expression and B-cell infiltrates was significantly higher and vascularization more pronounced in patients in whom arthritis extended to involve more joints with respect to those with persistent oligoarthritis (Finnegan et al., 2011).

The fact that persistent oligoarticular JIA is self-limiting, and in about half of all cases even self-remitting, suggests an endogenous regulation. Heat shock proteins (HSPs) are endogenous proteins that are expressed upon cellular stress and are able to modulate immune responses. HSPs are highly present at sites of inflammation, such as the inflamed joints of JIA patients (Boog et al., 1992). Studies have showed in JIA the presence of antigen-specific T cells against peptides derived from two types of HSPs, HSP60, and DnaJ (Kamphuis et al., 2005; Massa et al., 2007). T-cell recognition of self-peptides or of peptides with a high degree of homology with self was associated with immune mechanisms with regulatory function, including the presence of T cells with the regulatory functional phenotype. These responses are significantly augmented in patients with persistent oligoarticular JIA, which again suggests a direct role in modulation of autoimmune inflammation. The identification of HSP tolerogenic peptides could have therapeutic implications in the future.

## TREATMENT

The management of JIA has improved greatly over the past decade with the introduction of biologic agents, tight control strategies, and early disease-modifying antirheumatic drug treatment. The implementation by the Food and Drug Administration (FDA) and the European Medicines Agency of the so-called pediatric rule has also played a pivotal role in the improvement of treatment and outcome. According to this rule, an industry that wishes to register a new treatment for a given disease in adults has to conduct studies also in children if there is a pediatric counterpart of the illness. Pediatric rheumatology was able to take a quick advantage from this rule thanks to the existence of two very large networks that have worked in a highly integrated fashion, the Pediatric Rheumatology Collaborative Study Group in North America and the Pediatric Rheumatology International Trial Organization in Europe and the rest of the world (Ruperto and Martini, 2004).

Since JIA is not a single disease, different therapeutic approaches should be considered according to the diverse disease categories. Nonetheless, general guiding principles may be adopted (Beukelman et al., 2011; Ringold et al., 2013). The widespread use of intraarticular steroid injections has played an important role in preventing deformities, for example, valgus knee, secondary to joint contractures. The long-acting steroid triamcinolone hexacetonide is used worldwide since its induced remission lasts much longer compared to other steroids. Patients who do not respond to nonsteroidal anti-inflammatory drugs (NSAIDs) and intraarticular steroid injections are treated with MTX whose maximally effective dose has been established in a randomized trial (Ruperto et al., 2004). Although a trial has shown the efficacy of leflunomide in polyarticular JIA (Silverman et al., 2005), the experience with this drug in children is still scarce. In patients who do not respond adequately to MTX, the efficacy and safety of several anti-TNF agents such as etanercept (the soluble TNF- $\alpha$  receptor), adalimumab, and golimumab (two fully humanized monoclonal antibodies to TNF- $\alpha$ ) have been demonstrated in randomized controlled trials (RCTs) in polyarticular course JIA (Lovell et al., 2000, 2008; Brunner et al., 2017). Adalimumab is the anti-TNF of choice in the case of JIA-associated uveitis (Ramanan et al., 2017). Abatacept, cytotoxic T-lymphocyte antigen 4 (CTLA-4) Ig, an inhibitor of costimulatory signals during antigen presentation, is an approved therapeutic option for patients with polyarthritis who are resistant to TNF- $\alpha$ -inhibitors (Ruperto et al., 2008). The efficacy and safety of the IL-6 receptor inhibitor (tocilizumab) for the treatment of patients with polyarticular-course JIA has been recently demonstrated in phase III controlled trial (Brunner et al., 2015).

sJIA patients are often recalcitrant to standard treatments. Recent insights into its pathophysiological mechanisms have however led to major changes in the management of this disease, especially with the development of biologic treatments. Corticosteroid use has substantially decreased; severe anemia, myocarditis, serositis,

and MAS are still considered to be absolute indications. The treatment of MAS relies on high-dose steroids and cyclosporine.

In sJIA patients who are steroid dependent anti-IL-6 and anti-IL-1 treatments, as mentioned above, have shown a dramatic efficacy. The 2013 update of the 2011 American College of Rheumatology (ACR) Recommendations outlines the indications for use of IL-1 and IL-6 inhibitors, including anakinra, canakinumab, and tocilizumab (Ringold et al., 2013).

The safety profile of biological agents appears to be good. The initial concern raised by the FDA that treatment with anti-TNF agents could be associated with an increased rate of malignancy (Diak et al., 2010) has not been confirmed by retrospective studies that have on the opposite suggested that JIA itself and not anti-TNF therapy is associated (as adult RA) with a small increased risk of neoplasia (Beukelman et al., 2012).

With the improvement in JIA care, remission has become an achievable goal for a large proportion of patients.

## OUTLINE

General Introduction	691	The Role of HLA-B27 in the Pathogenesis of Spondyloarthritis	695
Historical Aspects	691	The Role of Non-MHC Genes in Spondyloarthritis	696
Epidemiology	692	Animal Models With Possible Relevance for the Pathogenesis of Spondyloarthritis	697
Clinical Features and Disease Associations	692	Treatment	698
Pathological Features	693	References	699
Autoimmune Features	693	Further Reading	701
Genetics	695		

## GENERAL INTRODUCTION

The spondyloarthritis (SpA) diseases comprise axial spondyloarthritis (axial SpA) including ankylosing spondylitis (AS), reactive arthritis (ReA), arthritis/spondylitis with inflammatory bowel disease (IBD), and arthritis/spondylitis with psoriasis. The main links between each of these are the associations with HLA-B27, similar clinical symptoms, such as inflammatory back pain, and similar patterns of peripheral joint involvement with an asymmetric arthritis predominantly of the lower limbs, and the possible occurrence of sacroiliitis, spondylitis, enthesitis, and uveitis. Most striking is the direct relationship between the prevalence of SpA and the prevalence of HLA-B27 in the general population. This strong correlation suggests that the environmental or genetic factors that are necessary in addition to HLA-B27 to get SpA must be ubiquitous (Sieper and Poddubnyy, 2017).

## HISTORICAL ASPECTS

The first most clear-cut descriptions of AS date back to the end of the 19th century. At that time, the disease was described independently by three people—in Russia by Vladimir Bechterew in 1893 (Bechterew, 1893), in Germany by Adolf von Strümpell in 1897 (Strümpell, 1897), and in 1898 by Pierre Marie in France (Marie, 1898). Therefore, *Spondylitis ankylosans* is sometimes referred to as *Morbus Bechterew* or *Bechterew–Strümpell–Marie disease*. With the availability of radiography, the involvement of the sacroiliac joints was noted in the 1930s

([Buckley, 1931](#)). In 1973, the association with HLA-B27 was described ([Brewerton et al., 1973](#)) that opened a new area of research on the pathology of the disease.

## EPIDEMIOLOGY

Axial SpA covers both nonradiographic (nr) axial SpA and AS. AS is characterized by the presence of structural changes in the bone on X-rays and is regarded as the SpA with the most severe outcome. Its prevalence has been estimated to be between 0.2% and 0.9% and the disease normally starts in the second decade of life. The male-to-female ratio has more recently been estimated to be around 2:1. HLA-B27 is found to be positive in 90%–95% of the patients, and inflammatory bowel disease, psoriasis, or preceding ReA can be found in about 10% of the AS patients.

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

Back pain is the leading clinical symptom in patients with axial SpA. Such back pain is characterized by morning stiffness and subsides by exercise. This disease starts in 90% or more cases with sacroiliitis. Further, in the course of the disease, the whole spine can be affected with spondylitis, spondylodiscitis, and arthritis of the small intervertebral joints. As a reaction to the inflammation, ankylosis occurs, which can involve the whole spine. Relapsing uveitis, peripheral asymmetric arthritis predominantly of the lower limbs, and enthesitis are the most frequent extraspinal manifestations. Diagnosis is made by a combination of clinical symptoms (such as inflammatory back pain or limitation of spinal mobility), laboratory findings, such as HLA-B27 and CRP, and positive imaging. Sacroiliitis on MRI (active inflammation) or on X-rays (structural damage) are crucial for the classification and diagnosis of axial SpA ([Rudwaleit et al., 2009a,b](#)). A new approach to an earlier diagnosis is also mandatory because of the major delay of 5–7 years between the occurrence of the first symptoms and conducting of the diagnosis.

ReA occurs after a preceding infection of the urogenital tract with *Chlamydia trachomatis* or of the gut with enterobacteria, such as *Yersinia*, *Salmonella*, *Campylobacter jejuni*, or *Shigella*, usually after a few days up to 4–6 weeks ([Sieper et al., 2000](#)). Between 30% and 60% of the patients with ReA are positive for HLA-B27; arthritis occurs in approximately 4% of the general population, but in about 25% of the HLA-B27 + carriers, after one of these infections. Arthritis is normally oligoarthritis, predominantly of the lower limbs, but in about 20%, it will manifest as polyarthritis. Other manifestations can be enthesitis, conjunctivitis/uveitis, or inflammatory back pain. Usually, the patients recover within 3–6 months; however, up to 20% can have chronic recurrence of longer than 12 months. Bacterial antigen and, in case of *Chlamydia*, DNA and RNA have also been detected in the joint, indicating that bacterial antigens persist in the joint and drive the local immune response. For conducting a diagnosis of ReA, a combination of the clinical manifestations (preceding infection, typical pattern of arthritis) and laboratory evidences of the previous or present bacterial infections is necessary ([Sieper et al., 2002](#)). While antibiotic treatment of urogenital tract infection with antibiotics prevents the occurrence of arthritis, this is not the case for bacterial enteritis. Once arthritis is established, long-term antimicrobial monotherapy does not seem to influence such arthritis ([Sieper et al., 2000](#)). However, as have been recently shown, improvement of chronic *Chlamydia*-induced arthritis can be achieved after prolonged, 6-month combined antimicrobial therapy, suggesting that antibiotic monotherapy is not effective in the eradication of the ReA-inducing microbes ([Carter et al., 2010](#)).

Arthritis with IBD often occurs concurrently with gut inflammation in approximately 10%–20% of the patients with IBD. Arthritis is often a case of transient peripheral arthritis of the lower limbs. About 5% of IBD patients, mostly those who are HLA-B27 + will develop AS. The frequency of HLA-B27 among patients with peripheral arthritis is only slightly higher but is present among 50%–70% of the patients with IBD and AS. Treatment should primarily be directed against the gut inflammation.

Up to 50% of the patients with psoriatic arthritis show a clinical picture compatible with SpA, such as oligoarthritis of the lower limbs and/or spinal inflammation. Among these patients, HLA-B27 is positive in approximately 25% (peripheral arthritis) to 60% (spinal manifestations). Treatment is similar to that for the other forms of SpA.

## PATHOLOGICAL FEATURES

Studies using MRI have shown that the most relevant inflammatory site in SpA is osteitis occurring at the bone/cartilage interface (McGonagle et al., 1999). Osteitis is detected in short-tau inversion recovery sequence and indicates a change in the homeostasis of the bone marrow. Osteitis in the sacrum and ilium adjacent to the sacroiliac joints is a primary finding in axial SpA (Rudwaleit et al., 2009a,b). Long-term disease and symptom occurrence duration may lead to structural changes in the subchondral bone, including erosions, joint space narrowing, and ankylosis, which can be detected by X-ray. Within the spine, osteitis can be detected mainly at the corners of the vertebral bodies, where at later points of time, syndesmophyte development is observed (Baraliakos et al., 2014).

Histological studies in AS are limited due to the difficulties of acquiring joint material from axial joints. The most comprehensive histological studies were performed by Cruickshank (1951, 1956). He investigated joints from autopsies of AS patients, such as hip joints, sacroiliac joints, and intervertebral joints and reported synovial proliferation, fibrosis of synovial tissue, and foci of metaplasia to cartilage and bone. Moreover, cartilage destruction and presence of a fibroblast-rich granulation tissue were commonly found. By comparing histology to radiographs, he found that the radiographic joint space narrowing was correlated with cartilaginous degeneration. The presence of the radiographic erosions correlated with the presence of the fibrous tissue within the marrow space. More recent histological analysis of biopsy specimen taken from the sacroiliac joints described that a proliferative connective tissue and inflammatory cells were present in patients with active sacroiliitis and short disease duration, whereas calcification and ossification were more often found in long-standing disease (Bollow et al., 2000). Comprehensive analysis of the facet joints, which are also often affected in AS, described the sequential features of the joint remodeling in SpA (Bleil et al., 2014). The transformation of the bone marrow into a fibrous tissue was found to precede the cartilaginous fusion of the joints. The presence of osteoclasts, which erode the subchondral bone, and the cartilage from the bone marrow site seem instrumental in the destruction of the joints. Osteoblasts are located as well at the edges of this invasive tissue that synthesize a collagen type I matrix, which is subsequently mineralized, leading to the intraarticular bony bridges promoting ankylosis of the joints (Bleil et al., 2016).

It suggests that the pathological immune reaction starts at the bone marrow sites, predominately at the regions where the ligaments attach, suggesting that the physiological–biomechanical stress contributes to the local inflammation.

## AUTOIMMUNE FEATURES

Exposure of the immune system to bacteria rather than the presence of one distinctive autoantigen seems to be important for triggering SpA. The best evidence for this comes from ReA, which is triggered usually by a genito-urinary infection with *C. trachomatis* or enteritis due to certain gram-negative enterobacteria, such as *Shigella*, *Salmonella*, *Yersinia*, or *Campylobacter*. The demonstration of microbial antigens within the synovium suggests that ReA may be related to the persistence of microbial antigens at the sites of inflammatory arthritis (Granfors et al., 1989). Approximately 20%–40% of the HLA-B27+ ReA patients develop the full clinical manifestations of AS after 10–20 years (Leirisalo-Repo, 1998). Although clinically diagnosed ReA arthritis precedes AS only in less than 10% of the occurrences, this percentage may be much higher because many of the gut or urogenital infections preceding the clinical manifestation of ReA can be asymptomatic.

The ReA-associated bacteria are obligate (such as *Chlamydia*) or facultative intracellular bacteria. T-helper 1 (Th1) cytokines, such as tumor necrosis factor alpha (TNF $\alpha$ ) and interferon gamma (IFN $\gamma$ ), are crucial for the effective elimination of these bacteria, while Th2 cytokines, such as interleukin (IL)-4, or antiinflammatory cytokines, such as IL-10, might inhibit effective elimination. Relative deficiency of Th1-cytokines was found in ReA patients, not only of TNF $\alpha$  but also of IFN $\gamma$ , both locally in synovial fluid and synovial membrane and systemically in peripheral blood (Yin et al., 1997a; Braun et al., 1999). The low TNF $\alpha$  production in peripheral blood is correlated with the longer duration of arthritic symptoms (Braun et al., 1999). Thus a relative lack of Th1-cytokines appears to be relevant for the occurrence and persistence of ReA. IL-10 was found relatively upregulated in ReA, which may contribute to bacterial persistence in ReA, possibly by down-regulation of the Th1-cytokines, IFN $\gamma$  and TNF $\alpha$  (Yin et al., 1997b). The persistence of bacterial antigens being disseminated to the joints might cause aberrant inflammation at these sites, which are also exposed to mechanical stress.

Alternatively, the persistence of antigens might cause the pathological priming of T cells cross-reacting to the autologous antigens.

The central role of bacteria in the pathogenesis of SpA is further supported by the relationship between IBD and SpA. Arthritis with IBD occurs in approximately 10%–20% of the patients with IBD. Among the AS patients, about 7% have concomitant IBD (Stolwijk et al., 2013). The presence of IBD and HLA-B27 positivity is associated with a high prevalence of AS in particular, as suggested by a study of Crohn's disease patients: in 13 out of 24 (54%) HLA-B27 + patients with Crohn's disease, AS was also diagnosed, but only in 5 out of 189 (2.6%) patients who were HLA-B27 –, AS was not diagnosed (Purmann et al., 1988). In IBD, leakage in the gut mucosa is observed as a consequence of the related inflammation, which presumably allows an interaction of the immune system with the normal gut bacteria. In addition to the high prevalence of overt IBD in AS, also in about 50% of the patients with axial SpA, macroscopic or microscopic mucosal inflammation, some of which resembling Crohn's disease, can be detected in the gut by colonoscopy (Mielants et al., 1988; Van Praet et al., 2013). This indicates that gut inflammation is a rather common feature of SpA suggesting a link between the gut and its microbiota and pathogenesis of axial SpA. This is also supported by findings from animal SpA models. HLA-B27 transgenic rats, representing the most relevant SpA model, develop gut inflammation, peripheral arthritis, and psoriasisiform skin and nail changes. The importance of environmental factors is emphasized by the observation that many of these features, including gut inflammation and arthritis, do not develop in HLA-B27 transgenic rats born and bred in a germ-free environment. Germ-free animals rapidly develop inflammatory disease on removal from the sterile environment. This can be partially prevented by treatment with antibiotics (Taurog et al., 1999).

Bacteria appear to play a crucial role as an initial event for the pathogenesis of AS; however, there is no clear evidence that they are also directly responsible for the immunopathology in AS. While bacterial antigens are found in the joints of ReA patients, no such antigen has been found so far in sacroiliac joints (Braun et al., 1997). However, considering that commensal bacteria from the gut comprise a great variety of different microorganisms, it is particularly difficult to detect distinct bacteria. As first evidence, in AS with peripheral arthritis, enhanced reactivity toward *Escherichia coli* proteins, a common mucosal bacterium, has been reported (Syrbe et al., 2012).

If such antigens persist in joints or if AS occurs as the result of bacteria-induced autoimmunity is a matter of debate. Surprisingly, given the strong association with the MHC class I molecule HLA-B27, it was in the HLA-B27 transgenic rat model that the disease induction is independent of the presence of CD8 + T cells but requires CD4 + T cells (Taurog et al., 2009). Whether these cells are activated by bacterial antigens or by autoantigens remains unclear; however, the Aggrecan G1 domain has been suggested as one source of a possible CD4 + T-cell autoantigen in AS and similar rheumatic diseases, based both on the results of animal models and from the studies conducted on patients (Zou et al., 2003). Thus in 60% of the patients, a CD4 + response against the whole G1 protein and against a set of overlapping peptides derived from this G1 protein was detectable (Zou et al., 2003). However, clinical trials suggest that classical disease modifying drugs, such as methotrexate and abatacept, targeting T-cell stimulation, are ineffective in AS. In contrast, genetic studies and studies on cytokine inhibition suggest a strong impact of the cytokines TNF $\alpha$ , IL-23, and IL-17 in AS. Thus treatment of AS patients with TNF $\alpha$  inhibitors is highly effective in improving the signs and symptoms of the disease (Braun and Sieper, 2004). Furthermore, anti-IL-17 antibody treatment has been approved for the treatment of the axial SpA patients and an anti-p40 mab (targeting the shared p40 subunit of the IL-12/IL-23 receptor) has shown some efficacy in a small clinical study of AS patients. In contrast, IL-6 blockade had no effect on axial SpA while it is effective in rheumatoid arthritis.

The cellular sources and triggers of pathogenic cytokine production are poorly defined in AS. In fact, in the blood of AS patients CD4 + and CD8 + T cells producing TNF $\alpha$  (and IFN $\gamma$ ) after mitogenic stimulation are even less abundant than in HLA-B27 – controls (Rudwaleit et al., 2001). However, in a small study where sacroiliac biopsies were acquired, abundant TNF $\alpha$  was found in the sacroiliac joints from AS patients (Braun et al., 1995).

Analyzing IL-17A expression in AS, no difference was found in the percentage of Th17 cells in the peripheral blood compared to controls while in the subchondral bone marrow of facet joints, acquired from patients with AS, an increased percentage of IL-17A + cells was found (Appel et al., 2011). Those IL-17A + cells were mostly of myeloid origin. Also, in inflamed peripheral joints of SpA patients, mononuclear and polymorphonuclear, synovial cell infiltrates were found to express IL-17 (Moran et al., 2011). This suggests that rather innate immune cells might contribute to pathogenic IL-17 production in AS than adaptive immune cells.

IL-23 is induced during the unfolded protein response triggered by protein misfolding. Stimulation of innate cells, such as macrophages with pharmacological inducers of the unfolded protein response, results in the enhanced LPS-elicited production of the inflammatory cytokines, in particular IFN $\beta$  and IL-23 (Smith et al.,

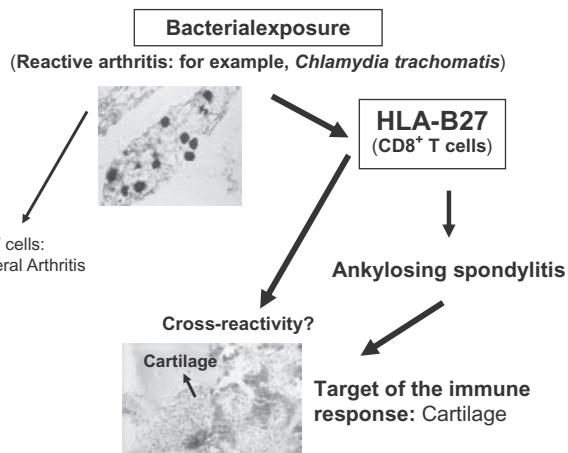

2008). A recent study shows that peripheral blood-derived macrophages from AS patients produced strikingly higher levels of IL-23 in response to the stimulation with lipopolysaccharide, even in the absence of unfolded protein response (UPR) induction (Zeng et al., 2011). Furthermore, IL-23 + cells were also found to have increased within bone marrow cells, again mostly among cells of myeloid origin, in facet joints from AS patients (Appel et al., 2013).

## GENETICS

### The Role of HLA-B27 in the Pathogenesis of Spondyloarthritis

The susceptibility to AS has been estimated to be more than 90% genetically determined, and so it has been suggested that there is a rather ubiquitous environmental factor. The most relevant genetic risk factor is HLA-B27 (Brewerton et al., 1973; Schlosstein et al., 1973). The association of HLA-B27 with SpA is the highest known MHC association for human diseases and the most relevant single factor for the pathogenesis of SpA. There are now considerable data from epidemiologic studies and transgenic animals to indicate a direct effect of HLA-B27, rather than that of a closely linked gene, in disease pathogenesis. It is also clear now that one copy of HLA-B27 (heterozygosity) is sufficient for increasing the risk of disease development. Besides HLA-B27, other MHC genes, such as HLA-B60 and HLA-DR1, seem to be associated, but are of minor importance. However, although MHC is the major susceptibility locus, it has been suggested that it contributes only approximately 36% to the overall genetic risk (Brown et al., 2002).

Although the association between HLA-B27 and SpA has been known for more than 40 years, the mechanism by which HLA-B27 confers susceptibility to SpA is still unknown. Three hypotheses are discussed that refer to the distinct properties of the HLA-B27 molecule. The arthritogenic peptide hypothesis suggests a link between the SpA induction and the main function of HLA class I molecules to present peptide antigens to cytotoxic T cells. Thus some HLA-B27 subtypes, due to their unique amino-acid residues, can bind distinct sets of peptides that are presented to CD8<sup>+</sup> T cells. In response to such exogenous peptides, T cells recognizing autoantigens with sufficient structural similarity might become activated and react toward self-peptides that are present particularly in spinal joints (Fig. 36.1). Major support for this hypothesis comes from studies in humans showing the differential association of some of the HLA-B27 subtypes with AS. While B\*2705, B\*2702, B\*2704, and B\*2707 are strongly associated with the disease, the HLA-B27 subtypes B\*2709 in Whites and B\*2706 in Southeast Asians are not at all or only rarely associated. Most interestingly, B\*2709 differs from the disease associated B\*2705 by only one amino-acid substitution, the exchange of Asp116 to His116. B\*2706 differs by only two amino-acid substitutions from the disease associated B\*2704 by exchange of His114 to Asp114 and Asp116 to Tyr116 (Khan, 2000).

**FIGURE 36.1** Hypothesis of how bacterial exposure induces a peripheral arthritis, probably via a CD4<sup>+</sup> T-cell response. However, axial manifestations might be mediated by CD8<sup>+</sup> T cells because of the high association with HLA-B27. The cartilage might become the primary target of the immune response through cross-reactivity with bacterial antigens.

As the arthritogenic peptide hypothesis suggests that a common antigen might bind to the disease associated HLA-B27 subtype, a recent study has searched for shared sequences and motifs in CD8+ T cells in HLA-B27-positive AS patients using next-generation sequencing (Faham et al., 2017). In this study, several T-cell receptor (TCR) beta motifs were identified that were enriched in B27+ AS patients as compared to B27+ healthy controls. Moreover, both bacteria-specific and autoreactive CD8+ T cells have been demonstrated in AS and ReA. For instance, in patients with *Yersinia*-induced ReA, a synovial CD8+ T-cell response to a peptide from *Yersinia* heat shock protein 60 was found and in patients with *Chlamydia*-induced ReA, an HLA-B27-restricted CD8+ T-cell response to peptides was derived from several chlamydial proteins (Kuon and Sieper, 2003). In AS patients, a CD8+ T-cell response to an Epstein–Barr virus epitope derived from the LMP2 protein was found, with cross-reactivity to a sequence-related self-peptide from the autoantigen vasoactive intestinal peptide receptor 1 (Fiorillo et al., 2000). However, the exact identity of a potentially arthritogenic peptide is yet to be determined. An oligoclonal expansion of T cells has also been demonstrated for CD4+ and CD8+ T cells in AS and for CD8+ T cells in ReA. Synovial T cells derived from different HLA-B27+ patients suffering from ReA and triggered by different bacteria revealed a high homology of the TCRs (May et al., 2002).

Besides the “classical” arthritogenic peptide theory, other hypotheses have emerged. One such concept, the HLA-B27 misfolding and UPR hypothesis, states that HLA-B27 itself is directly involved in the pathologic process of SpA. Thus HLA-B27 has a tendency for misfolding in the endoplasmatic reticulum, which might have implications for pathogenesis (Colbert, 2004). It is suggested that the misfolding is a particular feature of the HLA-B27 molecule: e.g., newly synthesized HLA-B\*2705 seems to fold and associate with β2-microglobulin more slowly compared with other MHC class I molecules. Moreover, Mear et al. (1999) observed that HLA-B\*2705 in cell lines showed a fraction of heavy chains undergoing degradation within the endoplasmic reticulum. These render the cells susceptible to the unfolded protein response, which is associated with the upregulation of IL-23, the main stabilizing factor for IL-17-producing T cells. The IL-23/IL-17 axis is intriguing because IL-23 receptor polymorphisms have been shown to be associated with SpA, psoriasis, and Crohn’s disease (Wellcome Trust Case-Control Consortium and Australo-Anglo-American Spondyloarthritis Consortium, 2007). Hence, the HLA-B27 misfolding and unfolded protein response hypothesis postulates a role for CD4+ T and NK cells in the pathogenesis of AS and other SpA. This hypothesis is also supported by the fact that disease development and severity is unimpaired in HLA-B27 transgenic rats that lack functional CD8+ T cells but require CD4+ T cells (Taurog et al., 2009). Similar results have been observed in the cell-transfer and depletion experiments (Breban et al., 1996; May et al., 2003) which challenge the arthritogenic peptide hypothesis.

A third hypothesis is related to the formation of noncanonical forms of HLA class I molecules on the surface of cells. Allen et al. (1999) reported that as a consequence of HLA-B27 misfolding, free HLA-B27 heavy chains can form abnormal heavy-chain homodimers. This homodimer formation could be facilitated by unpaired free cysteine residues at position 67 (Cys67) of the HLA-B27 heavy chain, α1 helix. Using fluorescence tagged tetramers of HLA-B27\*05 homodimers, Kollnberger et al. (2002) showed that they bind to cell surfaces of the NK inhibitory receptors, KIR3DL1, and KIR3DL2, and to leukocyte immunoglobulin-like receptor (LILR) B2, which is expressed on dendritic cells, monocytes, and macrophages. In HLA-B27+ SpA patients, KIR3DL2+ NK cells and CD4+ T cells are expanded in peripheral blood, compared with HLA-B27– SpA, rheumatoid arthritis, and other control patients and NK cells of these patients show higher levels of cytotoxicity and CD4+ T cells produce IL-17 (Chan et al., 2005). It is suggested that the binding of the HLA-B27 heavy-chain homodimers to KIR and LILR could promote inflammation by enhancing survival of the NK and T cells and by influencing the differentiation of LILR-expressing antigen-presenting cells (Kollnberger and Bowness, 2009).

## The Role of Non-MHC Genes in Spondyloarthritis

Only a small proportion of HLA-B27 carriers develop AS (1%–5% in most series), which cannot be explained by HLA-B27 subtypes. As we know from independent twin studies that the heritability of the susceptibility to AS is more than 90% (Brown et al., 1997; Petersen et al., 2006), it is likely that other genes contribute to the susceptibility. Genome-wide association studies performed in the last few years have identified definite associations of AS with the non-MHC genes ERAP1 and IL-23R, and with the gene deserts 2p15 and 21q22 [Wellcome Trust Case-Control Consortium and Australo-Anglo-American Spondyloarthritis Consortium, 2007; Australo-Anglo-American Spondyloarthritis Consortium (TASC), 2010; Australo-Anglo-American Spondyloarthritis Consortium (TASC) and Wellcome Trust Case Control Consortium 2 (WTCCC2), 2011]. Furthermore, a strong evidence to

support the association with AS has been demonstrated for the genes *IL-1R2*, *ANTXR2*, *TNFSF15*, *TNFR1*, and *STAT3* and a region on chromosome 16q including the gene *TRADD* (Wellcome Trust Case-Control Consortium and Australo-Anglo-American Spondyloarthritis Consortium, 2007; TASC, 2010; TASC and WTCCC2, 2011; Pointon et al., 2010; Zinovieva et al., 2009; Danoy et al., 2009).

The *ERAP1* gene encodes the enzyme endoplasmic reticulum aminopeptidase 1, which is involved in trimming of the peptides in the endoplasmic reticulum prior to HLA class I presentation and it may be involved in the trimming of cytokine receptors as well. The ERAP1 polymorphisms only affect the AS risk in HLA-B27 + individuals (Wellcome Trust Case-Control Consortium and Australo-Anglo-American Spondyloarthritis Consortium, 2007; TASC, 2010; TASC and WTCCC2, 2011) and the majority of evidences suggest that ERAP1 variants reducing aminopeptidase activity are associated with protection from AS (Tran and Colbert, 2015). This may suggest that HLA-B27 operates through a mechanism involving aberrant processing of antigenic peptides; however, it was also shown that ERAP1 polymorphisms may also modulate accumulation of HLA-B27 homodimers on the cell surface (Chen et al., 2015).

The protective association of the nonsynonymous single nucleotide polymorphism (Arg381Gln; rs11209026) in the *IL-23R* gene with AS was confirmed in several studies and *IL-23R* rs11209026 was also found to be associated with IBD and psoriasis (Wellcome Trust Case-Control Consortium and Australo-Anglo-American Spondyloarthritis Consortium, 2007; TASC, 2010). IL-23 signaling plays an important role in sustaining Th17 cell responses in vivo. The 381Q (Arg381Gln) variant results in reduced phosphorylation of STAT3, a downstream signaling molecule of the *IL-23R*, in response to IL-23 in T cells (Pidasheva et al., 2011). Also, STAT3 itself was found to be associated with Crohn's disease and also has suggestive association with AS (Barrett et al., 2008; Danoy et al., 2009). Thus the genetic association of *IL-23R* and *STAT3* with AS definitively suggests impact of the IL-23–Th17 axis in the pathogenesis of AS.

The association of the gene deserts 2p15 and 21q22 with AS was identified and confirmed by the TASC (2010) genome-wide association study. Gene deserts are lengthy regions without known genes. Therefore, these regions might contain regulatory elements, yet unidentified genes, or regions which are involved in epigenetic gene regulation.

Apart from these confirmed genetic associations, several other genes, such as *ANTXR2*, *IL-1R2*, *TNFSF15*, *TNFR1*, and *TRADD*, show suggestive association with AS (TASC, 2010; Pointon et al., 2010).

In earlier studies, two promoter polymorphisms of the *TNF $\alpha$*  gene at positions -308 (308.1 and 308.2) and -238 (238.1 and 238.2) have been investigated in AS. The 308.2 genotype was found significantly less frequently in AS than in controls. In some studies, the 308.2 genotype was associated with higher transcriptional activity (Hoehler et al., 1998). Thus there is some evidence that *TNF $\alpha$*  genotypes that may be associated with a low *TNF $\alpha$*  production are present in a higher percentage in patients with ReA or AS.

Also in earlier studies, which investigated the association of *TNF $\alpha$*  microsatellites, an association of ReA with a *TNF $\alpha$ 6*-allele has been described; this allele has previously been associated with a low *TNF $\alpha$*  secretion. Since, in this study from Finland, *TNF $\alpha$ 6* was also associated with HLA-B27, the association of *TNF $\alpha$ 6* with ReA was thought to be secondary to B27.

In another study analyzing *IL-10* gene polymorphism in ReA, a significant decrease in the promoter alleles G12 and G10 was found in the ReA group compared with HLA-B27 + controls, indicating that these alleles might have a protective effect against the occurrence of ReA (Kaluza et al., 2001). Although it is not yet clear whether these alleles are associated with a higher production of *IL-10*, these data suggest that the relative increase of *IL-10* found in ReA might be, at least partially, genetically determined.

## ANIMAL MODELS WITH POSSIBLE RELEVANCE FOR THE PATHOGENESIS OF SPONDYLOARTHRITIS

The most important animal model of SpA is certainly the HLA-B27 transgenic rat model (Taurog et al., 2009). In the early 1990s, several lines of HLA-B27/human  $\beta$ 2-microglobulin transgenic rats were established. The rats developed a spontaneous inflammatory disease, resembling several features of the human disease, such as peripheral arthritis, spondylitis, colitis, psoriasisiform skin and nail disease. Interestingly, the copy number of both transgenes has impact on the development of the disease. Low copy number of HLA-B27 and high transgenic expression of the human  $\beta$ 2-microglobulin resulted in a phenotype most reminiscent of AS characterized by

extensive spondylitis, with formation of syndesmophytes, sacroiliitis and peripheral arthritis, and dactylitis (Tran et al., 2006). Housing of HLA-B27 transgenic rats in germ-free isolators indicated that the regular microbiota from the gut is required for the disease induction (Taurog et al., 2009). Cell-transfer and depletion experiments clarified that the expression of the transgene on immune cells, that is, bone marrow derived hematopoietic cells rather than on mesenchymal cells matters for disease development (Taurog et al., 2009). Moreover, CD8+ T cells are not required for disease development as shown by genetic deletion of CD8+ T cells (Taurog et al., 2009). A recent study has analyzed the histopathological changes at inflamed axial sites (van Duivenvoorde et al., 2012). The authors found that spondylitis in B27/h $\beta$ (2) transgenic rats is characterized by inflammation in the connective tissue adjacent to the junction of the annulus fibrosus and vertebral bone but not by inflammation at the enthesis or by osteitis. Osteitis was found only at joints with severe inflammation where osteoclasts eroded the bone outside the cartilage end plate. Osteoproliferation was present in sections with moderate to severe inflammation and occurred at the border of inflammation, at a distance from bone destruction, which is different to what is observed in human SpA, in which osteophytes grow from the corner of the vertebral body.

Several other animal models reproduce some of the characteristic features of SpA in the absence of human HLA-B27, as recently reviewed (Vieira-Sousa et al., 2015). For instance, aging male DBA/1 mice develop spontaneous dactylitis and enthesial inflammation followed by endochondral bone formation. Manipulating the expression of cytokines, whose putative impact in AS is supported by genetic association of the gene itself or its receptors, has shed some light into the impact of these cytokines in SpA. Human TNF-transgenic mice develop a destructive polyarticular polyarthritis and sacroiliitis but lack spinal involvement. TNF $^{\Delta\text{ARE}}$  carry a 69-bp deletion of the TNF AU-rich elements (ARE), which leads to a steady-state increase in murine TNF mRNA and thereby to an overexpression of the murine TNF protein. TNF $^{\Delta\text{ARE}}$  mice also develop a spontaneous chronic peripheral arthritis as well as signs of sacroiliitis. Additionally, these mice also develop bowel inflammation, which precedes the development of joint inflammation. A third model exploring the effect of TNF is the tmTNF-transgenic mouse model. In this model, mice carry a mutant TNF gene where the cleavage site for TNF-converting enzyme-like protease is deleted, thus preventing enzymatic cleavage and generation of the soluble form of TNF. In these mice, arthritis is less severe than in the other TNF-overexpressing models, but mice also develop spondylitis. Moreover, tmTNF-transgenic mice do not show systemic inflammation.

IL-23 has attained attention through the identification of several susceptibility loci in the IL-23/IL-17 pathway associated with AS (Wellcome Trust Case-Control Consortium and Australo-Anglo-American Spondyloarthritis Consortium, 2007; TASC, 2010). In a model using hydrodynamic injection of minicircle DNA constructs encoding IL23p19, which leads to high and sustained overexpression of IL-23, Sherlock et al. (2012) reported severe paw swelling as early as 5 days after IL-23mc injection. Swelling was rather related to enthesial inflammation than to synovitis and retinoic acid receptor related orphan nuclear receptor  $\gamma$ T (ROR $\gamma$ T) + CD3 + CD4 – CD8 – enthesial resident lymphocytes were identified as the IL-23-responsive cell type.

The Curdlan-induced SKG mouse model displays features of RA as well SpA. In SKG mice, carrying the ZAP-70 W163C mutation, signaling downstream of the TCR is affected. These mice develop spontaneous autoimmune arthritis characterized by rheumatoid factor and anti-type II collagen. When these mice are immunized with the fungal component Curdlan, these develop dactylitis, deformities of the tail, and a hunched back apart from arthritis (Vieira-Sousa et al., 2015). Furthermore, mice developed ileitis, unilateral uveitis, and some dermal inflammation.

In summary, there are several valuable animal models for studying pathogenesis of SpA. However, the exact features, in particular of axial disease, are difficult to model. Upright walking of man certainly generates a distinctive biomechanical loading that might contribute to the specific occurrence of osteitis, which most of the models lack.

## TREATMENT

In the last few decades, only nonsteroidal antiinflammatory drugs (NSAIDs) were used, together with physiotherapy, as an effective mode of treatment. Rather surprisingly, disease modifying antirheumatic drugs and corticosteroids, which are highly effective in other chronic inflammatory diseases, such as rheumatoid arthritis, show only an effect in patients with predominant peripheral arthritis. On this background, the finding that the blockers of TNF are highly effective, both for patients with nr-axial SpA and AS (Sieper and Poddubnyy, 2016) means a breakthrough in the treatment of this disease (Braun and Sieper, 2004; van der Heijde et al., 2005; Inman et al., 2008). At least 50% of the active AS patients refractory to treatment with NSAIDs show a 50% or more

improvement when treated either with the monoclonal anti-TNF $\alpha$  antibody infliximab (Braun et al., 2003; van der Heijde et al., 2005) or the soluble TNF-receptor construct etanercept (Davis et al., 2003). Most recently, a similar level of response was also reported for the anti-IL-17 inhibitor secukinumab in patients with AS (Baeten et al., 2015). The relative role of the TNF-blockers and IL-17 inhibitors in the treatment of axial SpA is yet to be determined in the near future. Furthermore, whether other targeted therapies, for example, JAK inhibitors that had been proven to be effective in other chronic inflammatory diseases, are also effective in axial SpA, has to be investigated further.

## DEFINING AUTOIMMUNE MYOPATHIES

The autoimmune myopathies are an uncommon group of disorders, unified by autoimmune damage of skeletal muscle (Mammen, 2011). The process may occur as a distinct named disease [e.g., polymyositis (PM), dermatomyositis (DM), immune-mediated necrotizing myopathy (IMNM)], or as a feature of other systemic autoimmune diseases (e.g., systemic lupus erythematosus or scleroderma). While skeletal muscle is a primary target in the autoimmune myopathies, there are frequently other tissues that may also be affected, including skin (in DM), lung, cardiac muscle, and synovial joints. Although inclusion body myositis has features which might reflect autoimmunity (including autoantibodies such as cytosolic 5'-nucleotidase 1A; Larman et al., 2013), the pathology of this entity and the poor response to the types of immunosuppressive therapies which characteristically are highly effective in PM and DM suggest that this entity is distinct, and we have not considered it further in this chapter.

## CLINICAL AND PATHOLOGICAL DESCRIPTIONS OF DIFFERENT PHENOTYPES, INCLUDING IMMUNE-MEDIATED NECROTIZING MYOPATHY

Like most autoimmune rheumatic diseases, the autoimmune myopathies are quite heterogeneous in their clinical presentation. These diseases are frequently characterized by the subacute onset of painless weakness, predominantly affecting proximal muscles in a symmetrical way (Christopher-Stine et al., 2012; Miller, 2012; Robinson and Reed, 2011). In some cases, there may be an involvement of striated muscle of the nasopharynx and upper esophagus, with nasal regurgitation, weakness of phonation, tendency to aspiration, and difficulty in swallowing. In severe cases, the weakness of the respiratory muscles can occur, but this is infrequent. Muscle involvement is characterized by the leaking of various muscle enzymes, including creatine kinase (CK), aspartyl, and alaninyl transaminases, which are often incorrectly interpreted as arising from liver, as well as aldolase A. In addition, the inflammatory myopathies are characterized by an irritable myopathy on electromyography (EMG).

The involvement of tissues other than skeletal muscle is also frequent and may be accompanied by systemic inflammatory symptoms (malaise, fever). Skin involvement is a prominent feature in DM, with the pattern and type of skin involvement often being diagnostic features. Typical skin manifestations include (1) the characteristic heliotrope rash on the face around the eyelids; (2) Gottron's papules, inflammatory scaly papules limited to the dorsal aspect of the metacarpophalangeal and proximal interphalangeal joints; (3) a violaceous eruption involving the shawl area, the chest, the flanks, and the thighs; and (4) skin ulcers and palmar papules, which occur in a distinct subpopulation of patients with DM (Chaisson et al., 2012). Importantly, the small joints of the hands may be affected by a rheumatoid arthritis-like inflammatory synovitis; this is particularly evident in patients with the dermatopulmonary syndromes described below. Involvement of the lung is not infrequent in patients with autoimmune myopathies, with an estimated 20%–65% of patients having evidence of interstitial lung disease (ILD) (Labirua and Lundberg, 2010; Danoff and Casciola-Rosen, 2011). Johnson et al. (2016) recently assessed mortality in autoimmune myositis patients with and without associated ILD and found significantly higher mortality rates in the former, underscoring the importance of lung disease in myositis.

A distinct form of IMNM associated with an exposure to statins has recently been described (Christopher-Stine et al., 2010; Mammen et al., 2011). While statins are frequently associated with myalgias, which can sometimes necessitate the cessation of the drug, muscle pathology is generally self-limiting, and stopping the drug results in a complete resolution of the muscle process. A distinct subtype of this process presents with features of a severe autoimmune myopathy in the setting of statin exposure, where resolution does not follow a cessation of statin therapy. Patients with this statin-induced IMNM have proximal muscle weakness, very high serum CK levels, irritable changes on EMG, and a prominent necrotizing myopathy on biopsy (Grable-Esposito et al., 2010; Christopher-Stine et al., 2010; Mammen et al., 2011). Recent data from an exploratory case-control study showed that statin-exposed patients with anti-3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR) antibodies have severe skeletal muscle manifestations and that atorvastatin and type 2 diabetes mellitus may be associated with an increased risk of developing this myopathy (Basharat et al., 2016).

## CHARACTERISTIC PATHOLOGY, BUT SIGNIFICANT OVERLAP BETWEEN PHENOTYPES

Distinct pathological hallmarks of the different immune-mediated myopathies have been described. While PM is characterized by intrafascicular inflammation and regeneration (with evidence of lymphocytes surrounding morphologically normal muscle cells), the classic pattern of DM shows perifascicular atrophy and regeneration, associated with striking perivascular inflammation. In contrast, there is only a limited inflammatory infiltrate in IMNM. Although necrotic muscle cells are found in both PM and DM, they are highly enriched in IMNM. There is an increasing appreciation that the pathological pattern in any specific patient is often less distinct, with features of the different entities present in mixed combinations (Pestronk, 2011). Pinal-Fernandez et al. (2015) recently investigated the association between autoantibody status and muscle pathology in DM patients; their study showed that different histopathologic features in DM muscle biopsies varied according to autoantibody status.

It is noteworthy that biopsies reflect a single moment in time, capturing a highly dynamic and integrated homeostatic system. In the case of the autoimmune myopathies, this system includes normal, damaged and repairing muscle cells, and various inflammatory cell subsets. Prominent among the infiltrating cells are cytotoxic lymphocytes and cells of the monocyte–macrophage and dendritic cell lineages. These different cells are not

isolated but rather are components of a highly interactive and reinforcing system. Indeed, the different clinical and pathological phenotypes likely represent new metastable states, reflecting a balance between pathways of damage and repair (see below).

## EPIDEMIOLOGICAL CLUES INTO MECHANISM

The epidemiology of human disease can provide important insights into underlying mechanisms. In myositis, combining epidemiological associations with the specificity of the immunological response has been particularly instructive. For example, the recent recognition that patients with IMNM associated with statin exposure (see above) have high titer autoantibodies against HMGCR has highlighted the importance of environmental exposures in initiating autoimmunity to specific, ubiquitously expressed autoantigens, while driving injury relatively focused on skeletal muscle (Christopher-Stine et al., 2010; Mammen et al., 2011).

The association of myositis and cancer has the potential to provide similar insights into pathogenesis but is significantly more complex for numerous reasons, including the presentation of cancer either before or after myositis diagnosis, as well as effects of immunosuppressive therapy. Nevertheless, the nature of this association provides an important framework for understanding pathogenesis of spontaneous disease. The initial clinical observation that myositis and cancer are associated stimulated numerous studies over the past five decades to define the nature and kinetics of this association (Sigurgeirsson et al., 1992). Although the strength of the association of cancer with DM is higher than that with PM, there is now definitive evidence that cancer is associated with both phenotypes (Hill et al., 2001). Interestingly, the overall risk and frequency, as well as the types of cancers associated with myositis, differ between PM and DM. In one large study, cancer was found in 32% of DM patients, but in 15% of PM patients (Hill et al., 2001). Overall, the elevated risk of cancer in DM has been noted in various studies to be 3–6-fold over controls for DM but increased only 1.3–2.0-fold in PM (Hill et al., 2001; Buchbinder et al., 2001; Chow et al., 1995; Stockton et al., 2001). In DM the highest risk was observed for adenocarcinomas, although any tumor type could be associated (Hill et al., 2001). The most frequent cancers associated with DM include ovarian, lung, prostate, pancreatic, stomach, and colorectal cancers. Non-Hodgkin's lymphomas are also enriched in DM. PM has been associated with an increased risk of non-Hodgkin's lymphoma, lung, and bladder cancers.

Multiple studies have demonstrated a striking temporal clustering of cancer and myositis in both phenotypes, with most cancers occurring within  $\pm 2$  years of the myositis diagnosis. Indeed, standardized incidence ratios (SIRs) appear highest in the first year after the diagnosis of myositis and decrease thereafter (Stockton et al., 2001). This temporal clustering would not be expected to occur if the cancers are the result of immunosuppression, suggesting that cancer and autoimmunity might be mechanistically related (see below). Although the incidence of cancer is increased in patients with myositis, it is noteworthy that 70%–85% of DM and PM patients never develop a cancer. Possible reasons for a cancer association in only a minority of myositis patients are discussed below.

An emerging area of research that likely will further illuminate the mechanistic link between cancer and autoimmunity comes from the emergence of autoimmune syndromes following the use of checkpoint inhibitors in cancer patients. A recent retrospective study by Touat et al. (2018) described 10 patients with metastatic cancer who developed a form of inflammatory myositis during immune checkpoint inhibitor therapy, mostly within 2 months of treatment initiation, with a rapid progression of symptom severity. The similarity of the clinical features—likely a new clinical entity—among these patients was noteworthy; these included elevated CK levels, the presence of multifocal necrotic myofibers in muscle biopsies, and the absence of myositis-specific antibodies. After immune checkpoint inhibitor cessation and treatment with corticosteroids, these patients experienced significant clinical improvement. It is presently unknown if these patients express a distinct autoimmune response not previously described. Further studies are warranted to identify those cancer patients at high risk of experiencing an adverse event after treatment with immune checkpoint inhibitors, and to understand the mechanistic underpinnings that link adverse events and cancer control/elimination.

## SPECIFIC AUTOANTIBODIES ARE STRONGLY ASSOCIATED WITH PHENOTYPE, MAKING THEM USEFUL PROBES OF DISEASE MECHANISM

While the clinical damage in autoimmune myopathies is focused on skeletal muscle and related tissues, the well-described targets of the immune response in these diseases are all notably not muscle specific

(Suber et al., 2008; Casciola-Rosen and Mammen, 2012). Rather, they are expressed ubiquitously, raising questions about the mechanisms of the tissue-specific focus of the immune response.

Several recent studies provide tantalizing evidence that there may be additional important autoantibodies against muscle-specific proteins in myositis patients. New data emerging from screens performed using myositis patient sera and a muscle complementary DNA library describes anti-four and a half LIM domains protein (FHL1) as an autoantigen in 25% of patients in this disease spectrum (Albrecht et al., 2015). What distinguishes FHL1 from the other defined myositis autoantigens is that it is a muscle-specific protein. The authors noted patchy FHL1 expression in muscle tissue from anti-FHL1-positive patients, which differed from the homogeneous expression observed in antibody-negative myositis patients and healthy controls. In another study, Cottrell et al. (2012) used cultured differentiating muscle cells as an antigen source to screen for myositis autoantibodies. They found a new 28 kDa specificity that was muscle specific and differentiation stage specific (i.e., absent in myoblasts, with peak expression at day 4 of differentiation, coincident with myogenin expression). The authors subsequently identified this as embryonic myosin light chain 4 (MYL4) using a mass spec approach (Cottrell et al., 2012). Additional studies for both FHL1 and MYL4 antibodies will be needed to define and validate these tantalizing new specificities in other myositis cohorts. Targeting of tissue-specific—and, more importantly—differentiation-stage-specific proteins are likely to be highly relevant in amplifying and sustaining injury in myositis and other autoimmune rheumatic diseases.

Among the well-defined myositis autoantigens, there is a striking association of specific autoantibodies with distinct clinical phenotypes, suggesting that the targeting of specific molecules by the immune system might either (1) participate in generating the unique phenotype or (2) that the specific immune response is stimulated by a unique series of tissue events which make that specific antigen available to drive the immune response.

A key fact remains unknown regarding the kinetics of autoimmune myopathy evolution: does the immune response to myositis-specific autoantigens precede or coincide with the onset of clinical symptoms? For most autoimmune diseases where this has been studied (e.g., systemic lupus erythematosus, rheumatoid arthritis, and type I diabetes mellitus), evidence of autoimmunity precedes clinical symptoms by several years (Arbuckle et al., 2003; Nielsen et al., 2004; van der Helm-van Mil et al., 2005; Majka et al., 2008; Baekkeskov et al., 1984; Eisenbarth, 2003). For the autoimmune myopathies, no systematic data are yet available, but there have been cases where autoantibodies to histidyl-tRNA synthetase preceded clinical myositis (Miller et al., 1990), suggesting that the generation of the immune response may precede the establishment of the clinical phenotype.

## Myositis-Specific Autoantibodies

The autoantibodies elaborated in patients with myositis recognize a family of autoantigens which have important, conserved functions in general cellular processes. Prominent among these functions are protein translation [e.g., aminoacyl-tRNA synthetases, signal recognition particle (Mathews and Bernstein, 1983; Reeves et al., 1986)], gene expression [e.g., components of the nucleosome remodeling and deacetylation complex (Targoff and Reichlin, 1985)], DNA repair machinery [e.g., double-strand break and mismatch repair machinery (Suwa et al., 1996; Casciola-Rosen et al., 1995, 2001)], posttranslational modification [e.g., small ubiquitin-like modifier-activating enzyme subunit 1 (Okuma et al., 1999)], nuclear body formation [e.g., nuclear matrix protein NXP2 (Mimura et al., 2010)], and the exosome complex. In addition, several autoantigens (e.g., Ro52 and MDA5) are induced by interferons (Rhodes et al., 2002; Sato et al., 2009).

Autoantibodies in myositis have a striking association with phenotype (see Table 37.1). For example, antibodies recognizing aminoacyl-tRNA synthetases are frequently associated with the “synthetase syndrome,” a clinical syndrome with relatively mild myositis, Raynaud’s phenomenon, inflammatory arthritis of the small joints of the hands, mechanic’s hands, and ILD of variable severity (Friedman et al., 1996). Antibodies to the signal recognition particle are associated with a particularly severe form of necrotizing myopathy, with cardiac involvement. While antibodies to Mi-2 tend to be associated with the characteristic DM skin rash (including heliotrope and truncal rash), antibodies to MDA5 have been associated with a distinct dermatopulmonary syndrome, with mild or no myositis, mild-to-severe ILD, as well as unique dermatological features (including gum pain, palmar papules, and ulceration) (Fiorentino et al., 2011; Chaisson et al., 2012). Numerous additional phenotypic features associated with the different antibodies have been described; these are summarized in several excellent recent reviews (Fujimoto et al., 2016; Satoh et al., 2017; Betteridge and McHugh, 2016; Gunawardena, 2017).

An interesting feature of many of the autoantigens targeted in myositis is their striking susceptibility to cleavage by the cytotoxic lymphocyte granule protease, granzyme B (GrB) (Casciola-Rosen et al., 1999). While GrB is a

**TABLE 37.1** Association of Myositis-Specific Autoantibodies With Disease Subsets

Autoantibody	Disease subset
Antisynthetases (anti-Jo-1, PL-7, PL-12, EJ, OJ, KS, Ha, Zo)	Antisynthetase syndrome with polymyositis or dermatomyositis
Anti-Mi-2	Dermatomyositis
Antimelanoma differentiation-associated protein (anti-MDA5, anti-CADM140)	
Antitranscription intermediary factor 1 $\gamma$ (anti-p155)	
Antinuclear matrix protein 2 (anti-NXP2, anti-MJ)	
Anti-SAE1	
Anti-SRP	Necrotizing myopathy
Anti-3-hydroxy-3-methylglutaryl coenzyme A (anti-HMGCR)	

fastidious protease which cleaves a minority of proteins across the proteome, it efficiently cleaves the majority of myositis autoantigens. This unusual enrichment of GrB substrates among myositis autoantigens, together with the demonstrated activity of cytotoxic cells against muscle cells in myositis patients, possibly identifies an important amplification loop in this group of diseases (see below).

New studies suggest that the autoantibodies found in myositis patients with cancer may be distinct from those found in patients where cancer does not appear. Thus, recent studies suggest that antibodies to TIF1 $\gamma$  (TRIM33) may be enriched in DM patients with cancer, while cancer is very uncommon in patients with antibodies against Mi-2 or aminoacyl-tRNA synthetases (Fujimoto et al., 2012; Hoshino et al., 2010; Trallero-Araguas et al., 2012).

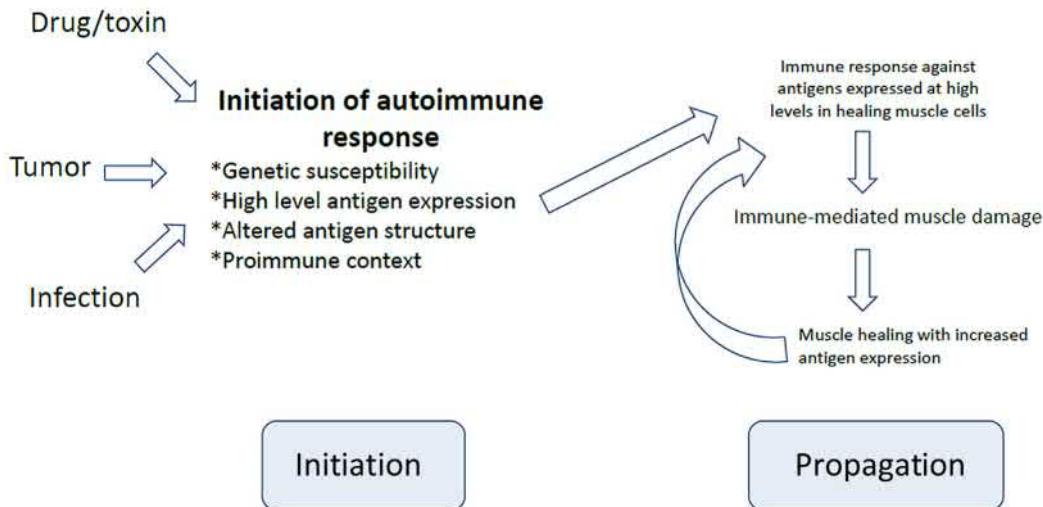

Since the majority of myositis autoantigens function in pathways of general relevance to cellular function and homeostasis, it has been reasonable to assume that these autoantigens are ubiquitously expressed. This remains true, with the noteworthy exceptions of the two muscle-specific autoantigens described to date (discussed above). Experiments to directly address the expression of ubiquitous autoantigens in normal and affected target tissues have shown that myositis autoantigens are expressed at very low levels in normal muscle but are robustly expressed in myositis muscle, with the highest levels of autoantigen expression being found in regenerating muscle cells (Casciola-Rosen et al., 2005). This restriction of high level autoantigen expression to cells repairing muscle injury strongly suggests that normal muscle is unlikely to be the source of antigen to initiate and drive autoimmunity to these molecules in myositis and focuses attention on other antigen sources (including cancer and repairing muscle cells) as more relevant in this regard (see Fig. 37.1 and text below). Consistent with this, aldolase A expression in the absence of CK in undifferentiated muscle cells (and those early in the differentiation process) may reflect preferential immune-mediated damage of early regenerating cells and may explain the occurrence of elevated serum aldolase A in the absence of CK in a subset of myositis patients (Casciola-Rosen et al., 2012).

Important insights have emerged from studies addressing myositis autoantigen expression in normal tissues and the relevant myositis-associated cancers. These demonstrated that myositis autoantigen expression in normal tissues is very low but is elevated in multiple malignancies, including lung and breast (Casciola-Rosen et al., 2005). It is possible that high level autoantigen expression in the tumor can induce an immune response which cross-reacts with muscle cells. In patients with a malignancy, this reflects an effective anticancer response, or perhaps selection of this immune target via distinct mechanisms.

### 3-Hydroxy-3-methylglutaryl Coenzyme A Reductase Autoantibodies in Statin-Associated Immune-Mediated Necrotizing Myopathy

Statin treatment is very frequent in the population, with an estimated 25 million users worldwide. Muscle-related complications related to statin therapy are widely recognized, with a spectrum from self-limited myalgias to statin-associated rhabdomyolysis (Bruckert et al., 2005; Franc et al., 2003; Graham et al., 2004). The vast majority of these cases resolve fully after stopping the statin. However, in a small group of patients, statin exposure appears to induce a self-sustaining, immune-mediated myopathy that persists despite statin discontinuation. In a recent series of studies, a novel autoantibody specificity recognizing an autoantigen migrating as a doublet of

## Autoimmunity in myositis—a simplified model

**FIGURE 37.1** The role of autoimmunity in myositis. Myositis arises when an immune response against myositis-specific autoantigens is initiated. The initiation phase may be separated spatially and temporally from propagation events, which are focused on muscle. In the absence of a stimulus inducing muscle injury and repair, it is possible that the autoimmune response may remain silent. In the case of cancer-associated myositis, it is possible that an unrelated muscle injury is the second hit which focuses the anticancer immune response onto repairing muscle and propagates the injury there. In statin-induced necrotizing myopathy, the site of immunization with HMGCR may be muscle. The autoantigens targeted are characterized by their shared expression patterns in immunizing tissue and regenerating muscle, and by their susceptibility to modification by immune effector pathways.

100k/200k bands was defined in a group of immunosuppression-responsive patients with a necrotizing myopathy and very high CK levels ([Christopher-Stine et al., 2010](#)).

Interestingly, the majority of patients in that study were statin-exposed. Since the target of statins is a 100 kDa protein called HMGCR, the key enzyme in the de novo cholesterol synthesis pathway, the association with statin exposure provided an important clue for identifying the autoantigen targeted in this syndrome. While HMGCR levels are low in most cells, they are dramatically upregulated by statin exposure ([Goldstein and Brown, 1990](#)). Antibodies from INNM patients recognized higher levels of the 100k/200k antigen in statin-treated cells, leading Mammen et al. to demonstrate that the intracellular C-terminal domain containing the HMGCR active site is indeed the target of these autoantibodies ([Mammen et al., 2011; Christopher-Stine et al., 2010](#)).

As has been noted with other myositis autoantigens, a high level expression of HMGCR was detected in regenerating muscle cells in biopsies of patients with HMGCR antibodies ([Mammen et al., 2011; Casciola-Rosen et al., 2005](#)). This suggests that ongoing immune effector pathways are focused onto cells attempting to repair muscle injury, thereby creating a feedforward cycle of damage and repair ([Casciola-Rosen et al., 2005](#)). The patients with HMGCR antibodies did not have the genetic polymorphism in the anion transporter frequently associated with statin myopathy, suggesting a novel mechanism underlying the targeting of this molecule in this patient subgroup. Since the majority of patients exposed to statins do not generate immune responses to HMGCR ([Mammen et al., 2012b](#)), [Mammen et al. \(2012a\)](#) examined whether there might be any major histocompatibility complex (MHC) associations with the HMGCR subgroup and showed a striking association of HMGCR antibodies with human leukocyte antigen (HLA) class II DRB1\*11:01. This magnitude of this association is one of the largest ones described to date, suggesting that the immune response to HMGCR might be restricted by this HLA molecule and that patients with this HLA molecule might be particularly susceptible to this syndrome.

[Tiniakou et al. \(2017\)](#) recently studied disease severity and response to therapy in a large cohort of anti-HMGCR antibody-positive myositis patients. In this subgroup, they found that younger patients had more severe disease and a worse prognosis than those who were older. Interestingly, this persistent muscle weakness could not be explained by coexisting muscular dystrophy since this was not detected in these patients. In another study

from this group, the severity of weakness in IMNM patients with anti-HMGCR or antisignal recognition particle antibodies was compared (Pinal-Fernandez et al., 2017). Overall, patients with the latter specificity were significantly weaker than anti-HMGCR-positive patients ( $P = .001$ ), indicating that these antibodies are likely associated with distinct forms of IMNM.

## MECHANISMS OF DISEASE

Autoimmune myopathies represent a chronic, self-sustaining process, characterized by inflammation, muscle damage, and muscle repair. While the mechanisms of disease are likely heterogeneous in different individuals, with distinct pathways playing different relative roles in different patients, recent data enables the proposal of a unifying model which incorporates the essential features of the disease spectrum described above. This model will include the following components: (1) the important association of malignancy with myositis as a potential initiating force; (2) the enhanced expression of myositis autoantigens in regenerating muscle cells to focus propagation on muscle; and (3) the modification of autoantigen expression or structure by immune effector pathways to generate a self-sustaining phenotype. Each of these components is discussed in detail below (see Fig. 37.1).

### The Association of Malignancy With Autoimmunity: Insights Into Disease Initiation

In 10%–20% of myositis patients who also have cancer, the two processes cluster together temporally (Chow et al., 1995; Hill et al., 2001). This kinetic clustering suggests strongly that the two processes are mechanistically related. Recent studies at this interface have been especially informative in the scleroderma disease spectrum; the emerging principles (reviewed below) are highly applicable to the myositis–cancer interface.

Shah et al. (2010) investigated whether autoantibodies could define subsets of patients with scleroderma who might have an associated cancer. This study showed an unexpectedly close temporal relationship between disease onset and malignancy detection in patients with RNA polymerase III antibodies. These authors and other collaborators (Joseph et al., 2014) subsequently sequenced tumors from 16 scleroderma patients, 8 with anti-RNA polymerase III antibodies, and 8 with other scleroderma antibody specificities. They found genetic alterations in the *POLR3A* gene locus in 6/8 cancers for the anti-RNA polymerase III-positive patients, but not in tumors from the scleroderma patients with other antibody specificities. Since *POLR3A* gene mutations are very rare in cancer, it is conceivable that they play a role in initiating the immune response when presented to the immune system in the context of the appropriate MHC (see below for further details in the context of myositis; also reviewed in Shah et al., 2015). Interestingly, ~85% of patients with scleroderma and anti-RNA polymerase III antibodies do not manifest a cancer. In these patients, it is possible that a potent antitumor immune response successfully eradicates malignancy.

Similar tantalizing connections between myositis autoantibodies and cancer susceptibility have been made (Fiorentino et al., 2013). Fiorentino et al. demonstrated a higher prevalence of cancers within 3 years of myositis diagnosis in myositis patients with antibodies against TIF1 $\gamma$  or NXP2. Interestingly, even in patients with these antibodies, ~80% did not manifest any cancer—consistent with the anti-RNA polymerase III antibody findings in scleroderma. Given these observations, and in the context of the recent cancer scleroderma findings, it is reasonable to assume that similar principles operate at the cancer–myositis interface.

A likely model for myositis initiation would be as follows. Mutations in myositis-specific autoantigens (TIF1 $\gamma$  and NXP2 are attractive candidates) in cancers initiate an autoimmune response. The initial mutation-specific immune response spreads to the wild-type protein. In turn, this induces tissue damage, notably focused on tissues in which there is a prominent expression of the autoantigen. For example, regenerating cells would be prominent targets in muscle. In some patients, the immune response is robust enough to challenge the cancer, effectively maintaining it in equilibrium or eliminating it. Myositis in the absence of cancer would manifest in this scenario. In others, the cancer might escape from this immune response through genetic changes such as loss of heterozygosity; in this subset of myositis patients, cancer emerges.

Further studies to define the critical immune effector pathways will be insightful for understanding the observed damage and dysfunction of normal tissue. Therapies that effectively kill cancers may eliminate the driving immune stimulus in affected individuals. In turn, this might enable the peripheral immune-mediated damage to resolve. Such approaches highlight the immune response in autoimmune diseases as a positive force.

The regulation of antigen expression in the target tissue(s) may allow beneficial anticancer effects of the immune system to focus exclusively on the cancer, thus avoiding damage to self-tissues.

That cancer can both precede and follow the diagnosis of myositis is important, as it reinforces that cancer is not emerging exclusively due to immunosuppressive therapy once myositis is diagnosed. The short interval separating the two diagnoses, and the occurrence of cancers in tissues often unaffected in myositis, also makes it unlikely that the inflammatory microenvironment enhances transformation and cancer growth. The available data is consistent with a mechanism in which shared antigen expression patterns in cancers and regenerating muscle cells may explain numerous features of the disease, including the kinetics noted above. In this model, natural anticancer immunity (including CD4 T cell and cytotoxic lymphocyte responses) develops in response to an incipient cancer.

### Enhanced Expression of Myositis Autoantigens in Regenerating Muscle Cells to Focus Propagation on Muscle

The evidence showing that myositis antigens are expressed at high levels in cancers and also in myositis tissue, where robust expression is noted in regenerating muscle cells, suggests a possible mechanism whereby an initial anticancer immune response targeting one of the myositis autoantigens becomes secondarily focused on injured muscle, thus beginning the propagation of a self-sustaining cycle at that site (Casciola-Rosen et al., 2005). The reasons for the unusual restriction of immune responses in myositis to such a limited group of antigens remain uncertain but may reflect the ability of only a very limited group of molecules to participate in a feedforward cycle (due to the need to both respond to and stimulate additional immune response—see below). It is possible that anticancer immune responses directed even at myositis antigens might be silent, since the number of regenerating cells in unperturbed muscle is very low. Very few cells in normal muscle are therefore susceptible to immune injury focused on these “regenerating cell” antigens. In the setting of a second insult which damages muscle (strenuous exercise, drugs, viral infection), the preformed anticancer immune response could respond to antigens now expressed in regenerating muscle cells. When these cells are damaged, a self-sustaining damage-healing cycle is generated, driven by immune-mediated cytolysis and the need to continuously provide additional precursors to accomplish tissue repair. This model explains several additional features of the disease, including the patchy nature of pathology, the inexact kinetic relationships between cancer and myositis, and the antigen expression patterns.

### Modification of Autoantigen Expression or Structure by Immune Effector Pathways to Generate a Self-Sustaining Phenotype

A central feature of any feedforward loop is that the activity of one component augments the amplitude of the other, which in turn augments the first. Several immune effector pathways (discussed below) are highly represented in myositis muscle. These dramatically influence antigen expression and structure and may play important roles in driving ongoing immune responses.

Several prominent myositis autoantigens (MDA5 and Ro52) are strongly interferon-regulated, and interferon signatures are prominent in the muscle (PM and DM) and skin (DM) in myositis patients. In addition, cells with the capacity to secrete large amounts of both type I (plasmacytoid DC, pDCs) and type II interferons (activated CD8 T cells) are enriched in DM and PM muscle (Greenberg et al., 2005; Goebels et al., 1996). This capacity of effector pathways to augment antigen expression and thus create additional targets for cytolytic damage and additional interferon secretion may be important pathogenically and might be particularly amenable to therapeutic manipulation.

A second potential intersection of the immune effector and antigen arms centers on the susceptibility of most myositis autoantigens to cleavage by GrB (Casciola-Rosen et al., 1999). It is noteworthy that the expression of this protease is highly restricted to the cytolytic effector arm of the innate and adaptive immune systems (Darrah and Rosen, 2010). Furthermore, since GrB has a unique specificity among proteases, most antigens will not have been cleaved by GrB during the development of tolerance. The potential for GrB-mediated cleavage to generate fragments that have not been tolerized would provide another feedforward loop to contribute to driving myositis. In such a model, immune effector pathways generate forms of antigens not previously seen and tolerized by the immune system, thus driving the immune response, which further drives antigen generation. Multiple studies suggest that such effects are likely to be driven at the level of CD4 T cells, but this remains to be demonstrated directly.

## THERAPEUTIC INSIGHTS

The therapy of myositis currently focuses entirely on the modification of the immune side of the pathogenic cycle. Since myositis is a rare autoimmune phenotype, there is little randomized trial-derived data about the efficacy of specific agents, but clinical experience suggests efficacy with multiple immunosuppressive agents. As with all unfocused immunosuppressive strategies, the major limitations are infectious side effects. Since autoantigen expression in cells which are repairing tissue injury may be an important partner in driving the ongoing immune response and tissue damage in myositis, it is possible that focusing attention on modifying pathways of antigen expression in the target cell may be an effective strategy. If cancer is an important driver of the initial immune response, perhaps early anticancer treatment strategies might be of benefit (see above).

## CONCLUDING REMARKS

Although the autoimmune myopathies are uncommon, their interesting presentations and associations provide unique insights into the mechanisms of human autoimmunity, which are potentially of broad relevance, and may be of importance therapeutically. The highly focused immune response on a limited number of antigens which function in pathways of general relevance is of great interest. The association of myositis with cancer and the shared antigen expression patterns between cancer and regenerating muscle cells may be of importance in disease propagation. The participation of multiple interacting pathways in augmenting the amplitude of response of other partners may be critical in generating a self-sustaining feedforward loop which characterizes these diseases and may provide novel therapeutic opportunities. Of particular importance are the reinforcing interactions between immune effector pathways, antigen, and the target tissue.

## GENERAL INTRODUCTION

Immunoglobulin G4-related disease (IgG4-RD) is a multiorgan immune-mediated condition recognized only within the past 15 years to be a distinct disorder (Stone et al., 2012; Mahajan et al., 2014). The expanding knowledge of this disease has linked numerous conditions once regarded as isolated, single-organ diseases, including “Küttner’s tumor” (bilateral submandibular gland enlargement), autoimmune pancreatitis (AIP), retroperitoneal fibrosis (RPF), Riedel’s thyroiditis, and many more. Moreover, understanding the immune dysregulation

associated with IgG4-RD has provided important insights into the processes of B and T lymphocyte cross talk, the impact of B cell–directed therapies on the T-cell compartment, and fibrosis (Perugino et al., 2017).

Observations of restricted repertoires of both plasmablasts and of a particular CD4+ cytotoxic T lymphocyte (CD4+ CTL) suggest that IgG4-RD is an antigen-driven disease (Mattoo et al., 2014a; Mattoo et al., 2016). Galectin-3 has recently been identified as a candidate antigenic trigger in approximately 30% of patients with this disease in one cohort (Perugino et al., 2019). It appears likely that multiple antigens can trigger this disease, but the precise identities of other disease-associated antigens remain unknown.

## HISTORICAL ASPECTS

Although “discovered” only in the early years of this century, IgG4-RD is clearly not a new disease. Mikulicz appears to have described the first case in the medical literature in 1892, when he wrote of a 44-year-old German farmer with massive enlargements of lacrimal, parotid, and submandibular glands (Mikulicz, 1892). The disorder termed “multifocal fibrosclerosis” in the 1960s is also clearly part of the spectrum of what we now consider to be IgG4-RD (Comings et al., 1967). The concept of AIP was also formulated in the 1960s (Sarles et al., 1961). In 2001 Japanese investigators reported the relationship between “sclerosing pancreatitis” and high serum concentrations of IgG4 (Hamano et al., 2001). In 2003 other Japanese investigators recognized that the histopathological findings characteristic of sclerosing pancreatitis (i.e., type 1 AIP in the current parlance) could also be found in extrapancreatic organs such as the submandibular glands and lungs (Kamisawa et al., 2003a, b). Between 2003 and the present time, IgG4-RD was described in virtually every organ and the concept of a multiorgan inflammatory disease characterized by histopathological features consistent across all organs was established (Kamisawa et al., 2015).

## EPIDEMIOLOGY

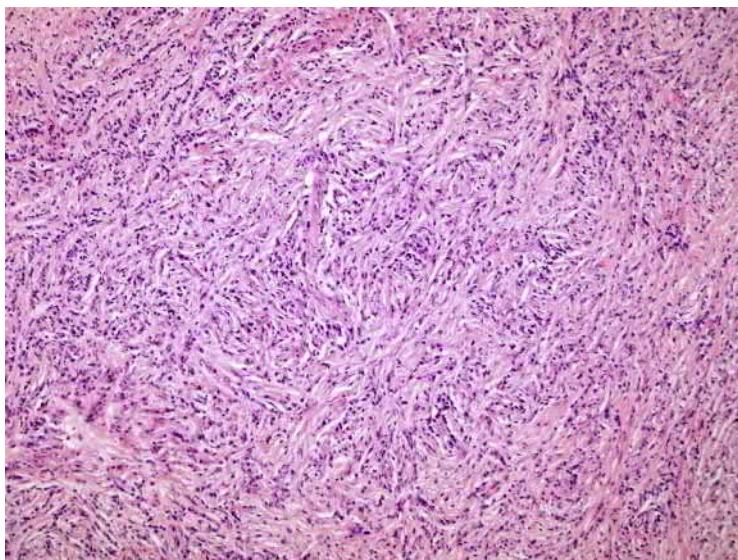

The typical patient with IgG4-RD is a middle-aged to elderly male. In AIP the mean age at diagnosis is on the order of 67 years, and the male:female ratio is approximately 3:1 (Kanno et al., 2012). When all types of IgG4-RD organ involvement are considered, however, this ratio may be closer to 3:2. Although the disease is somewhat less common in women—in contrast to the situation with classic autoimmune diseases—it does not appear to be less severe in women (Wallace et al., 2015).

IgG4-RD was recognized first in the pancreas. The overall prevalence of type 1 (IgG4-related) AIP was estimated to be 2.2 cases per 100,000 population in Japan (Kanno et al., 2012), but because the study was conducted only shortly after the first publications about the disease, this figure clearly underestimates the true prevalence of AIP. Moreover, the pancreas is only one of more than a dozen organs affected by IgG4-RD. Although likely still an orphan disease, IgG4-RD appears to be more common than autoimmune conditions such as vasculitis associated with antineutrophil cytoplasmic antibodies and systemic sclerosis. IgG4-RD has a clinical phenotype that is now increasingly recognized as the knowledge of this condition grows. This is emphasized by the recently completed 2018 Classification Criteria for IgG4-RD, a worldwide effort funded by the American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) (Wallace et al., in press) (see below). The numbers of cases recognized and reported will undoubtedly grow substantially in the near future.

## PATHOLOGY

### Histological Features

The hallmark morphologic findings of IgG4-RD include a dense lymphoplasmacytic infiltrate rich in IgG4+ plasma cells (Deshpande et al., 2012). This lymphoplasmacytic infiltrate is enmeshed by an irregularly whorled fibrotic process that is termed “storiform” fibrosis (Fig. 38.1). Obliterative phlebitis, resulting in destruction of the venous lumen, is another characteristic lesion observed in the majority of cases. Obliterative arteritis is also observed in some organs, particularly the lung. Eosinophilic infiltration occurs in approximately 50% of cases, regardless of the organ involved.

**FIGURE 38.1** Lymphoplasmacytic infiltrate with storiform fibrosis. This pancreatic tissue has a swirling pattern, characteristic of the type of fibrosis that is classic for IgG4-related disease. IgG4, Immunoglobulin G4.

### Immunostaining

The preponderance of plasma cells within tissue lesions stain for IgG4. Even in the presence of an increase in the number of IgG4+ plasma cells/high power field (hpf) and an elevated IgG4+/IgG+ plasma cell ratio, however, careful clinicopathologic correlation and sound clinical judgment must be exercised before rendering an IgG4-RD diagnosis. Neither the number of IgG4+ plasma cells per hpf nor the IgG4+/IgG+ plasma cell ratio is specific for the diagnosis of IgG4-RD.

The IgG4+/IgG+ plasma cell ratio can also be a useful metric to aid in diagnosis. Most cases of documented IgG4-RD have an IgG4+/IgG+ plasma cell ratio >40%. The IgG4+/IgG+ plasma cell ratio can be particularly helpful in the setting of advanced fibrosis (e.g., in RPF), when the paucity of cells makes large concentrations of IgG4+ plasma cells unlikely.

## PATHOPHYSIOLOGY

IgG4-RD involves antigen-driven interactions among cells of the B lymphocyte lineage (plasmablasts, activated B cells) and at least two CD4+ T lymphocytes, and CD4+ T follicular helper cells and a CD4+ CTL (Perugino et al., 2017). The CD4+ CTL is currently regarded as the linchpin of this disease. These CD4+ CTLs are clonally restricted, abundant in IgG4-RD tissues, and likely contribute to fibrosis.

At present, activated effector CD4+ CTLs have been identified as the dominant T-cell driving IgG4-RD (Mattoo et al., 2016). CD4+ CTLs often represent up to 80% of all infiltrating CD4+ T cells within tissues affected by IgG4-RD and appear to be universally present among IgG4-RD patients. These cells secrete several profibrotic cytokines, including interleukin (IL)-1 $\beta$ , transforming growth factor-beta (TGF- $\beta$ ), and interferon-gamma (IFN- $\gamma$ ). Moreover, they express perforin and granzymes, and their cytolytic capacity has been demonstrated in vitro using Epstein-Barr virus (EBV)-transformed B cells.

This CD4+ CTLs may contribute to fibrosis *in situ* by multiple mechanisms, including profibrotic cytokine secretion and via the induction of apoptosis in targeted cells. Because B-cell depleting therapy with the anti-CD20 monoclonal antibody, rituximab, leads to both profound clinical responses and to declines in CD4+ CTLs, a plausible hypothesis is that activated B cells drive the activation of CD4+ CTLs at the sites of disease through antigen presentation (Perugino et al., 2017).

SLAMF7 (Signaling Lymphocytic Activation Molecule Family), an antigen previously known to be expressed only on cells of the B lymphocyte lineage, is also found on CD4+ CTLs in IgG4-RD. SLAMF7 is one of a family of six surface receptors expressed by hematopoietic cells. Nonlymphoid cell types lack SLAMF7 expression altogether (Hsi et al., 2008). SLAM receptors act via homotypic interactions; that is, SLAMF7 on one cell binds to SLAMF7 on another. It is conceivable that such homotypic SLAMF7 interactions between infiltrating B and T cells in IgG4-RD are critical to the disease process.

The effect on the cell of binding SLAMF7 depends on the type of intracellular adaptor molecule expressed. For example, natural killer (NK) cells express Ewing's sarcoma-associated transcript 2 (EAT-2), which mediates intracellular calcium influx via phospholipase C- $\gamma$ , resulting in granule polarization, enhanced exocytosis, and NK cell activation (Pérez-Quintero et al., 2014).

## B Cells

B cells and the cells of their lineage play an important role in IgG4-RD (Mattoo et al., 2014a; Wallace et al., 2014). These cells play a variety of roles in IgG4-RD, including the production of IgG4 (albeit the centrality of IgG4 to disease pathophysiology is debated); B cells and plasmablasts are speculated to play important roles in antigen presentation to T cells. The cells making most of the serum IgG4 are short-lived plasmablasts and plasma cells. Plasmablasts are found in high concentrations in IgG4-RD, regardless of the serum IgG4 concentration (Mattoo et al., 2014a; Wallace et al., 2014). Both total plasmablasts and IgG4+ plasmablasts are useful biomarkers for disease activity in IgG4-RD.

## T Cells

CD4+ T cells are typically dispersed throughout localized IgG4-RD lesions and are the most abundant cell found within affected tissues. Next-generation sequencing studies of the effector T-cell V $\beta$  repertoire have identified a CD4+ CTL that is believed to be the linchpin of IgG4-RD. Four strong pieces of evidence support CD4+ CTLs as principal drivers of IgG4-RD. These cells (1) undergo large clonal expansions; (2) infiltrate tissues affected by the disease in large numbers; (3) actively secrete cytokines in these tissues, indicating recent antigen activation; and (4) decline with rituximab-induced disease remission (Mattoo et al., 2016; Maehara et al., 2017).

The gene signature of the CD4+ CTL found in IgG4-RD consists of both cytolytic (e.g., granzyme, granulysin, and perforin) and myeloid (e.g., IL-1 $\beta$ ) features. In addition, these cells were found to secrete two other profibrotic cytokines, TGF- $\beta$ , and IFN- $\gamma$ .

One appealing way to link the findings pertaining to both the B- and T-cell lineages is to presume that the CD4+ T cells orchestrating the disease are sustained by continuous antigen presentation by B cells. A T-follicular helper cell response that is separate from the CD4+ CTLs is likely to be responsible for the development of germinal centers within lymph nodes (and involved organs) (Maehara et al., 2018). In theory, such T-follicular helper cells could produce the cytokines (e.g., IL-4) that drive the IgG4 class-switch, culminating in the creation of IgG4-secreting plasmablasts and long-lived plasma cells. The fact that B-cell depletion does not lead to the complete normalization of serum IgG4 concentrations implies the presence of long-lived plasma cells that continue to make this immunoglobulin.

## SERUM IMMUNOGLOBULIN G4 CONCENTRATIONS

Serum IgG4 concentrations are known to increase over the professional lives of beekeepers, presumably as a guard against anaphylaxis (Aalberse et al., 2009). The same observations have been made in patients treated with desensitizing immunotherapy, following which the induction of IgG4 responses corresponds to reduced allergic symptoms. For these reasons, IgG4 has traditionally been considered a noninflammatory, perhaps antiinflammatory, and antibody, especially in conditions mediated by IgE.

Nevertheless, serum IgG4 measurements play an important role in the diagnosis and management of IgG4-RD, and there remains a possibility that IgG4 contributes to the pathophysiology of tissue injury in this disease either directly or indirectly. Patients with IgG4-RD can have elevations of all IgG subclasses, but the elevations of IgG4 are usually disproportionate to those of IgG1, -2, and -3. Patients with multiorgan disease can have dramatic elevations in serum IgG4 concentrations, occasionally exceeding 4 mg/dL.

Large elevations of serum IgG4 concentrations, for example, on the order of six to eight times, the upper limit of normal for a given assay strongly suggests the diagnosis but are not confirmatory in and of themselves.

---

## AUTOIMMUNE FEATURES

---

### Does the Immunoglobulin G4 Molecule Participate in Autoimmunity?

IgG4 normally accounts for approximately 4% of the total immunoglobulins among healthy individuals and is usually the least abundant of all of the subclasses. Despite the substantial elevations in serum IgG4 concentrations observed in most patients with IgG4-RD, IgG4 itself is unlikely to drive the pathogenesis of this disorder. IgG4 demonstrates weak binding to C1q and to Fc-gamma receptors because of a critical few amino acid differences in its CH2 domain (Bruhns et al., 2009; Vidarsson et al., 2014). The ability of IgG4 to activate the classical complement pathway and participate in antibody-dependent cell-mediated cytotoxicity is therefore substantially less than that of other IgG subclasses, for example, IgG1 (Vidarsson et al., 2014).

IgG4 also has the unique ability to form “half-antibodies” through the process of Fab-arm exchange. Fab-arm exchanges result in the formation of IgG molecules with two different binding specificities (Vidarsson et al., 2014). Amino acid variation at the hinge region of IgG4 permits the reduction of the disulfide bonds that join the two halves of an IgG4 molecule. Recombination of the dissociated arms leads to the random formation of “asymmetric antibodies” composed of half-antibody fragments directed against different antigens (Bruhns et al., 2009; Vidarsson et al., 2014). The consequence is a reduced ability to cross-link antigens and form immune complexes. IgG4 may therefore play the role of a noninflammatory “antigen sink,” the purpose of which is to “mop up” antigen through its monovalent binding in a process that tends to downregulate inflammation.

It remains possible that a “disease-causing” IgG fraction produced by a subset of antibody-secreting cells contributes to tissue injury, perhaps through immune complexes or Fc-receptor engagement. There are certain diseases, for example, pemphigus vulgaris and idiopathic membranous glomerulonephropathy, in which IgG4 antibodies themselves appear to be pathogenic. Many IgG4-RD patients have concurrent elevations in other IgG subclasses (e.g., IgG1) that are more likely than IgG4 to form immune complexes, engage Fc receptors, and incite or participate in an ongoing immune response.

### Evidence for Autoimmunity in Immunoglobulin G4-Related Disease

Single-cell-sorted plasmablasts from patients with IgG4-RD, cloned and used to express monoclonal antibodies from dominantly expanded plasmablasts, are self-reactive to eukaryotic cells (Perugini et al., 2019). The passive transfer model of purified human IgG to neonatal mice also suggests autoreactivity (Shiokawa et al., 2016). These observations provided reasonably compelling evidence that IgG4-RD might be driven by a self-antigen. More recently, one such an antigen has been identified.

#### **Galectin-3**

Antigalectin-3 autoantibodies are present in a sizeable subset of IgG4-RD patients. These autoantibodies are predominantly of the IgG4 subclass and correlate with galectin-3 levels in plasma, suggesting that overexpression of this protein leads to a breach of immune tolerance for this autoantigen. The findings also suggest that the marked elevations of circulating IgG4 and IgE observed in this disease are, at least in part, due to the development of IgG4- and IgE-specific autoantibody responses. These findings were based on a series of experiments summarized below.

Using single-cell clones of dominantly expanded plasmablasts sorted from a patient with IgG4-RD, recombinant human monoclonal antibodies were generated. Paired heavy- and light-chain cDNAs from the top two dominant clones, identified by identical heavy-chain variable/diversity/joining gene segments (V) (VDJ), light-chain variable/joining gene segments (VJ), and predicted complementarity determining region 3 (CDR3) amino acid sequences, were expressed as monoclonal antibodies. The monoclonal antibodies were then used to purify relevant antigens from a pancreatic cell line using immunoaffinity chromatography. Mass spectrometry was used to identify the affinity-purified antigens of interest, and findings were validated by enzyme immunoassay.

The two most frequent clones accounted for 77% of all the sorted cells. The two monoclonal antibodies expressed from these dominant clones stained human pancreatic tissue sections and permeabilized pancreatic cancer cell lines. Galectin-3 was identified as the antigen, specifically recognized by both antibodies. Finally, antigalectin-3 autoantibody responses were identified in the plasma of nearly 40% of IgG4-RD patients in a large cohort. Total 28% of the antibodies were of the IgG4 isotype and 11% were IgE. Responses involving IgG1, IgG2, or IgG3 isotypes were not observed.

## GENETICS

Human leukocyte antigen (HLA) associations and other potential genetic links of IgG4-RD remain incompletely characterized. Familial cases are very rare, but detailed genetic studies have not yet been undertaken in populations of sufficient size.

## AN ANIMAL MODEL

An animal model that recapitulates some aspects of human IgG4-RD has been developed in mice (Shiokawa et al., 2016). Purified IgG subclass molecules from the serum of patients with IgG4-RD and controls were transferred to neonatal mice, inducing pathologic changes in both the pancreas and submandibular glands. Transfer of either purified IgG1 or IgG4 alone produced the disease phenotype, yet the transfer of both molecules together led to reduced IgG1 deposition and a decrease in the histopathologic severity of disease within affected organs.

The induction of disease by IgG4 transfer in this model appears contrary to the concept of IgG4 as an antiinflammatory molecule. It is possible, however, that a subset of IgG4 antibodies not subject to Fab-arm exchange might have been responsible for the findings observed (the extent to which Fab-arm exchange occurs *in vivo* is unknown). It is also possible that under some conditions, IgG4 participates in the formation of immune complexes, which contribute to tissue injury. For example, there is clear evidence of IgG4 immune complex deposition in IgG4-related tubulointerstitial nephritis (TIN) and some suggestion that a similar process contributes to IgG4-related AIP.

## CLINICAL FEATURES AND DISEASE ASSOCIATIONS

### Lymphadenopathy

The lymphadenopathy associated with IgG4-RD is typically either a generalized lymphadenopathy or localized disease adjacent to an affected organ. The lymph nodes involved are generally 1–3 cm in diameter and non-tender. The disease does not have a predilection for any particular set of lymph nodes. Establishing the diagnosis of IgG4-RD through lymph node biopsy is often difficult because it is unusual for lymph nodes to undergo the degree of fibrosis observed in other organs. In addition, the histopathology of lymph nodes in IgG4-RD spans a broad range of findings. One form, for example, strongly resembles the lymph node findings in Castleman's disease.

### Lacrimal and Salivary Glands

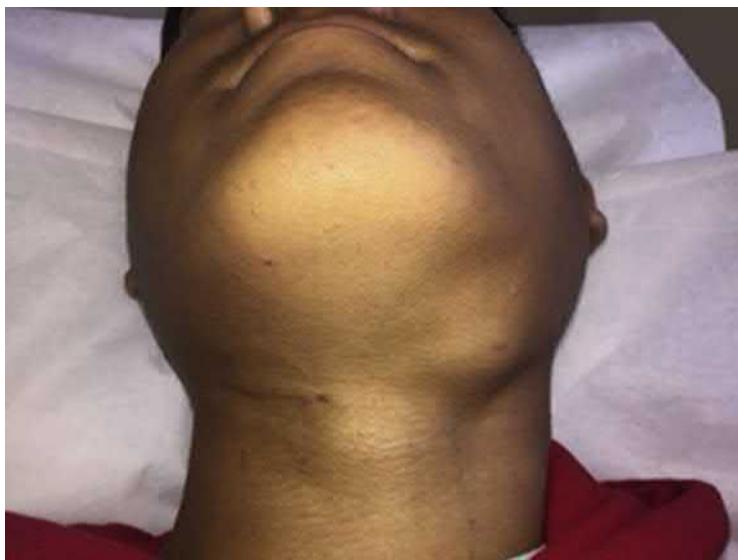

Lacrimal gland enlargement (dacryoadenitis) is the most common feature of ophthalmic disease in IgG4-RD. For more than 100 years, the triad of dacryoadenitis and enlargement of both the parotid and submandibular glands was referred to as "Mikulicz' disease" (Fig. 38.2). It is now known to be a classic feature of many patients with IgG4-RD. Fine-needle aspirates of major salivary glands are useful for excluding malignancy, but excisional biopsies are usually required for diagnostic confirmation.

### Orbits

Proptosis can result from the combinations of orbital lesions, such as pseudotumors that do not affect the lacrimal gland and inflammation and thickening of the extraocular muscles involvement.

### Ear/Nose/Throat

Mild-to-moderate peripheral eosinophilia and serum IgE concentration elevations that sometimes exceed 10 times the upper limit of normal are not unusual in IgG4-RD. Allergic rhinitis, nasal polyps, chronic sinusitis, nasal obstruction, and rhinorrhea are common in IgG4-RD. A subset of nonatopic IgG4-RD patients has peripheral blood eosinophilia and elevated IgE levels (Della Torre et al., 2014). This suggests that processes inherent to IgG4-RD rather than to atopy per se contribute to the eosinophilia and IgE elevation. Circulating

**FIGURE 38.2** Nontender enlargement of the left submandibular gland in a patient with IgG4-related sialadenitis. The right submandibular gland has been removed for diagnostic purposes. IgG4, Immunoglobulin G4.

T helper cell 2 (Th2) memory cells are not generally detected in IgG4-RD but can be found in IgG4-RD patients with preexisting histories of atopy (Mattoo et al., 2014b).

Mass lesions can occur in the sinuses and destructive lesions in the middle ear and facial bones have been reported. IgG4-RD can also lead to diffuse inflammation in the pharynx, hypopharynx, and Waldeyer's ring.

## Pancreas

Type 1 AIP, which demonstrates the classic histopathological findings of lymphoplasmacytic sclerosing pancreatitis, is a major complication of IgG4-RD. The most common clinical presentation of type 1 AIP is obstructive jaundice, induced by concomitant IgG4-related sclerosing cholangitis. Secondary diabetes mellitus commonly results, but exocrine pancreatic failure leading to massive weight loss is an even bigger problem. Computed tomographic features of AIP include diffuse pancreatic enlargement with delayed enhancement and a capsule-like low-density rim (Fig. 38.3). Diffuse, irregular narrowing of the main pancreatic duct on endoscopic retrograde, and magnetic resonance cholangiopancreatography is also highly specific for AIP.

## Immunoglobulin G4-Related Sclerosing Cholangitis and Cholecystitis

IgG4-related sclerosing cholangitis frequently occurs with type 1 AIP. IgG4-related sclerosing cholangitis must be differentiated from both primary sclerosing cholangitis and hilar cholangiocarcinoma. Neither serum IgG4 concentrations nor cholangiographic or cholangioscopic findings differentiate these diseases from each other with clarity. Moreover, the superficial nature of endoscopic biopsies limits their utility for diagnosing IgG4-related sclerosing cholangitis.

## Lung

IgG4-RD demonstrates multiple findings in the lung. Thickening of the bronchovascular bundle, best appreciated on computed tomographic examination, underscores the tendency of IgG4-RD to track along bronchi and blood vessels, which course together. Other radiologic features of IgG4-RD include pulmonary nodules, ground-glass opacities, pleural thickening, and interstitial lung disease. The interstitial lung disease mimics nonspecific interstitial pneumonitis and other forms of interstitial fibrosis.

## Kidney

TIN is the most characteristic form of IgG4-related kidney disease. Profound hypocomplementemia is often found in patients with IgG4-related TIN. The basis of this hypocomplementemia remains poorly understood, but it could result from the formation of immune complexes that contain IgG1 or IgG3, subclasses that bind

**FIGURE 38.3** Dacryoadenitis (inflammation and enlargement of the right lacrimal gland).

complement more effectively and are often elevated to a lesser degree. IgG4 appears unlikely to explain the hypocomplementemia by itself because the molecule does not bind complement effectively in most settings.

CT scanning in IgG4-related TIN can reveal substantial renal enlargement and hypodense lesions within the renal parenchyma. Advanced renal dysfunction and even end-stage renal disease can result. Proteinuria can develop, but the levels are usually subnephrotic. Kidneys affected by IgG4-RD can undergo atrophy, even in the setting of good clinical responses to therapy.

Membranous glomerulonephropathy also occurs in IgG4-RD, perhaps through a different pathophysiology. The anti-phospholipase A2 receptor antibody now linked to “idiopathic” membranous glomerulonephropathy in a high percentage of cases is not found in IgG4-related membranous glomerulonephropathy, even though that antibody is generally an IgG4 molecule.

### Thoracic Aorta and Coronary Lesions

IgG4-related aortitis, often suspected on the basis of an incidental radiological finding, is also sometimes an unexpected finding at surgery. IgG4-related aortitis can lead to aneurysms or dissections in the thoracic aorta. Coronary artery lesions in IgG4-RD, sometimes associated with aneurysm formation, are documented. Definitive histopathological investigations of primary aortic branch vessels have not been undertaken.

### Chronic Periaortitis and Retroperitoneal Fibrosis

IgG4-RD is responsible for up to two-thirds of the cases of “idiopathic,” RPF which is now considered to belong to a larger disease spectrum known as chronic periaortitis. The three major components of chronic periaortitis are IgG4-related RPF, IgG4-related abdominal aortitis, and IgG4-related perianeurysmal fibrosis.

IgG4-related RPF and chronic periaortitis commonly present with poorly localized pain in the back, flanks, lower abdomen, or thighs; lower extremity edema; and hydronephrosis from ureteral involvement. The disease targets three sites: (1) periaortic/arterial regions, involving connective tissue around the abdominal aorta or its first branches (Fig 38.4); (2) periureteral areas, leading to ureteral obstruction and hydronephrosis; and (3) a plaque-like mass that broadly involves the retroperitoneum.

### Nervous System

Involvement of the brain parenchyma by IgG4-RD is extremely rare, but this condition is among the most common causes of “idiopathic” hypertrophic pachymeningitis. IgG4-RD is also an established cause of hypophysitis. IgG4-related hypophysitis can lead to hormone deficiencies from both the anterior and posterior pituitary. Magnetic resonance imaging (MRI) shows sellar enlargement and thickening of the pituitary stalk. Peripheral

**FIGURE 38.4** Type 1 (IgG4-related) autoimmune pancreatitis. Computed tomographic study showing an enlarged, sausage-shaped pancreas that has lost its normal markings. IgG4, Immunoglobulin G4.

nerve lesions in the area of the orbit also occur commonly, typically observed on MRI in the absence of overt clinical manifestations. The trigeminal and infraorbital nerves are affected most commonly.

### Other Immunoglobulin G4-Related Disease Lesions

The clinical entity long known as “Riedel’s thyroiditis” is in fact IgG4-RD of the thyroid gland. Riedel’s thyroiditis is emblematic of organ manifestations of IgG4-RD that tend to present with overwhelmingly fibrotic lesions, described back in the 1960s as “multicentric fibrosclerosis” (Comings et al., 1967). Sclerosing lesions of both the mesentery and mediastinum are described. Sclerosing mesenteritis often appears to originate at the mesenteric root. The ensuing process often merges imperceptibly with RPF and sometimes encases vital organs and blood vessels, making surgical resection difficult or impossible. Fibrosing mediastinitis can lead to the compression of vital mediastinal structures from proliferation of invasive fibrous tissue. The relationship between these cases and antecedent histoplasmosis infections, if any, remains unclear.

Several clinical presentations of IgG4-related skin disease have been reported. The most common cutaneous manifestation is the presence of erythematous papules. These lesions typically affect the region of the head and neck but have also been described on the trunk and extremities. Biopsy-proven IgG4-related prostatic disease leading to prostatic enlargement has been reported. The diagnosis of IgG4-related prostate disease is often made presumptively when the initiation of treatment for IgG4-RD in other organs mediates abrupt symptomatic relief of “benign prostatic hyper trophy.”

## CLASSIFICATION CRITERIA

The 2018 ACR/EULAR Classification Criteria for IgG4-RD incorporate clinical, serological, radiological, and pathological features of IgG4-RD (Wallace et al., 2018). These criteria, which feature both exclusion and inclusion criteria, have a specificity of 98% and a sensitivity of 83%.

## TREATMENT

Glucocorticoids are currently the first-line treatment for IgG4-RD. Most data on the use of glucocorticoids are derived from the treatment of AIP. Treatment of IgG4-RD with glucocorticoids typically results in a symptomatic response within 2 weeks and the absence of clinically evident disease within 2–3 months (Khosroshahi et al., 2015). Unfortunately, many patients relapse as glucocorticoids are tapered or discontinued, and the optimal approach to remission maintenance remains unclear (Khosroshahi et al., 2015). The consequences of prolonged or

recurrent glucocorticoid treatment regimens are substantial in this disease that tends to affect a middle-aged to elderly population and often targets the pancreas.

## B Cell–Targeted Treatments

Anti-CD20-targeted therapy is an effective approach to treating IgG4-RD ([Khosroshahi et al., 2010; Carruthers et al., 2015](#)). Rituximab is an appealing alternative to glucocorticoids both for the induction and maintenance of remission in IgG4-RD. B-cell depletion leads to swift clinical improvement and steady declines in serum IgG4 concentrations over a period of a year or longer. Blood concentrations of the SLAMF7 + CD4+ CTL also decline overtime. Clinical responses have a variable duration from months to sometimes greater than a year, but relapses are the rule for most patients.

XmAb5871 is a novel molecule with an antigen-binding site specific for CD19, thereby also targeting cells of the B-cell lineage. The mechanism of XmAb5871 differs, however, from the antibody-dependent cellular cytotoxicity (ADCC) mechanism of anti-CD20-directed therapy. XmAb5871 capitalizes upon the natural inhibitory mechanism of Fc $\gamma$ RIIb, the only Fc receptor expressed by B cells, which acts as a negative regulator in conditions of antigen excess and immune complex formation ([Chu et al., 2014](#)). When Fc $\gamma$ RIIb is colligated with CD19, B-cell function is inhibited and plasmablasts are rendered dormant.

Preliminary analyses of this approach are promising and this medication is now being tested in a large phase 3 trial.

## Costimulatory Blockade

Abatacept, a fusion protein composed of the extracellular domain of CTL-associated protein 4 and the IgG1 constant domain, ameliorates autoimmune disease by binding to CD80/86 on antigen-presenting cells, thereby interfering with ligation to the costimulatory CD28 molecule on T cells. This treatment approach has been reported effective in a small number of patients and is now being tested in a larger phase 2 study.

## CD4+ Cytotoxic T Lymphocytes

CD4+ CTLs have strong appeal as a potential therapeutic target. Elotuzumab, an immunostimulatory mAb directed against SLAMF7, is approved for the treatment of refractory multiple myeloma. The proposed mode of action of elotuzumab is via the activation of NK cells and resultant ADCC of the SLAMF7-expressing cellular target.

**TABLE 38.1** Names of Previously Recognized Conditions Now Classified Frequently as Immunoglobulin G4 (IgG4)-Related Disease

---

Autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis)
Sclerosing cholangitis (a subset is in fact IgG4-related sclerosing cholangitis)
Mikulicz's disease (affecting the salivary and lacrimal glands)
Küttner's tumor (affecting the submandibular glands)
Multifocal fibrosclerosis (commonly affecting the orbits, thyroid gland, retroperitoneum, mediastinum, and other tissues/organs)
Riedel's thyroiditis
Inflammatory pseudotumor (orbits, lungs, kidneys, and other organs)
Mediastinal fibrosis
Retroperitoneal fibrosis
Sclerosing mesenteritis
Periaortitis/periarteritis
Inflammatory aortic aneurysm
Hypertrophic pachymeningitis
Eosinophilic angiocentric fibrosis (affecting the orbits and upper respiratory tract)
Idiopathic hypocomplementemic tubulointerstitial nephritis with extensive tubulointerstitial deposits

---

## PERSPECTIVES

IgG4-RD was recognized as a discrete disease entity only during the first years of this century, yet a remarkable amount has been learned about this condition in a short period of time. Its generally slow-moving course makes it an excellent disorder in which to study human immunology from a clinical and translational perspective. The ability to bring clinical samples from well-characterized patients together with cutting-edge laboratory techniques may lead to substantial progress in the next few years, with major implications for processes such as fibrosis and diseases beyond the IgG4-RD spectrum (Table 38.1).

Aire-Deficient Mouse as a Model for Autoimmune Polyendocrine Syndrome Type 1	739		

Autoimmune polyendocrinopathies denote syndromes characterized by immune-mediated destruction of two or more endocrine glands. Often many nonendocrine organs and tissues are also affected. They can be broadly divided into the ultrarare monogenic autoimmune polyendocrine syndrome (APS) type 1 (APS-1) and the common APS type 2 (APS-2) with complex inheritance. The former is caused by mutations in the *Autoimmune Regulator (AIRE)* gene, and the latter is associated with certain major histocompatibility complex genotypes and variants in a range of other genes, most of which are involved in the adaptive and innate immune system. In both conditions numerous autoantibodies can be detected, which correlates with clinical components, and can be utilized for diagnosis and prognosis.

Recent years have provided significant progress in our knowledge about disease genes and immunopathology of APS. We have come to appreciate that AIRE has a dual role in the thymus, both to promote expression of tissue-specific antigens and to facilitate the generation of a specific subset of regulatory T cells (Tregs). Moreover, several autoantibodies with unique specificities that can be utilized for diagnostic purposes have been identified.

In this overview, we summarize recent developments in the understanding of APS-1 and APS-2, and how these findings translate into improved diagnosis and management.

## HISTORIC BACKGROUND

In 1855 Thomas Addison published observations linking the clinical features of “general languor and disability, feebleness of the heart’s action” and hyperpigmentation of the skin to disease in the suprarenal capsules (adrenals) (Addison, 1855). This disorder has since been known as Addison’s disease (Wilks, 1862). Previously Schmidt (1926) noticed the propensity for polyendocrinopathy by demonstrating lymphocytic infiltration in both the adrenal and thyroid glands (Schmidt syndrome, OMIM 269200); later, Carpenter et al. (1964) added insulin-dependent diabetes mellitus to this list. The first clinical reports on patients with Addison’s disease presenting with chronic *Candida* infection and hypoparathyroidism appeared in the 1950s (Hetzl and Robson, 1958), although Thorpe and Handley (1929) reported a case with hypoparathyroidism and candidiasis. In the 1960s several reports pointed to the clinical and genetic heterogeneity among patients with Addison’s disease (Blizzard and Gibbs, 1968; Spinner et al., 1968), proposing that, depending on the associated disorders, Addison’s disease could be part of two separate and distinct clinical syndromes; APS types 1 and 2 (Neufeld et al., 1981). In addition, APS type 3 was defined as a disorder with autoimmune thyroid disease combined with polyglandular disorders.

A major breakthrough in separating APS-1 and APS-2 was the cloning and characterization of the AIRE gene in 1997 (Finnish-German-Consortium, 1997; Nagamine et al., 1997), which has helped to uncover how central immunological tolerance is developed and how it is compromised in autoimmune diseases. Subsequent use of animal models and advances in genomics and single-cell technologies have helped researchers to unravel many of the molecular mechanisms involved in the break of tolerance, summarized in this chapter.

## CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

### Autoimmune Polyendocrine Syndrome Type 1

APS-1 (OMIM 240300) has a broad spectrum of clinical manifestations (Table 39.1, Fig. 39.1). The disease is also referred to as autoimmune–polyendocrinopathy–candidiasis–ectodermal dystrophy or polyglandular autoimmune syndrome type 1. The most frequent clinical entities include chronic mucocutaneous candidiasis (CMC), hypoparathyroidism, and Addison’s disease. Traditionally, two of the three major components should be present in order to make the diagnosis clinically. However, a phenotypic variability and delay in appearance of these main manifestations for many years make the diagnosis difficult in many instances. Typically, APS-1 starts in childhood with CMC as the first manifestation followed by hypoparathyroidism and Addison’s disease (Ahonen et al., 1990; Orlova et al., 2017). As more patient cohorts have been published, it has become apparent that the phenotypic variation is large, even within the same family. Some patients develop manifestations late and display only a few components and never develop two of the main components (Perheentupa, 2002, 2006). Others are severely sick and can harbor more than 10 manifestations. Some of the minor components such as periodic fever with rash, nail dystrophy, and keratoconjunctivitis can be the first to appear and may not be recognized as APS-1 (Ferre et al., 2016).

The majority of patients develop CMC either with intermittent bouts of infection or more as a chronic infection with white thrush on the tongue. The infection may spread to nails and in some cases even to skin of the hands and face. Candidal esophagitis is often present but asymptomatic until stricture and dysphagia develops. Several cases of carcinoma in the oral cavity and esophagus have been reported, suggesting that oral candidiasis might be carcinogenic, especially in the combination with cigarette smoking (Perheentupa, 2002). CMC is associated with reduced numbers of IL-22 and IL-17F-producing T cells and the presence of autoantibodies against the Th17 cell mediators IL-17F, IL-17A, and IL-22 (Kisand et al., 2010; Puel et al., 2010), which seem to be the main cause for the increased propensity for CMC. In addition, patient-derived anti-IL-22 increased the susceptibility to CMC in mouse model (Bichele et al., 2017). APS-1 patients were also shown to have reduced expression of STAT1 in peripheral blood (Zimmerman et al., 2017).

Hypoparathyroidism is the most frequent and sometimes only endocrine component in APS-1 (Li et al., 2017) followed by adrenal insufficiency seen in about half of the patients (Meloni et al., 2012; Perheentupa, 2006; Wolff et al., 2007). Gonadal insufficiency is very common in females (female/male ratio, 3:1) and manifests itself in teenage and early twenties (Reato et al., 2011). Other endocrinopathies in falling frequencies are type 1 diabetes,

**TABLE 39.1** Manifestations and Organ-Specific Autoantibodies in APS-1

Main disease component		Autoantigen	Characteristics/Prevalence
APS-1			
Main triad	Hypoparathyroidism	IFN $\omega$ , IFN $\alpha$	Almost all patients are positive
	Addison's disease	NALP5	70%–80%, childhood
	Candidiasis	P450c21	65%–85%, childhood
Other endocrine manifestations	Ovarian failure	IL-22, IL-17F, IL-17A P450scc, P450c17, NALP5	80%–100%, childhood 60%
	Testicular failure	TSGA10	Adult prevalence up to 60%
	Autoimmune thyroid disease	TPO, TG	~10%, relatively rare
	Type 1 diabetes	IA-2	0%–25%
	Hypophysitis	TDRD6	Rare
Gastrointestinal	Malabsorption	TPH	Common, diarrhea, severe constipation, fatty stools
	Autoimmune gastritis		10%–30%
	Autoimmune hepatitis	AADC, CYP1A2	5%–20%, childhood, severe sometimes fatal
	Exocrine pancreatitis	n.d.	Rare
Hematological	Hypo/asplenia		10%–20%, risk of septicemia
	Hypergammaglobulinemia		5%
	Pure red cell anemia		Rare
Nephrological	Mineralocorticoid excess with hypertension		Rare
	Interstitial nephritis		Rare
Lung	Bronchiolitis obliterans	KCNRG	Rare, can be fatal
Ectodermal	Keratoconjunctivitis	BPIFB1	Prevalence approx. 10% may result in blindness
	Retinitis		Rare
	Alopecia	SOX9	Common, prevalence 30%–40%
	Vitiligo	TH	Prevalence ~20%
	Periodic rash with fever		Rare
	Squamous cell carcinoma		Associated with candidosis and smoking, can be fatal
	Enamel dysplasia		Prevalence 50%–70%
Muscular, neurological	Metaphysial dysplasia		Rare
	Polyarthritits		Rare
	Myopathy		Rare
	Neuropathy		Rare
	Ptosis		Rare

AADC, Aromatic L-amino acid decarboxylase; APS, autoimmune polyendocrine syndrome; IFN $\alpha$ , interferon alfa; IFN $\omega$ , interferon omega; IA-2, islet antigen-2; NALP5, NACHT-LLR-PYD-containing domain 5; KCNRG, putative potassium channel regulatory protein; SOX9, sex-determining region Y-box 9; TDRD6, tudor domain-containing 6; TG, thyroglobulin; TH, tyrosine hydroxylase; TPH, tryptophan hydroxylase; TPO, thyroperoxidase; TSGA10, testis-specific gene 10 protein.

**FIGURE 39.1** Clinical manifestations of autoimmune polyendocrine syndrome type 1. Carpal spasm caused by hypocalcemia (Trousseau's sign; upper left); vitiligo (middle right); enamel hypoplasia (middle left); *Candida* infection of the nail (middle right); alopecia areata; candidiasis of the tongue. Courtesy of Dr. Martina Erichsen.

autoimmune thyroid disease and hypophysitis. Many patients suffer from gastrointestinal autoimmunity, notably enteropathy with malabsorption and/or obstipation, hepatitis, autoimmune gastritis with and without vitamin B12 and iron deficiencies, and exocrine pancreatitis.

APS-1 patients often display a number of organ-specific lesions affecting ectodermal structures, namely enamel dysplasia, vitiligo, alopecia, keratoconjunctivitis, and nail dystrophy. Hyposplenism or splenic atrophy has been reported (Perheentupa, 2002, 2006), which render them susceptible to serious bacterial infections. Hypertension and increased mineralocorticoid sensitivity (Ahonen et al., 1990), interstitial nephritis (Landegren et al., 2016a), pneumonitis (Alimohammadi et al., 2009), and pure red cell aplasia are rare but serious complications (Orlova et al., 2017). Finally, a number of rare components associated to APS-1 have recently been reported, including retinitis (Orlova et al., 2010), lipodystrophy (Sorkina et al., 2016), ptosis (Orlova et al., 2017), polyarthritis (Gutierrez et al., 2017), peripheral neuropathy (Valenzise et al., 2009), and metaphyseal dysplasia (Harris et al., 2003).

On average each patient has about 4–5 different diseases, but up to 20 have been reported. While CMC, hypoparathyroidism, periodic fever with rash, and keratitis commence early, other manifestations like autoimmune thyroid disease, vitamin B12 deficiency, testicular failure, interstitial nephritis, and hyposplenism usually appear in adult age (Ferre et al., 2016; Orlova et al., 2017).

## Autoimmune Polyendocrine Syndrome Type 2

APS-2 is a genetically complex disease with a multifactorial etiology. The clinical onset usually occurs in adulthood, although it can start at any time during the life span, though seldom before puberty. APS-2 affects more often middle-aged Caucasian women with a male/female ratio of 1:2–3. The classical definition of APS-2 (Neufeld et al., 1981) comprises a combination of Addison's disease with autoimmune thyroid disease and/or

type 1 diabetes. Probably any combinations of autoimmune disorders within the complex represent the same disorder with an inherited propensity to develop organ-specific autoimmunity (Schatz and Winter, 2002). Type 1 diabetes can develop before and after Addison's disease (Erichsen et al., 2009). In common with APS-1, manifestations such as vitiligo, alopecia, hypergonadotropic hypogonadism, and autoimmune gastritis with or without pernicious anemia are prevalent although less common and usually not present in childhood.

At least half of the patients with autoimmune Addison's disease develop another autoimmune disorder (Betterle and Morlin, 2011; Dalin et al., 2017; Erichsen et al., 2010). Using the prevalence numbers for Addison's disease, which are most recently found to be between 16 and 22 per 100,000 inhabitants (Olafsson and Sigurjonsdottir, 2016), the prevalence of APS-2 is about 8–11 per 100,000 inhabitants. A recent analysis of heritability using the Swedish twin registry found Addison's disease to have an exceptionally high heritability, even higher than celiac disease (Skov et al., 2017). Interestingly, when monozygotic twins developed APS-2, the second organ-specific manifestation was often the same, as opposed to dizygotic twins where they often differed. Unfortunately, studies of epidemiology and inheritance in other populations are largely lacking.

## AUTOIMMUNE FEATURES

Each of the major organ manifestations in APS-1 and APS-2 has corresponding autoantibodies correlating to the presence of their particular components. Thus reactivities to thyroid peroxidase, thyroglobulin, and the TSH receptor are typical for autoimmune thyroid disease. In type 1 diabetes the main autoantigens are glutamic acid decarboxylase-65 (GAD65), islet antigen-2 (IA-2), and the beta-cell-specific zinc transporter Zn8 (ZnT8). In Addison's disease the steroid 21-hydroxylase (P450c21 or CYP21) (Winqvist et al., 1992) is the major autoantigen with similar frequencies of positivity in APS-1 and APS-2 patients (Bruserud et al., 2016; Erichsen et al., 2009; Eriksson et al., 2017). The main autoantigen in hypoparathyroidism was identified as NALP5, a protein highly expressed in the parathyroid gland (Alimohammadi et al., 2008). Autoantibodies against gonadal tissues target side-chain cleavage enzyme (P450ccc or CYP11A1) and steroid 17-alpha-hydroxylase (P450c17 or CYP17) (Brozzetti et al., 2010a; Krohn et al., 1992; Reato et al., 2011; Uibo et al., 1994; Winqvist et al., 1993, 1995). It remains perplexing as to why certain diseases of APS coexist. Initially antigenic epitope sharing in the affected glands was thought to provide an explanation for the involvement of certain organs, but with the identification of large number of autoantigens, other mechanisms interrupting immune tolerance to specific organs should be considered.

Autoantibodies to several other organ-specific self-antigens have been reported in APS-1 (Table 39.1). One group is of decarboxylases and hydroxylases involved in neurotransmitter biosynthesis. Examples are autoantibodies against aromatic L-amino acid decarboxylase correlated to type 2 autoimmune hepatitis (Husebye et al., 1997), tryptophan hydroxylase connected to autoimmune enteropathy (Ekwall et al., 1998), and tyrosine hydroxylases correlated to alopecia (Hedstrand et al., 2000). Patients also react with glutamic acid decarboxylase 2 (GAD2/GAD65) (Skoldberg et al., 2004; Soderbergh et al., 2004) and with GAD1/GAD67 (Tuomi et al., 1996). The other group is of cytochrome P450 enzymes, the steroidogenic enzymes mentioned above. In addition, autoantibodies against CYP1A2 are associated with autoimmune hepatitis in APS-1 (Gebre-Medhin et al., 1997).

While these established autoimmune biomarkers were identified with the traditional techniques of Western blot, screening of expression libraries or by the use of bioinformatics (ZnT8), several novel autoantigens have recently been identified by the screening of protein arrays (Fishman et al., 2017; Landegren et al., 2016b). These studies have confirmed many, but not all the traditional autoantigens, a discrepancy that can be explained by differences in the techniques that affect exposure of epitopes. Among novel antigens identified by protein array screening is transglutaminase-4 (TGM4), a prostate-specific autoantigen. TGM4 is the first sex-specific autoantigen since females normally do not express this protein (Landegren et al., 2015). Furthermore, the reactivity toward a number of cancer-testis autoantigens was found, including PDILT and different MAGE proteins (Fishman et al., 2017; Landegren et al., 2016b). Another interesting finding was the large spectrum of autoantigens identified and that only a handful of patients reacted with a particular protein (Fishman et al., 2017; Meyer et al., 2016). In addition to AIRE-regulated tissue-specific transcripts, the genes for many of the identified autoantigens were not regulated by AIRE (Fishman et al., 2017). From those, many were intracellular phosphoproteins and proteins expressed in lymphoid cells. Although the patient sample was limited, there was a trend to have more autoantibodies with time and more autoantibodies if there was a nonsense mutation as opposed to a missense mutation (Fishman et al., 2017).

In addition to the organ-specific autoantibodies, APS-1 patients display autoantibodies to a number of interferons and interleukins. These are targeting type 1 interferon alpha and omega (IFN- $\alpha$  and IFN- $\omega$ ) IL-17A, IL-17F, and IL-22 (Meager et al., 2006; Kisand et al., 2010). Autoantibodies to various isoforms of IFN- $\alpha$  and IFN- $\omega$  are present in almost all patients, are neutralizing, occur in extremely high titers up to 1–10<sup>6</sup>, are detected at very early stage of APS-1, and persist for decades. Such high frequencies of positivity render assay of IFN- $\alpha$  and IFN- $\omega$  antibodies a very useful tool to identify patients with APS-1 (Meloni et al., 2008; Oftedal et al., 2008). Anti-IFN- $\alpha$  antibodies-reduced interferon-stimulated gene expression in vivo and high levels of these autoantibodies were related to the protection against type 1 diabetes (Kisand et al., 2008; Meyer et al., 2016). Other interleukins are targeted albeit at lower frequencies including IFN- $\lambda$ 1, -2, -3, IL-5, IL-6, and IL-32 (Karner et al., 2016; Meyer et al., 2016). The prevalent autoantibodies against interleukins IL-17A, IL-17F, and IL-22 were found to correlate with the presence of candidiasis (Kisand et al., 2010; Puel et al., 2010), although the mechanism by which these autoantibodies could trigger CMC remains elusive.

Type 1 interferon autoantibodies are highly specific but not entirely exclusive for APS-1 as they are also found in patients with myasthenia gravis, particularly in association with the late-onset form of thymoma (Meager et al., 2006). Recently patients with mild RAG mutations and Omenn syndrome were found to display such autoantibodies (Walter et al., 2016). There is also a considerable overlap between APS-1 and APS-2 for some of the organ-specific autoantibodies, in particular autoantibodies to P450c21, P450c17, and P450scc (Betterle et al., 2002; Hoek et al., 1997; Soderbergh et al., 2004). APS-2 patients with type 1 diabetes frequently have autoantibodies to GAD65 and/or IA-2 protein, while anti-GAD65 autoantibodies do not correlate to type 1 diabetes in APS-1 patients; instead an association to malabsorption (Soderbergh et al., 2004) and vitiligo was reported (Fishman et al., 2017). Taken together these new discoveries have provided clinicians with a useful toolkit of assays to diagnose both APS-1 and APS-2, with high sensitivity and specificity.

## GENETIC FEATURES

APS-1 is inherited in an autosomal recessive manner and occurs as a defect in the *AIRE* gene. The prevalence worldwide is very low and population dependent. The frequency is higher among certain populations such as Finns (1/25,000) (Aaltonen et al., 1994), Persian Jews (1/9000) (Zlotogora and Shapiro, 1992), and among Sardinians (1/14,400) (Rosatelli et al., 1998). The prevalence, reported from Norway at 1/80,000 (Wolff et al., 2007), probably reflects the frequency in most countries.

*AIRE* was identified by positional cloning on chromosome 21q22.3 (Finnish-German-Consortium, 1997; Nagamine et al., 1997), and to date, more than 120 mutations (<http://www.hgmd.cf.ac.uk/ac/gene.php?gene=AIRE> and about 500 genetic variants ([https://www.ncbi.nlm.nih.gov/SNP/snp\\_ref.cgi?locusId=326](https://www.ncbi.nlm.nih.gov/SNP/snp_ref.cgi?locusId=326)) have been identified. The mutations are spread throughout the coding region with two mutational hotspots. From these, the most common mutation is R257X in exon 6, which is found in 83% of the Finnish APS-1 chromosomes (Björres et al., 2000) but is also common in APS-1 patients of other ethnic origins (Scott et al., 1998). Another frequently occurring mutation is 967-979del13bp, which has been reported in patients from different populations (Wang et al., 1998; Pearce et al., 1998; Heino et al., 1999; Proust-Lemoine et al., 2010). Furthermore, R139X mutation is common among Sardinian (Rosatelli et al., 1998), R203X among Sicilian (Giordano et al., 2011), and Y85C among Persian Jews (Björres et al., 2000; Heino et al., 1999; Pearce et al., 1998; Wang et al., 1998). Many *AIRE* mutations are nonsense mutations or deletion/insertions leading to nonsense-regulated mRNA decay and no protein translation (Huang and Wilkinson, 2012). Most of the missense mutations occur in the N-terminus of *AIRE*, a region responsible for the homodimerization and correct intracellular localization of the protein. Recent reports on the critical role of NF- $\kappa$ B containing enhancer in regulation of *AIRE* expression (Haljasorg et al., 2015; LaFlam et al., 2015) suggest that the mutations in this upstream regulatory region may be involved in APS-1.

APS-1 patients have considerable phenotypic variation but no clear correlation with the genotype. Among Iranian Jews, the Y85C mutation has much lower frequencies of candidiasis and Addison's disease than other cohorts (Zlotogora and Shapiro, 1992). Moreover, in a study of 160 Finnish patients with the three most prevalent mutations, candidiasis was found more often in patients with homozygous R139X and R257X mutations (i.e., truncating *AIRE* before SAND domain) than with homozygous 967-979del13bp mutation (Kisand et al., 2010; Kisand and Peterson, 2011).

APS-1 was until recently considered to be mainly an autosomal recessive disease requiring two disease-causing mutation in order to elicit clinical manifestations. Recent studies have revealed certain heterozygous

missense mutations giving rise to APS-1 with dominant inheritance (Oftedal et al., 2015). Most of these mutations are located in the first plant homeodomain (PHD1) and in two cases, in the SAND domain (Cetani et al., 2001; Abbot et al., 2017). In many cases, these patients display milder disease with clinical overlap with APS-2 and isolated organ-specific autoimmune disease. Intriguingly, PHD1 mutations seem to predispose for vitamin B12 deficiency/pernicious anemia and vitiligo while the SAND-domain mutation G228W has a propensity for autoimmune thyroid disease (Cetani et al., 2001). Based on the frequencies at around 0.001 of these variants in public data bases, the dominant nonclassic APS-1 can be much more common than we believe.

APS-1 association with Human leukocyte antigen (HLA) has remained controversial, although some components of the disease seem to correlate with certain HLA alleles (Halonen et al., 2002; Gylling et al., 2003). In contrast to monogenic inheritance of APS-1, APS-2 is a polygenic disease. As for most autoimmune diseases, APS-2 is strongly associated with the HLA gene locus in chromosome 6p21 (Table 39.2). Genetic studies have demonstrated a consistent association of APS-2 with HLA DRB1\*03:01 (DR3) DQA1\*05:01 DQB1\*02:01 (DQ2) and DRB1\*04:01 (DR4) DQA1\*03:01 DQB1\*03:02 (DQ8) haplotypes, which both are in strong linkage equilibrium with each other (Falorni et al., 2008; Flesch et al., 2014; MacLaren and Riley, 1986; Partanen et al., 1994). The haplotype is associated with isolated disease components of APS-2; type 1 diabetes, Graves' disease, autoimmune

**TABLE 39.2** Autoimmune Polyendocrine Syndrome Type 2-Associated HLA Alleles and Non-HLA Genes

Genes	Details	Reference
MHC class II	DR3-DQ2 DR4(0404)-DQ8	Antigen presentation; DR3/DR4(0404) heterozygotes have OR ~30 for AAD
	DQ5	Protective; OR 0.4 for AAD
MHC class I	HLA-B8	Antigen presentation, DR3-B8 haplotype associated with familial AAD
	HLA-B15 (protective)	Protective for progression to overt AAD
Other genes in the MHC region	MICA5.1	Involved in NK and T-cell activation, OR 18 for homozygotes with AAD
	21-Hydroxylase	Steroidogenic enzyme and main autoantigen in AAD; effect could be secondary due to LD
	Tumor necrosis factor	Inflammatory cytokine; effect could be secondary due to LD
Non-MHC genes	CTLA-4	Involved in downregulation of T-cell responses; A to G SNP at position 49; 3' untranslated region microsatellite
	PTPN22	Involved in T-cell activation; AAD associate to the 1858T allele and rare variants
	NALP1	Involved in inflammatory responses; OR 1.15 for AAD
	CLEC16A	C-type lectin of unknown function; OR 0.76 for AAD
	CIITA	Govern MHC class II expression; OR 1.7 for AAD
	PD-LI	Downregulate cytokine production and T-cell responses (CTLA-4/CD28 family of costimulatory receptors); OR 1.33 for AAD
	CYP27B1	25 hydroxyvitamin D3-1-alpha hydroxylase; OR 1.1-1.7 for AAD
	FCRL3	Immune regulatory; OR 1.6 for AAD
	BACH2	OR 2.01 for AAD

AAD, Autoimmune Addison's disease; CIITA, class II, major histocompatibility complex, transactivator; CLEC16A, C-type lectin domain family 16; CTLA-4, cytotoxic T lymphocyte antigen 4; CYP27B1, 25 hydroxyvitamin D3-1-alpha hydroxylase; FCRL3, Fc receptor like 3; HLA, human leukocyte antigen; MHC, major histocompatibility complex; MICA5.1, major histocompatibility complex class I chain-related MIC-A polymorphisms in exon 5; NALP1, NACHT-LRR-PYD-containing protein 1; OR, odds ratio; PTPN22, protein tyrosine phosphatase, nonreceptor type 22.

hypothyroidism, and Addison's disease. The increased risk of DR4 was attributed to DRB\*0404 in Addison's disease, and not DR4\*0401 in variance with type 1 diabetes (Erichsen et al., 2009; Falorni et al., 2008; Gambelunghe et al., 2005). The association was strongest for the DRB1 locus alleles DRB1\*03:01 and DRB1\*04:04 (Skinningsrud et al., 2010). Conditioning for DRB1-indicated independent effects of HLA-B and MICA5.1 (Falorni et al., 2008; Skinningsrud et al., 2010), a positive association to HLA-B8 (Baker et al., 2010), while HLA-B15 was not protective to the formation of P450c21 antibodies, but to the progression to overt disease (Baker et al., 2011). Conversely, the haplotypes DRB1\*01 (DR1) DQA1\*01:01 DQB1\*05:01 (DQ5), DRB1\*13:01 DQB1\*06:03 DQA1\*01:03, DRB1\*13:02 DQB1\*06:04 DQA1\*01:02, and DRB1\*07 DQB1\*02:01 DQA1\*02:01 are protective against Addison's disease (Erichsen et al., 2009). Alleles of other genes located in HLA region, such as TNF and P450c21 have been associated with APS-2 (Falorni et al., 2008; Partanen et al., 1994; Peterson et al., 1995), but these associations could be secondary to the strong linkage disequilibrium in the HLA region.

The cytotoxic T-lymphocyte-associated protein 4 (*CTLA-4*) gene on chromosome 2q33 is associated with autoimmune endocrinopathies from different population (Brozzetti et al., 2010b). In particular the allelic variants of an A–G single-nucleotide polymorphism at position 49 (*rs231775*) and microsatellite marker in the 3' untranslated region of the *CTLA-4* gene are well known to associate with type 1 diabetes and thyroiditis (Levin and Tomer, 2003). These two variants of the *CTLA-4* gene as well as *rs231727* are increased among Addison's disease and APS-2 patients of European origins (Brozzetti et al., 2010b; Kemp et al., 1998; Wolff et al., 2015). The associated allelic variation was correlated with lower messenger RNA levels of the soluble alternative splice form of *CTLA-4* (Ueda et al., 2003); however, the mechanism by which *CTLA-4* confers susceptibility remains incompletely understood (Esensten et al., 2016).

In addition, a number of other susceptibility genes have been characterized in Addison's disease and APS-2 (Table 39.2). The majority of these associations are to genes involved in immunity and inflammation, and none of the associations are specific for Addison's disease or APS-2. These include PTPN22 (Rycroft et al., 2009; Skinningsrud et al., 2008a), where both association to the 1858T allele and to rare variants were found; NALP1 that could be involved in inflammation (Magitta et al., 2009); the class II, major histocompatibility complex transactivator (Ghaderi et al., 2006; Skinningsrud et al., 2008b), the programmed death ligand 1 (Mitchell et al., 2009), the lymphocyte cell surface molecule FCRL3 (Owen et al., 2007), and BACH2 (Eriksson et al., 2016).

An influence of *AIRE* gene polymorphisms in APS-2 or other major autoimmune diseases has been suggested. The *AIRE* gene was described as a susceptible locus for the predisposition to rheumatoid arthritis in the Japanese population (Terao et al., 2011), but neither *AIRE* mutations R257X and 967-979del13bp nor SNP analyses across the *AIRE* gene contributed to the susceptibility to type 1 diabetes, Graves' disease, autoimmune hepatitis, or Addison's disease (Boe Wolff et al., 2008; Meyer et al., 2001; Nithiyanthan et al., 2000; Turunen et al., 2006; Vaidya et al., 2000). Nevertheless, a meta-analysis of *rs2075876* and *rs760426* in the *AIRE* gene confirmed their association with an increased risk of rheumatoid arthritis among Asian populations (Bérczi et al., 2017).

## ENVIRONMENTAL FEATURES

The associations with environmental factors such as vitamin D, smoking, socioeconomic status, infections, or vaccines are less clear than with genetic factors (Anaya et al., 2016). An increase in the incidence of type 1 diabetes mellitus and other autoimmune endocrine diseases in most of the developed countries points to the novel environmental influences as the genetic background have largely remained unchanged. The role of environment has been best studied in patients with type 1 diabetes [see Chapter 41: Autoimmune (Type 1) Diabetes] in which analysis of twins shows that the genetic background cannot be the only reason for the disease (Hyttinen et al., 2003). National prosperity and good hygiene level seem to correlate in uncertain ways with type 1 diabetes (Patterson et al., 2001). The role of viral infections in polyendocrinopathies remains unclear, and no clear inciting agent has been identified. Studies on the interaction of the intestinal microbiome with the immune system showed that segmented filamentous bacteria seems to induce the generation of Th17 cells involved in the early phases of the immune response and linked to autoimmunity (Ivanov et al., 2009). Thus environmental factors could mediate their effect via the intestinal microbiome (see Chapter 25: Epigenetics of Autoimmune Diseases).

## ANIMAL MODELS

### Aire-Deficient Mouse as a Model for Autoimmune Polyendocrine Syndrome Type 1

Aire-deficient mice present the autoimmune features such as multiorgan lymphocytic infiltration and circulating autoantibodies (Anderson et al., 2002; Ramsey et al., 2002). The disease severity is dependent on mouse genetic background with C57Bl/6 having very mild and nonobese diabetes (NOD) mouse presenting exocrine (but no endocrine) pancreatitis with wasting disease. Studies on Aire mouse have been critical in elucidation of APS-1 pathogenesis and thymic tolerance (for review, see Anderson and Su, 2016). The studies in these experimental models have established that Aire promotes the expression of self-antigens in thymic medullary epithelial cells needed for efficient negative selection of autoreactive T cells (Anderson et al., 2005; Liston et al., 2003). Aire is also involved in the presentation of self-proteins (Kuroda et al., 2005) as it enhances the capacity of medullary thymic epithelial cells (mTECs) to cross-present antigen to thymic dendritic cells (Hubert et al., 2011; Koble and Kyewski, 2009) and has been implicated in the differentiation of mTECs (Nishikawa et al., 2010; Wang et al., 2012) and migration of thymocytes (Laan et al., 2009). More recent studies have shown defect in the neonatal output of Tregs (Yang et al., 2015), thymic  $\gamma\delta$  T cells (Fujikado et al., 2016) and B cells (Gavanescu et al., 2008). Although Aire-deficient mice have been central in understanding of AIRE function in thymic medullary epithelial cells, the mice are also at variance with APS-1 patients in several aspects, for example, the Aire-deficient mice do not share autoantibody targets seen in humans (Kekalainen et al., 2007a). Furthermore, none of the Aire-deficient mouse models spontaneously display the three main components of the APS-1, although autoimmunity toward liver, gastric mucosa, and ovaries are shared. Clearly, more human-like experimental models are needed to understand the pathologies in the patients.

### Spontaneous Animal Models

Most studied spontaneous animal models for polyendocrine autoimmunity are biobreeding (BB) rat and NOD mouse. These rodent models indicate that MHC genes are major genetic factors in disease development, and that other non-MHC genes are also involved. BB rat and NOD mouse also have impaired regulation of immune responses, including tolerance defects and abnormal function of Tregs. The NOD mouse is mostly studied as a model for type 1 diabetes [see Chapter 41: Autoimmune (Type 1) Diabetes]. The BB rat develops type 1 diabetes, lymphocytic infiltration in thyroid glands (Awata et al., 1995), and has autoantibodies to gastric parietal cells and smooth muscle (Crisa et al., 1992); however, no lymphocytic infiltration to adrenal gland has been observed. They have severe T-cell lymphopenia which is strongly associated with the diabetes development. The T-cell lymphopenia is due to a single-nucleotide deletion in *Gimap5* gene (Hornum et al., 2002; MacMurray et al., 2002). A number of breeds such as the standard poodle and Portuguese water dog are susceptible to the development of Addison's disease (Van Lanen and Sande, 2014).

### Thymectomy Animal Model

A well-studied mouse model for polyendocrinopathy is thymectomy at day 3 in the Balb/C strain, which leads to multiorgan autoimmunity characterized by gastritis, thyroiditis, oophoritis, and other infiltrations. The infiltrations are T-cell predominant, and the mice develop autoantibodies to affected tissues. Thymectomy-induced autoimmunity depends on time of thymectomy, that is, between the second and fifth day after birth (Bonomo et al., 1995). The lack of CD4 + CD25 + Tregs was proposed to cause autoimmunity, and the injection of purified Tregs into the thymectomized mice was used to prevent autoimmunity (Asano et al., 1996). However, in adult age, the Treg numbers in thymectomized mice are restored. Thymectomy causes lymphopenia in which development of autoimmune diabetes rather appears to be linked to effector and not to Tregs (Gagnerault et al., 2009), and in this respect, the prolonged neonatal lymphopenia and homeostatic expansion of peripheral T cells in Aire-deficient mouse resemble thymectomized model (Kisand et al., 2014). Further implication of this model in endocrine autoimmunity was demonstrated with NALP5 (MATER), an ovarian autoantigen in APS-1, which, when transgenically expressed in MHC class II cells in thymus and secondary lymphoid system, was sufficient to mediate a significant reduction in autoimmune oophoritis after thymectomy (Otsuka et al., 2011).

## PATHOGENIC MECHANISMS

The endocrine glands in APS are gradually destroyed, resulting in atrophy or parenchymal cells are replaced by fat cells (Perheentupa, 2002). Adrenalitis in APS patients appears to be diffuse, affecting all three layers of the cortex. As an indication of T-cell-mediated autoimmunity, it mainly consists of lymphocytes, but macrophages and plasma cells have also been detected (Carpenter et al., 1964; Muir et al., 1993). The infiltrating lymphocytes are of both B and T lineages, while the T-cell population includes both the CD4 + and CD8 + subsets. Strikingly, adjacent nontargeted tissue is spared and intact. At the end of the disease, atrophy and fibrosis become prominent in affected glands.

Only few studies have addressed the autoreactive T cells in APS patients, partly due to the lack of specific and sensitive methods, and to the fact that T cells in contrast to autoantibodies are sequestered in the specific tissue lesions and are thus difficult to access. Recombinant P450c21 or corresponding peptides have been demonstrated to elicit CD4 + or CD8 + T-cell responses; and CD8 + T cells could lyse 21-hydroxylase-expressing target cells (Bratland et al., 2009; Dawoodji et al., 2014). Autoantibodies have long been regarded as having a bystander role, yet they still could have an important role as amplifiers of the immune response toward the adrenal cortex. Increased serum levels of proinflammatory CXCL10 chemokine have been found in patients with isolated Addison's disease, APS-2 (Rotondi et al., 2005), and APS-1 (Kisand et al., 2008). The adrenocortical cell is likely to be an active participant in the autoimmune process as of itself it can produce CXCL10 in response to interferon gamma (Bratland et al., 2013; Rotondi et al., 2005).

APS-1 patients have an increased frequency of highly differentiated CD8 + effector T cells (Laakso et al., 2011). Although the specificity of these cells is unknown they may represent autoreactive population (Arstila and Jarva, 2013). CD4 + T-cell numbers and proportion of memory or activated T cells have been reported to be increased or normal (Heikkilä et al., 2016; Perniola et al., 2005; Tuovinen et al., 2009) and controversial results have been found on iNKT and monocyte cell numbers (Hong et al., 2009; Lindh et al., 2010; Perniola et al., 2008). IL-17F and IL-22 responses are lower, while IL-17A responses are normal (Kisand et al., 2010; Laakso et al., 2014; Ng et al., 2010). Most consistent findings in APS-1 patients are in Treg compartment. Tregs in APS-1 patients are decreased in number, have impaired function, and have decreased expression of FoxP3 (Kekäläinen et al., 2007b; Ryan et al., 2008; Wolff et al., 2010). TCR repertoire spectratyping of CD4 + and CD8 + T cells did not reveal abnormalities in CDR3 length (Niemi et al., 2015); however, longer CDR3 was found in naive but not in activated/memory Tregs, suggesting failure of thymic selection (Koivula et al., 2017). In addition, dysregulated responses to commensal antigens suggest a failure in intestinal tolerance and defect in Treg functions (Hatemaki et al., 2016).

Autoimmunity in APS-1 has been postulated, based on studies in Aire-deficient mice, to be a consequence of defective central tolerance to the autoantigens. The lack of AIRE expression in thymus may thus lead to a defect in clonal deletion of autoreactive T cells and ultimately to autoimmunity (Liston et al., 2003). However, direct data are lacking on the clonal deletion in human APS-1 patients. In contrast, a growing number of studies on Aire-deficient mouse and APS-1 patients point to the defective selection or function of Treg. A decrease in the number of Tregs of thymic origin is evident already in the neonatal period (Yang et al., 2015), and lower numbers have been also reported in adult mice (Malchow et al., 2013). Aire seems to affect a certain subset of Treg clones as their development is Aire dependent (Malchow et al., 2013), whereas most frequent Treg clones seem to be independent of Aire (Perry et al., 2014). A scenario where Aire deficiency may cause the diversion of Tregs into pathogenic conventional T cells has been proposed (Malchow et al., 2016).

The organs targeted in APS-1 patients are limited, and the syndrome typically starts with CMC, followed by hypoparathyroidism and Addison's disease indicating the abovementioned phenotypic differences between human patients and Aire mouse models. Whereas the candidiasis is associated with the decrease in Th17 responses and early generation of anti-IL-17 and IL-22 autoantibodies, the reason for the high prevalence of autoimmune hypoparathyroidism and Addison's disease remains unclear. The autoantibodies against type 1 IFN and Th17 cytokines in APS-1 have implications similar to those of thymoma patients where autoantibodies to type 1 IFN and other cytokines have also been found. The defects in central T-cell tolerance in APS-1 provoke wide-ranging deviation of B-cell tolerance (Meyer et al., 2016); nevertheless, the mechanism how AIRE mutations affect B-cell tolerance and how much T- and B-cell reactivities overlap remains elusive. An active autoimmunization process within the thymus tissue has been proposed to occur in both APS-1 and thymoma patients as both diseases are associated with thymus dysfunction (Kisand et al., 2011; Meager et al., 2008) and share similarities in

autoantibody profiles (Wolff et al., 2014). According to this hypothesis, the thymus in AIRE deficiency exports abnormal and already activated T cells capable of helping autoantibody production of B cells (Kisand and Peterson, 2011).

## IMMUNOLOGIC MARKERS IN DIAGNOSIS

Autoantibodies are often diagnostic or even predictive markers for the clinical disease. The presence of high titer and persistent anti-IFN- $\alpha$  and  $\omega$  autoantibodies in almost 100% of APS-1 patients provides an easy, early, and cost-efficient way to screen for APS-1. Positive tests should be confirmed by sequencing AIRE gene since these antibodies can be found in other conditions.

In addition, autoantibodies to the steroidogenic enzymes (P450c21, P450c17, and P450scc) are significant and specific markers for onset of Addison's disease. Antibodies against at least one of the three antigens are found in 84% of the patients with Addison's disease (Brozzetti et al., 2010a; Soderbergh et al., 2004). Furthermore, hypogonadism is well associated with the presence of autoantibodies to P450scc protein and recently against NALP5 (Brozzetti et al., 2015). For type 1 diabetes, autoantibodies against GAD65, IA-2, and Zn8T are used. The presence of anti-P450c21 antibodies in patients with autoimmune thyroid disease or type 1 diabetes, but without Addison's disease (Barker et al., 2005), would indicate risk for later development of overt Addison's disease, although the progression to overt Addison's disease may take years. Among relatives with organs-specific autoimmunity, individuals with normal adrenal function and P450c21 autoantibodies, about 15%, progressed to adrenal failure within 5 years (Coco et al., 2006).

## TREATMENT AND OUTCOME

In patients with APS-1, anticandidal drugs such as amphotericin B, ketoconazole, or fluconazole are used in treatment of the candidiasis. Itraconazole has been reported to be effective for nail candidiasis; however, 4–6-month treatment is needed to eliminate the infection (Rautemaa et al., 2007; Rautemaa et al., 2008a; Rautemaa et al., 2008b). Clinical follow-up of oral candidal infection is needed at least once or twice per year, and, because of risk of cancer, attention should be paid to suppression of the oral infection. Smokers are at particular risk.

Replacement therapy with hormones has been efficiently used for Addison's disease and hypoparathyroidism. Patients with Addison's disease are treated with hydrocortisone at the smallest dose that relieves symptoms, usually 10 + 5 + 5 mg a day (the corresponding doses of cortisone acetate is 12.5 + 6.25 + 6.25 mg). A dual release formulation of hydrocortisone is now available, given once daily. Fludrocortisone is used to replace aldosterone, 0.05–0.02 mg once daily.

The therapy of hypoparathyroidism is aimed at maintaining normal calcium levels, and serum calcium and phosphate levels should be monitored regularly. Therapies are calciferol sterols (vitamin D hydroxylated forms, calcidiol, or calcitriol) and calcium salt preparations, preferably calcium carbonate, but these, however, do not efficiently substitute for parathyroid hormone and are difficult to regulate. As the calcium levels may vary significantly over a short time, there are significant risks for both hypo- and hypercalcemia. Recently available recombinant parathyroid hormone may improve the treatment of the hypoparathyroidism in APS-1 patients (Winer et al., 2012) but is currently not recommended due to the risk of osteosarcoma in children and lack of studies proving efficiency in relation to cost. The patients should receive advice and written information about the symptoms complications and risk elements of the disease. APS-1 may cause great psychosocial burden as the persistent risk of developing new disease components can be a source of continuous distress (Perheentupa, 2006).

There is unfortunately no established immune modulation treatment of APS. Treatment with immunosuppressive drugs, cyclosporine A, directed against T cells, produce temporary remission of the disease in APS-2 patients (Csaszar and Patakfalvi, 1992). In a pilot trial, one out of six patients with recent-onset autoimmune Addison's disease regained adrenocortical function after treatment with rituximab (Pearce et al., 2012). Immunotherapy of type 1 diabetes with anti-CD3 monoclonal drugs might be considered a treatment option. In APS-1, immunotherapy is indicated for some of the components. Autoimmune hepatitis can be successfully treated with steroid and

azathioprine (Perheentupa, 2006), interstitial lung disease could respond to rituximab and cyclosporine A (Popler et al., 2012), and cyclosporine A and mycophenolate mofetil have shown beneficial effects on malabsorption in individual patients (Ulinski et al., 2006; Ward et al., 1999). For keratitis topical treatment with steroids and cyclosporine can induce remission if started early. Unfortunately, systematic studies of the effect of immunotherapy is lacking in APS-1.

## CONCLUDING REMARKS—FUTURE PROSPECTS

Recent years have provided remarkable progress in our knowledge about the mechanisms of autoimmune polyendocrinopathies in APS-1 and APS-2. The autoimmune reaction destroys with high precision the endocrine organs, which often express tissue-specific proteins. The identification of the autoantibody targets in APS has revealed that the autoantigens often belong to related protein families, raising the question of exactly how the immune system selects specific targets for autoimmune reactivity. Clinically, assay of autoantibodies can be used for diagnostic purposes. The presence of antibodies against IFN- $\alpha$  and IFN- $\omega$  is almost diagnostic for APS-1 if myasthenia gravis and thymoma has been ruled out. The pattern of autoantibodies is an early phenomenon which correlates to organ manifestations and could, therefore, predict future disease, for instance oophoritis.

Much effort is being put into the identification of genes involved in APS-2. Clearly, MHC genes have the dominant role, but whether an Addison-specific gene association exists is not yet clear. Environmental factors in APS-2 certainly remain to be clarified and deserve more attention. Although a monogenic disease, APS-1 seems to be influenced by environmental, stochastic, and/or other genetic factors to account for the variety of clinical symptoms and disease expressions. The possibility that heterozygous deficiency of *AIRE* in combination with other genetic defects might contribute to the occurrence of autoimmunity is worthy of further investigations.

### Acknowledgment

The authors are grateful to Dr. Kai Kisand for valuable comments to the manuscript.

## AUTOIMMUNE THYROIDITIS

### Historic Background

The clinical features of myxedema, the end stage of autoimmune thyroiditis (AT), were defined in 1874 by Gull, and Murray, in Newcastle-upon-Tyne, was the first to give thyroid extract as treatment in 1891. The characteristic lymphocytic infiltration (struma lymphomatosa) was first noted by Hashimoto in 1912. Proof that AT was due to the loss of self-tolerance came from Rose and Witebsky (1956) who showed that rabbits immunized with homologous thyroid extract and adjuvant developed a thyroid lymphocytic infiltrate and thyroglobulin (TG) antibodies. The latter were detected in Hashimoto's thyroiditis during the same year by Roitt et al. (1956).

### Clinical, Pathologic, and Epidemiologic Features

Several types of AT have been described (Table 40.1). Two in particular, goitrous (Hashimoto's) thyroiditis and atrophic thyroiditis (primary myxedema), result in hypothyroidism (Pearce et al., 2003). The goiter in Hashimoto's thyroiditis is usually firm and painless, with an irregular surface. Patients are often euthyroid at

**TABLE 40.1** Types of Autoimmune Thyroiditis

Type	Course	Features
Goitrous (Hashimoto's) thyroiditis	Chronic: leads to hypothyroidism	Goiter: moderate-to-extensive lymphocytic infiltration and variable fibrosis
Atrophic thyroiditis (primary myxedema)	Chronic hypothyroidism	Atrophy: fibrosis and variable lymphocytic infiltrate
Juvenile thyroiditis	Chronic but may remit	Small goiter with moderate lymphocytic infiltrate
Postpartum thyroiditis	Transient thyrotoxicosis and/or hypothyroidism 3–6 months after delivery	Small goiter with some lymphocytic infiltrate
Silent thyroiditis	Transient thyrotoxicosis and/or hypothyroidism	Small goiter with some lymphocytic infiltrate
Focal thyroiditis	Progressive in some patients	Occurs in 20%–40% thyroid specimens at autopsy: associated with thyroid carcinoma

presentation but serum thyroid-stimulating hormone (TSH) levels can be elevated even if thyroxine (T4) levels are within the reference range, representing subclinical thyroid failure. Primary myxedema is typically identified when hypothyroidism is apparent clinically and biochemically.

Autoimmunity accounts for over 90% of the noniatrogenic hypothyroidism in iodine-sufficient countries. Women are 5–10 times more likely to be affected, with a peak incidence at 50–60 years of age. The prevalence of AT in the general Caucasian population is 0.5 per 1000 (but only half this in black people), whereas thyroid autoantibodies can be found in up to 20%, reflecting the presence of focal thyroiditis (Eaton et al., 2010).

Pathological changes in AT range from mild focal thyroiditis to extensive lymphocytic infiltration and scarring (Fig. 40.1). In Hashimoto's thyroiditis, there is a dense infiltration by lymphocytes, plasma cells, and macrophages, and germinal center formation. Thyroid follicles are progressively destroyed and, in the process, the cells undergo hyperplasia and oxyphil metaplasia to become Hürthle cells. In rare cases, there are concurrent changes of Graves' disease, so-called hashitoxicosis. There is a variable degree of fibrosis and, when this is extensive, the picture may resemble primary myxedema, in which the gland is atrophic and there is extensive fibrosis with the loss of normal lobular architecture and minimal or modest lymphocytic infiltration. Patients with high serum IgG<sub>4</sub> levels and increased IgG<sub>4</sub>-positive plasma cells in the thyroid have more stromal fibrosis, lymphoplasmacytic infiltration, and hypothyroidism (Kottahachchi and Topliss, 2016). The histology in postpartum and silent thyroiditis resembles Hashimoto's thyroiditis.

## Autoimmune Features

### Autoantibodies

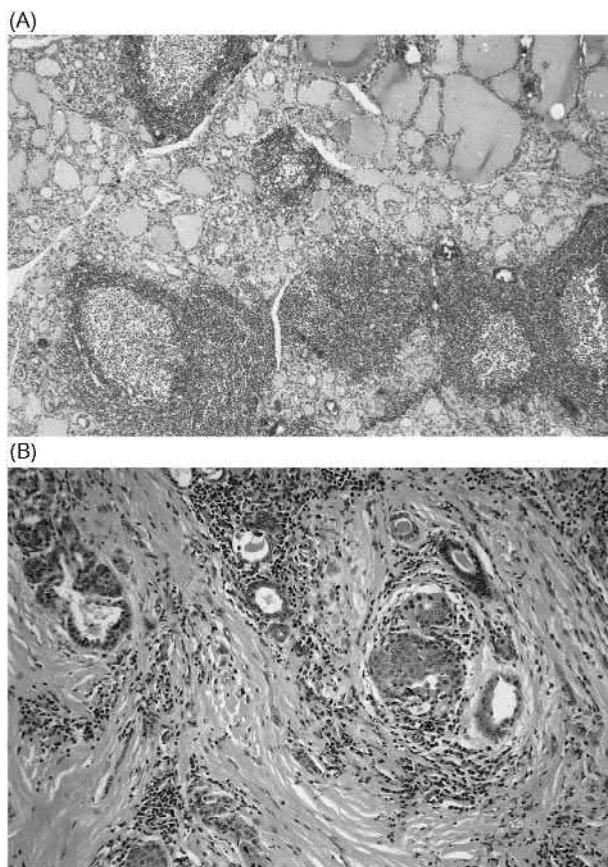

Circulating autoantibodies against TG and thyroid peroxidase (TPO) are found, often at very high levels, in most patients with AT. These antibodies are common, albeit at low levels, in association with focal thyroiditis.

### THYROGLOBULIN ANTIBODIES

TG is a 660-kDa homodimeric glycoprotein secreted by thyroid follicular cells (TFC) and stored in the luminal colloid. At 4–8 hormonogenic sites, iodinated tyrosine residues couple to form T4 or triiodothyronine (T3). The iodination state of TG alters its immunogenicity in animals and in man (Saboori et al., 1999). There are two major and one minor antibody epitopes on each 330-kDa subunit, and the wide spacing of these prevents IgG cross-linking and therefore complement fixation. The restriction of the response to three epitopes is only relative, as TG antibodies recognize an increasing number of determinants as their titer rises and somatic hypermutation occurs (McIntosh et al., 1998). Antibody reactivity is predominantly in the IgG<sub>1</sub> and IgG<sub>4</sub> subclasses but not light chain-restricted.

### THYROID PEROXIDASE ANTIBODIES

TPO is a 100–105-kDa apical membrane protein responsible for tyrosine iodination and coupling in the formation of thyroid hormones. The molecular characterization of this autoantigen has been reviewed extensively

**FIGURE 40.1** Pathology of autoimmune hypothyroidism (A) Hashimoto's thyroiditis showing germinal center formation; (B) primary myxedema with extensive fibrosis. (Original magnification:  $\times 100$ ). Photo courtesy of Dr. Judith Channer, Northern General Hospital, Sheffield.

(McLachlan and Rapoport, 2007). Antibodies to TPO have a similar IgG subclass distribution to TG but are kappa light chain-restricted (McIntosh et al., 1998). A total of 80% of the TPO antibodies recognize an immunodominant region involving overlapping, conformational epitopes in two extracellular domains: specific patterns of TPO autoantibody recognition are stable in an individual and genetically transmitted in AT families (Jaume et al., 1999). In vitro, TPO can bind C4 complement component, which may contribute to the susceptibility of TFC to destruction (Blanchin et al., 2003).

#### OTHER AUTOANTIBODIES

TSH-receptor (TSH-R) blocking antibodies (TBAb) are found in around 20% of the patients with AT (Diana et al., 2017). They contribute significantly to hypothyroidism in some patients, but there is no close correlation with the presence or absence of a goiter (Feingold et al., 2009). Other thyroid-specific autoantibodies, found in 10%–20% of the patients, recognize the  $\text{Na}^+/\text{I}^-$  transporter and pendrin, but any importance of these in pathogenesis is unknown (Brix et al., 2014). Autoantibodies against T4 and T3 occur in 15%–35% of the patients with AT. AT occurs in association with many other autoimmune disorders (Boelaert et al., 2010), and the respective autoantibodies may help in diagnosing these associated conditions.

#### T-Cell Responses

A major site of autoreactivity is within the thyroid itself, although autoimmune responses can also be detected within the draining lymph nodes and bone marrow (Weetman et al., 1984). The recruitment of lymphocytes to the thyroid requires upregulation, on endothelial cells, of various adhesion molecules and selectins, and the infiltrating lymphocytes express the reciprocal adhesion molecules, including CD11a, CD18, CD29, CD49a, and CD49e (Marazuela, 1999). The local infiltrate produces an array of chemokines which aid homing, including CXCL12, CXCL13, and CCL22, particularly when lymphoid follicles are present, and the TFC contribute to

the chemokine pool, exacerbating the autoimmune process (Liu et al., 2008). Most phenotyping and functional studies on T cells have used the readily sampled peripheral blood: this source may reflect poorly (if at all) the responses within the autoimmune target.

### STUDIES OF T-CELL PHENOTYPES

The number of circulating HLA-DR<sup>+</sup> (activated) T cells is elevated and CD8<sup>+</sup> T cells are reduced, but only in active thyroiditis (Iwatani et al., 1992). CD4<sup>+</sup> T cells predominate in the thyroid infiltrate and many of these are activated (Aichinger et al., 1985). The majority of T cells express the  $\alpha\beta$  receptor and no obvious bias in T-cell receptor usage is apparent (McIntosh et al., 1997). Although a pauciclonal T-cell response seems likely in early AT, by the time of clinical presentation, there is spreading of the immune response to produce a polyclonal T-cell response, directed against an array of autoantigens and epitopes.

#### **Functional Studies**

Weak T-cell proliferative responses against TG and TPO are found in many patients and can be enhanced by IL-2 supplementation (Butscher et al., 2001). To identify T-cell epitopes for TPO, circulating T cells from patients with AT have been stimulated with overlapping synthetic peptides (Tandon et al., 1991). No dominant epitope has been identified; instead there is considerable heterogeneity both within and between individual patients. A T-cell epitope on TG has been identified as a strong and specific binder to the major histocompatibility complex (MHC) class II disease susceptibility HLA-DR $\beta$ 1-Arg74 molecule, and this stimulates T cells from both mice and humans with AT (Menconi et al., 2010). Such an epitope could initiate an immune response that then spreads to involve other autoantigens and fits with observations in an animal model of AT that self-tolerance may be broken first for TG and subsequently for TPO (Chen et al., 2010). Impaired activity in T regulatory cells (Tregs) has been demonstrated in patients with AT and with Graves' disease (Glick et al., 2013).

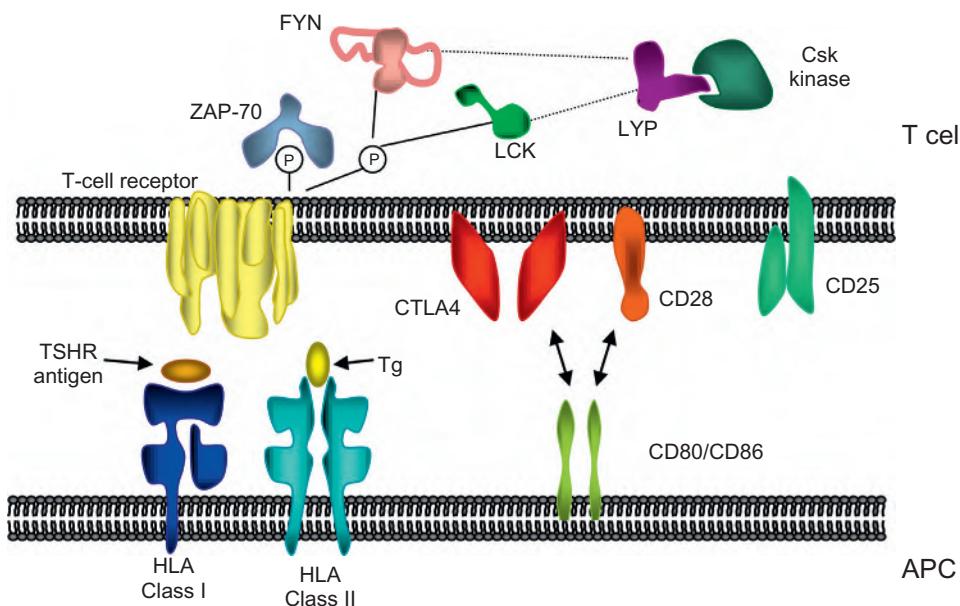

Reverse transcription of cytokine mRNA and cDNA amplification has revealed a mixed Th1 and Th2 response in Hashimoto's thyroiditis (Aijan et al., 1996). The demonstration of MHC class II expression on TFC in Hashimoto's thyroiditis and Graves' disease gave rise to the concept that such "aberrant" expression could initiate or perpetuate the autoimmune response by converting the TFC into antigen-presenting cells (Bottazzo et al., 1983). However, class II expression is restricted to TFC adjacent to T cells producing IFN- $\gamma$  (Hamilton et al., 1991), and only this cytokine is capable of initiating class II expression in vitro. MHC class II expression is found on TFC in experimental AT (EAT) induced by neonatal thymectomy (see below) but always follows the appearance of a lymphocytic infiltrate. TFC do not express costimulatory molecules even after cytokine exposure (Marelli-Berg et al., 1997). Together these results indicate that TFC are unlikely to initiate the autoimmune response.

T-cell lines and clones derived from the thyroids of patients can be activated by class II-expressing TFC (Londei et al., 1985). Such T cells are likely to have been previously activated by classic antigen-presenting cells and are no longer dependent on B7 costimulation (Marelli-Berg et al., 1997). Anergy can be induced in B7-dependent, naïve T cells by class II-positive TFC, and this type of peripheral tolerance may be important in regulating autoreactive T cells within the normal thyroid. In established AT, however, T cells are resistant to tolerance induction (Dayan et al., 1993) and class II-expressing TFC may then help to perpetuate the autoimmune response. TFC may participate in the autoimmune process in other ways besides MHC class II expression, through the expression of other immunologically active molecules such as CD40 and CD56.

### Genetic Features

The role of genetic factors in AT (Fig. 40.2) is suggested by the frequent presence of thyroid autoantibodies in other family members and the association of thyroiditis with other endocrinopathies as part of the type 2 autoimmune polyglandular syndrome. Twin studies show a 0.55 concordance rate in monozygotic, but not dizygotic, twins, and similar findings have been reported for the aggregation of thyroid autoantibodies in the euthyroid twins of individuals with AT (Brix et al., 2000, 2004).

As with most autoimmune disorders, associations with HLA alleles have been extensively investigated, producing conflicting results (Tomer and Davies, 2003). Initially it appeared that primary myxedema and Hashimoto's thyroiditis in Caucasians had distinct associations with HLA-DR3 and -DR5, respectively, but subsequent studies have shown that Hashimoto's thyroiditis is associated with HLA-DR3 and to a lesser extent HLA-DR4. Postpartum thyroiditis has a weak association with HLA-DR5.

**FIGURE 40.2** Genetic associations in autoimmune thyroid disease. HLA classes I and II polymorphisms on the APC interact with presentation of the polymorphic thyroid antigens TSH-R and Tg. The binding of CTLA-4 and CD28 with CD80/CD86 (B7), IL-2 signaling via CD25, and *PTPN22*-encoded signaling all regulate T-cell activation. APC, Antigen-presenting cell; Tg, thyroglobulin; TSH-R, thyroid-stimulating hormone receptor. From Zeitlin, A.A., et al., 2008. *Genetic developments in autoimmune thyroid disease: an evolutionary process*. *Clin. Endocrinol. (Oxf.)* 68, 671–682, with permission.

Polymorphism in *CTLA-4* confers a relative risk of around 1.3–1.5 (Ji et al., 2013). The existence of many genes with individual small effects, gene–gene interactions, and subset effects may explain why it has been more difficult to show the consistent effects of other individual genes in patient populations than would be expected from the twin data on genetic susceptibility (Tomer, 2010). Genome-wide association studies are beginning to reveal novel loci such as *LPP* and *BACH2* which are implicated in other autoimmune disease as well as AT (Cooper et al., 2012), and polymorphisms in *MAGI3* are associated with progression from TPO antibody-positivity to full-blown AT (Medici et al., 2014). Around 45% of the Turner's syndrome patients have TPO antibodies and a third become hypothyroid (Mortensen et al., 2009); there is a similar propensity in Down's syndrome, and in both cases, there may be progression to Graves' disease (Aversa et al., 2014).

## Environmental Influences

The female preponderance of AT may be due to the influence of sex steroids, although skewed X chromosome inactivation may be a further factor. Certainly in EAT, estrogens or progesterone exacerbates thyroiditis, and this is reversed by testosterone (Okayasu et al., 1981; Ansar-Ahmed et al., 1983). Pregnancy ameliorates AT, but there is an exacerbation in the year after delivery, reflected by a rise in TPO antibody levels. In some women with a previously mild thyroiditis, the enhanced autoimmune response is sufficient to cause biochemical or clinical thyroid dysfunction, and this is termed postpartum thyroiditis (Alexander et al., 2017). These changes may be related to the fluctuations in regulatory factors operating to maintain fetal tolerance during pregnancy. Although usually a transient phenomenon, around a quarter of such women develop permanent hypothyroidism within 10 years, so that pregnancy is a risk factor which precipitates clinical disease in predisposed subjects. Fetal microchimerism may play a pathogenic role via intrathyroidal chimeric cells breaking immunological tolerance, and such a possibility is supported by the increase in the prevalence of high titer TPO antibodies with advancing parity (Greer et al., 2011).

A strong influence of exogenous environmental factors is suggested by epidemiological data, such as the 10-fold rise in AT prevalence over three decades in Italy (Benvenega and Trimarchi, 2008). There is no convincing evidence for a direct role of infection in etiology (Tomer and Davies, 1993). AT is more prevalent in the areas of increased prosperity and hygiene, compatible with the 'hygiene hypothesis' which suggests that exposure to microbial antigens may skew the immune response to protect against autoimmunity (Kondrashova

et al., 2008). Indirect evidence for dietary iodine-induced injury is provided by studies of iodine-deficient regions, and an increase in thyroid autoantibodies and lymphocytic thyroiditis shortly after iodine supplementation has generally been reported. As well as causing thyroid injury through the generation of reactive oxygen metabolites (Bagchi et al., 1995), iodine enhances the immunogenicity of TG (Barin et al., 2005). Deficiency of both vitamin D and selenium has also been associated with AT, but trials of selenium supplementation have shown only a modest effect on thyroid autoantibody levels (Wichman et al., 2016).

Smoking is associated with a lower risk of AT and smoking cessation temporarily increases the risk (Wiersinga, 2013); alcohol consumption is also a protective influence (Effraimidis et al., 2012). The administration of lithium may exacerbate AT both immunologically and biochemically, but the adverse effect of the cytokine IFN- $\alpha$  and other antineoplastic drugs on autoimmune thyroid dysfunction is more striking (Hamnvik et al., 2011).

## In Vivo Models

AT can be induced experimentally in animals, and also occurs spontaneously, with features most closely resembling Hashimoto's thyroiditis.

### **Immunization-Induced Thyroiditis**

In mice and rats, the strength of the autoimmune response to immunization with TG in adjuvant is strain dependent. Murine EAT susceptibility (as shown by the severity of lymphocytic thyroiditis) is governed by the class II I-A subregion of the H-2 major histocompatibility complex (Vladutiu and Rose, 1971). H-2<sup>k,s</sup> strains may even develop EAT with syngeneic TG immunization alone, demonstrating that untolerized autoreactive T cells exist in normal animals, in which they are usually under active regulation (ElRehewy et al., 1981). The influence of I-E is strain dependent but less clear. MHC classes I, K, and D alleles also influence susceptibility, presumably by determining the strength of effector cytotoxic T-cell interaction with the thyroid cell target. Transgenic mice expressing HLA-DR3, but not HLA-DR2, develop EAT after TG immunization, confirming a role for this HLA specificity in thyroiditis (Kong et al., 1996).

Female animals have worse EAT than males, and this is dependent on sex hormones, estrogen excess worsening thyroiditis, and testosterone ameliorating it (Okayasu et al., 1981). Another important influence in mice is the level of circulating TG, which can induce Tregs (Kong et al., 2009). The thyroiditis after immunization consists of CD4<sup>+</sup> and CD8<sup>+</sup> T cells and macrophages, with only a small percentage of B cells. Disease can be transferred by T cells but not by TG antibodies, and the critical effector cells are CD8<sup>+</sup> cytotoxic T cells which require specific CD4<sup>+</sup> T cells for their induction (Creemers et al., 1983). Immunization with the immunodominant T-cell epitope of murine TPO will also induce EAT (Ng and Kung, 2006).

### **Experimental Autoimmune Thyroiditis Resulting From Immune Modulation**

Neonatal thymectomy in certain strains of mice or rats, or thymectomy plus sublethal irradiation in certain strains of rats, results in severe EAT (Penhale et al., 1973; Kojima et al., 1976), as well as other autoimmune endocrinopathies. From these initial observations came the understanding of the crucial role of CD4<sup>+</sup>, CD25<sup>+</sup> Tregs in preventing autoimmunity (Sakaguchi et al., 2001). Other maneuvers affecting T cells, such as treatment of neonatal mice with cyclosporin A or T-cell depletion and reconstitution, can induce EAT (Sakaguchi and Sakaguchi, 1989). The depletion of CD7/CD28 in knock-out mice also prevents generation of CD4<sup>+</sup>, CD25<sup>+</sup> Tregs and results in EAT (Sempowski et al., 2004). The induction of EAT by T-cell modulation elegantly demonstrates the presence of thyroid-reactive T cells in the normal newborn repertoire. These CD4<sup>+</sup> T cells may be destined for deletion after birth, but there is now compelling evidence for incomplete tolerance and active suppression by Tregs even later.

In addition to MHC and non-MHC genes, environmental factors play an important role in susceptibility. Rats raised under specific pathogen-free conditions until weaning are resistant to EAT following thymectomy and irradiation, but the transfer of normal gut microflora results in EAT in the germ-free animals (Penhale and Young, 1988). It is unclear whether radiation-induced damage to the intestine is involved in this effect of gut microflora.

### **Spontaneous Autoimmune Thyroiditis**

Several species develop spontaneous thyroiditis. Lymphocytic infiltration of the thyroid and TG antibodies occur in around 60% of the diabetic and 10% of the nondiabetic BioBreeding (BB) rats, but diabetes-prone

sublines have a range of prevalence, from 100% in the NB line to 5% in the BE line, suggesting that diabetes is not tightly linked genetically to EAT (Crisa et al., 1992). The Buffalo strain rat has a low spontaneous incidence of thyroiditis, reaching a maximum of 25% in old, multiparous females (Noble et al., 1976). Nonobese diabetic (NOD) mice infrequently develop thyroiditis, but this trait is greatly enhanced by deficiency of the chemokine receptor CCR7, possibly related to the roles of CCR7 in negative selection of autoreactive T cells in the thymus and Treg control (Martin et al., 2009). CD28-knockout NOD mice have a deficiency of Tregs and develop severe thyroiditis, with thyroid fibrosis and hypothyroidism (Ellis et al., 2013).

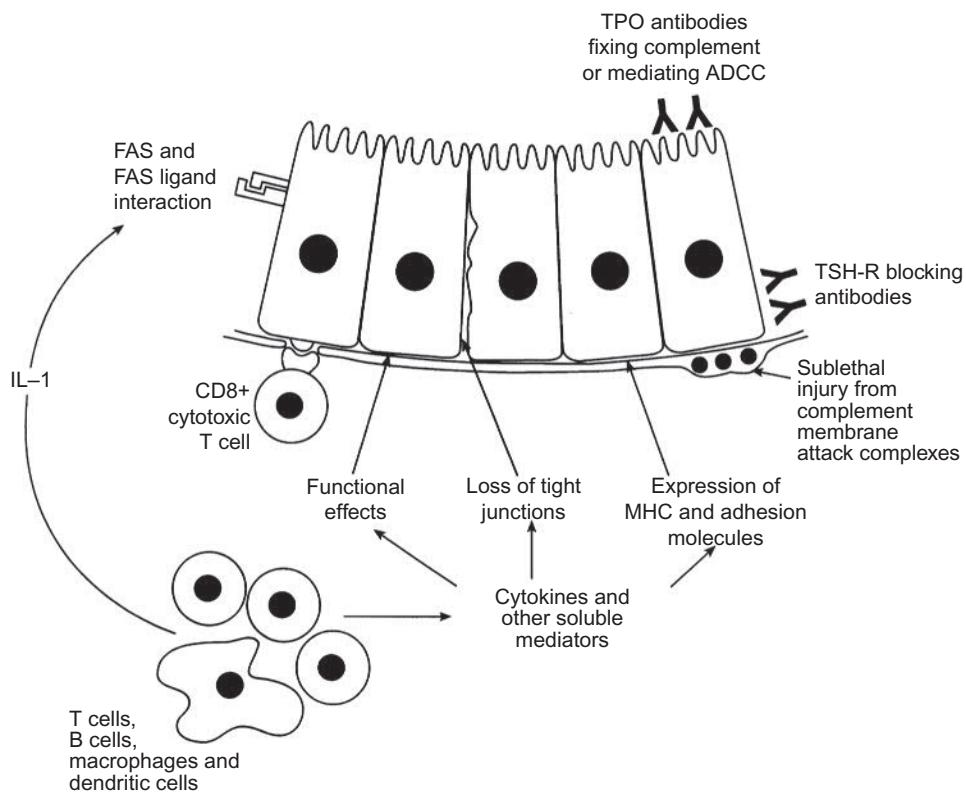

Spontaneous AT in the Obese strain (OS) chicken is the closest animal model of Hashimoto's thyroiditis. The birds were originally bred from a White Leghorn flock of Cornell strain chickens for phenotypic features of hypothyroidism. Over time, the factors influencing disease development have changed: the importance of MHC genes and sex has diminished and the main genetic determinants in current OS chickens govern target organ susceptibility, T-cell hyperreactivity, and corticosteroid responses (Wick et al., 2006). Unlike other models, OS chickens develop severe hypothyroidism as well as a lymphocytic thyroiditis and TG antibodies, and require T4 supplementation to thrive. The disease is T-cell dependent as thymectomy at birth prevents disease, although later thymectomy exacerbates thyroiditis, presumably by altering the balance of T cell-mediated regulation.

## Pathologic Effector Mechanisms

Several antibody-dependent and cell-mediated mechanisms contribute to thyroid injury in autoimmune hypothyroidism, and differences in the relative importance of each may determine some of the clinical and pathological variants described above (Fig. 40.3).

### Antibody-Mediated Injury

Immune complexes are deposited in the basement membrane around the thyroid follicles in Hashimoto's thyroiditis (Pfaltz and Hedinger, 1986), and terminal complement complexes are also present at this location indicating the formation of membrane attack complexes (Weetman et al., 1989). TFC are relatively resistant to lysis,

**FIGURE 40.3** Mechanisms of thyroid destruction in autoimmune hypothyroidism. From Weetman, A.P., 2002. *Autoimmune thyroid disease*. In: Wass, J.A.H., Shalet, S.M. (Eds.), *Oxford Textbook of Endocrinology and Diabetes*. Oxford University Press, pp. 392–408, with permission.

through enhanced expression multiple regulators of complement activation, especially CD59, in response to cytokines derived from the infiltrating lymphocytes and macrophages (Tandon et al., 1994). After sublethal complement attack, TFC are less able to respond to TSH stimulation and also release cytokines (IL-1, IL-6), prostaglandin E<sub>2</sub>, and reactive oxygen metabolites, which may have proinflammatory effects (Weetman et al., 1992).

TPO antibodies are generally assumed to be the major mediators of complement fixation and activation within the thyroid and may also provoke damage by antibody-dependent cell-mediated cytotoxicity (Rebuffat et al., 2008). Cytokines such as IL-1 may be critical in dissociating the junctional complex and thus allowing access of autoantibodies to apically expressed TPO and other such antigens (Nilsson et al., 1998), in turn implying a secondary role for these antibodies in pathogenesis and explaining why neonates born to mother with TPO antibodies have normal thyroid function. TBAb directly impair thyroid cell function, as shown by their placental transfer which causes transient neonatal hypothyroidism (Matsuura et al., 1980).

### **T-Cell Mediated Injury**

Despite the strong lead provided by studies in EAT, there is only modest direct evidence that T-cell mediated injury is important in autoimmune hypothyroidism. Two groups have derived CD8<sup>+</sup> T-cell clones and lines from patients with Hashimoto's thyroiditis which lyse autologous TFC in a MHC class I-restricted fashion (MacKenzie et al., 1987; Sugihara et al., 1995). The autoantigen specificity of these T cells has not been elucidated. Indirect evidence for the importance of cytotoxic T cells in pathogenesis is provided by the demonstration of frequent perforin-containing T cells in the intrathyroidal CD8<sup>+</sup> T-cell population in Hashimoto's thyroiditis (Wu et al., 1994). T cells may also provoke thyroid dysfunction by release of cytokines. There is an increase in intrathyroidal Th17 lymphocytes and enhanced synthesis of Th17 cytokines in AT, implying a role for these proinflammatory cells in pathogenesis (Figueroa-Vega et al., 2010). Circulating platelet-derived microvesicles are increased in AT patients and can inhibit the differentiation of Tregs and induce Th17 cell differentiation (Rodríguez-Muñoz et al., 2015). Hürthle cell formation results from the overexpression of immunoproteasome subunits secondary to chronic inflammation (Kimura et al., 2009).

Attention has also focused on the expression of death receptor-mediated apoptosis as a major pathway for TFC destruction, based on the finding of both Fas (CD95) and Fas ligand (CD95L) on TFC in Hashimoto's thyroiditis (Giordano et al., 1997). Fas expression by TFC was upregulated by IL-1 $\beta$ , leading to the suggestion that cytokines could induce cytotoxicity through this pathway by suicide or fratricide as Fas interacted with FasL. Moreover, it has been proposed that FasL on TFC induces apoptosis in the infiltrating lymphocytes, suggesting that a T cell-mediated cytotoxic mechanism for thyroid destruction is less important than autocrine/paracrine Fas–FasL interaction (Stassi et al., 1999). Other interpretations have been put on the role of such apoptosis, not least because of the possible role of other decoy death receptors and regulators of apoptosis signaling, and these multiple complex pathways may explain why induction of apoptosis in AT results in the destruction of thyroid cells, while apoptosis in the graves' disease leads to the damage of thyroid-infiltrating lymphocytes (Wang and Baker, 2007).

### **Autoantibodies as Potential Immunological Markers**

The diagnosis of autoimmune hypothyroidism is usually straightforward, patients having biochemical evidence of hypothyroidism plus TG and/or TPO antibodies which can easily be measured by passive hemagglutination or immunoassays. An abnormal thyroid ultrasound pattern is also highly predictive of AT (Raber et al., 2002). Fine-needle aspiration biopsy is used in difficult cases, especially to exclude an associated lymphoma.

### **Treatment and Outcome**

Treatment consists of T4 replacement (Jonklaas et al., 2014), which is generally straightforward, and future attempts at immunomodulation seem unlikely to improve outcome. In around 10% of the patients, there may be a spontaneous remission 4–8 years after starting T4, and this is associated with the disappearance of TBAb (Takasu et al., 1992). However, the permanence of such remissions has not been established. Lymphoma is a rare complication of AT.

## Concluding Remarks—Future Prospects

Considerable progress in understanding the pathogenesis of AT has been made in the half century since the first demonstration of EAT and the realization that a similar process accounts for Hashimoto's thyroiditis. Additional work is needed to determine the exact genetic basis for AT and to clarify the relationships between these disorders and Graves' disease, which are associated together in families and sometimes in the same individual. It may also be possible in future to use autoantibody patterns to predict which patients are at most risk of developing hypothyroidism. Determining the exact role for T cell-mediated, thyroid-specific immunoregulation in preventing AT remains complex. There is no doubt that Tregs are important, but so far, the precise mechanisms that control thyroid-specific T cells that have escaped central tolerance in human AT are elusive and not yet able to be exploited therapeutically.

## GRAVES' DISEASE

### Historic Background

The first description of this disorder was by Caleb Parry in 1825, but it was Robert Graves whose name became attached to the disease through his report of four cases published in 1835. Basedow was the first to highlight the association with exophthalmos in 1840. Originally believed to have a cardiac and then neurological origin, the role of the thyroid in Graves' disease became established in the 1890s as thyroidectomy for apparently coincidental goiter improved the other manifestations. The cause remained obscure until [Adams and Purves \(1956\)](#) showed that the serum from Graves' patients contained a long-acting thyroid stimulator (LATS) which was distinct from TSH: working separately, Kriss and McKenzie went on to show this stimulator was an IgG.

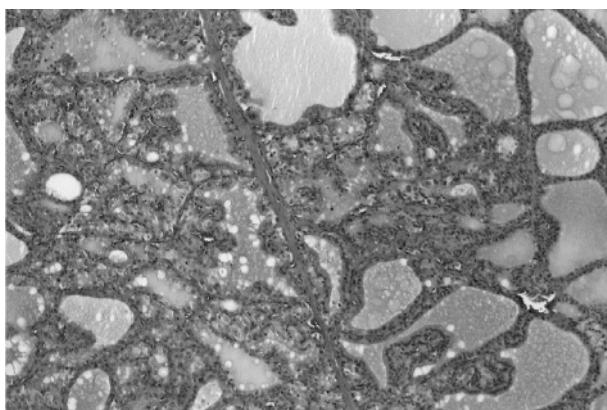

### Clinical, Pathologic, and Epidemiologic Features

Although sharing many immunological features with AT, it is the production of TSH-R-stimulating antibodies (TSAb), which characterizes Graves' disease ([Smith and Hegedüs, 2016](#)). It is the commonest cause of hyperthyroidism, accounting for 60%–80% of the cases. The prevalence is around four per 1000, with a five- to 10-fold higher frequency in women, and it is more common in black and Asian/Pacific Island people ([Eaton et al., 2010](#)). Over 70% of the patients with Graves' disease have thyroid-associated ophthalmopathy (TAO), which can be revealed by scanning techniques showing enlarged extraocular muscles ([Bahn, 2010](#)). Clinically obvious eye disease is apparent in around 50% of the patients ([Fig. 40.4](#)). TAO is not exclusive to Graves' disease, as around 5% of the patients have AT, and another 5% have little evidence of thyroid dysfunction. Thyroid dermopathy (or pretibial myxedema, reflecting the usual site for this complication) occurs in only around 1% of the patients, who typically also have marked TAO ([Fatourechi, 2012](#)).

In the untreated state, there is both hypertrophy and hyperplasia of the thyroid follicles; the epithelium becomes columnar and folded into the follicular lumen, new small follicles form, and there is little colloid ([Fig. 40.5](#)). A variable degree of lymphocytic infiltration occurs, and germinal centers may form. Antithyroid

**FIGURE 40.4** Eye signs in a patient with thyroid-associated ophthalmopathy showing exophthalmos, scleral injection, and periorbital edema.

**FIGURE 40.5** Pathology of Graves' disease showing columnar and folded thyroid epithelium, small new follicles, and active colloid resorption, with "scalloping" of the colloid. dugs diminish the lymphocytic infiltrate and the epithelium reverts to a normal appearance. Lymphoid hyperplasia may occur in the lymph nodes, thymus, and spleen, but reverses with antithyroid drugs.

## Autoimmune Features

### Autoantibodies

TG and TPO autoantibodies occur up to 80% of the patients. TSAb can be detected in over 95% of the patients with current assays. The TSH-R consists of a 398 amino acid extracellular domain with a series of leucine-rich repeats and a hinge region, a 266 amino acid transmembrane spanning domain with seven hydrophobic regions, and an 83 amino acid intracellular domain (Rapoport and McLachlan, 2007). The receptor undergoes complex posttranslational processing at the hinge region to form A- and B-subunits linked by a disulfide bond. Thyroid cells shed the A-subunit, which binds TSAb more strongly than the holoreceptor, and this is an important factor in the induction and affinity maturation of TSAb (Rapoport and McLachlan, 2016). TSAb-induced activation of the TSH-R typically causes a rise in cAMP, but TSH-R antibodies may also cause activation of other intracellular signaling pathways.

The original bioassay method measured release of radioiodine from preloaded thyroid glands after injection of serum or IgG into intact animals, and this activity was termed LATS (Adams and Purves, 1956). Other early assays measured cAMP release from primary TFC cultures or thyroid cell lines (such as FRTL-5); more recently TSH-R-transfected eukaryotic cells have been utilized (Ajjan and Weetman, 2008). A separate type of assay measures displacement of TSH from solubilized or recombinant TSH-R by TSH-R antibodies in a radiolabeled or chemiluminescent format; these antibodies are called TSH-binding inhibiting immunoglobulins or TBII. Current TBII assays have a sensitivity and specificity which exceeds 95% but measure both TSAb and TBAb (which inhibit TSH-induced cAMP release). Therefore the level of TBII gives no direct information on functional activity, but in practice these assays are very useful when interpreted in the clinical context (McLachlan and Rapoport, 2013). Unlike TG and TPO autoantibodies, TSAb are IgG<sub>1</sub> subclass restricted and are often  $\lambda$  light chain-restricted (Zakarija, 1983), suggesting a pauciclonal origin for TSAb in some patients.

The majority of TSH-R B-cell epitopes appear to be conformational and overlap with the binding site for TSH (Rapoport and McLachlan, 2007). Heterogeneity between patients in their antibody binding sites is apparent, for instance by studies using chimeric TSH/luteinizing hormone receptors or monoclonal TSH-R antibodies, and mutated receptors have revealed that a component of the epitope for TSAb is on the N terminus. The epitopes for TBAb overlap with those for TSAb but are more focused on the C terminus and recognize holoreceptor more efficiently. TSH-R neutral antibodies have also been identified which do not stimulate cAMP production but can induce thyroid cell apoptosis in vitro (Morshed et al., 2010).

### T-Cell Responses

Many studies have found a reduction in circulating CD8<sup>+</sup> T cells and an increase in HLA-DR<sup>+</sup> T cells in active Graves' disease (Weetman and McGregor, 1994). Intrathyroidal T cells are CD4<sup>+</sup> and CD8<sup>+</sup> in varying

proportions; similar homing mechanisms to AT account for their localization (Marazuela, 1999). Using overlapping TSH-R peptides covering the extracellular domain, a heterogeneous response was obtained using circulating or intrathyroidal T cells in proliferation assays, with multiple peptides stimulating different patients' cells (Tandon et al., 1992). There is no distinct Th1 or Th2 pattern of response by the stage of disease that specimens are available for study (Okumura et al., 1999). Cytokines such as IL-1, IL-6, IL-8, and IL-10 are strongly expressed, with some cytokines being in part derived from the TFC themselves. As in AT, there are plentiful Tregs in the thyroid in Graves' disease, apparently without the ability to halt disease (Marazuela et al., 2006). This Treg defect may at least in part be the result of impaired plasmacytoid dendritic cell function and elevated levels of thyroid hormone (Mao et al., 2011).

## Genetic Features

Monozygotic twins are around 20%–30% concordant for Graves' disease, at least 10-fold higher than for dizygotic twins (Brix et al., 1998). A consistent but weak association exists between the serologically defined specificity HLA-DR3 and Graves' disease in Caucasians, with a relative risk of 2–3 (Tomer and Davies, 2003). The relative weakness of the contribution of HLA genes is underlined by the low concordance (7%) for Graves' disease in HLA-identical siblings (Stenszky et al., 1985). Many candidate gene polymorphisms (encoding immune receptors, immunoglobulins, and cytokines) have been tested for associations with Graves' disease with inconsistent results (Fig. 40.2). Polymorphisms in *CTLA-4* confer a relative risk of around 2–3 (Yanagawa et al., 1995), and polymorphism in other genes affecting B and T-cell responses, *PTPN22*, *CD25*, *FCRL3*, and *CD226*, have also been associated with Graves' disease (Tomer, 2010). The sharing of these genetic associations with many other autoimmune diseases probably accounts for the frequent concurrence of other autoimmune diseases with Graves' disease and AT.

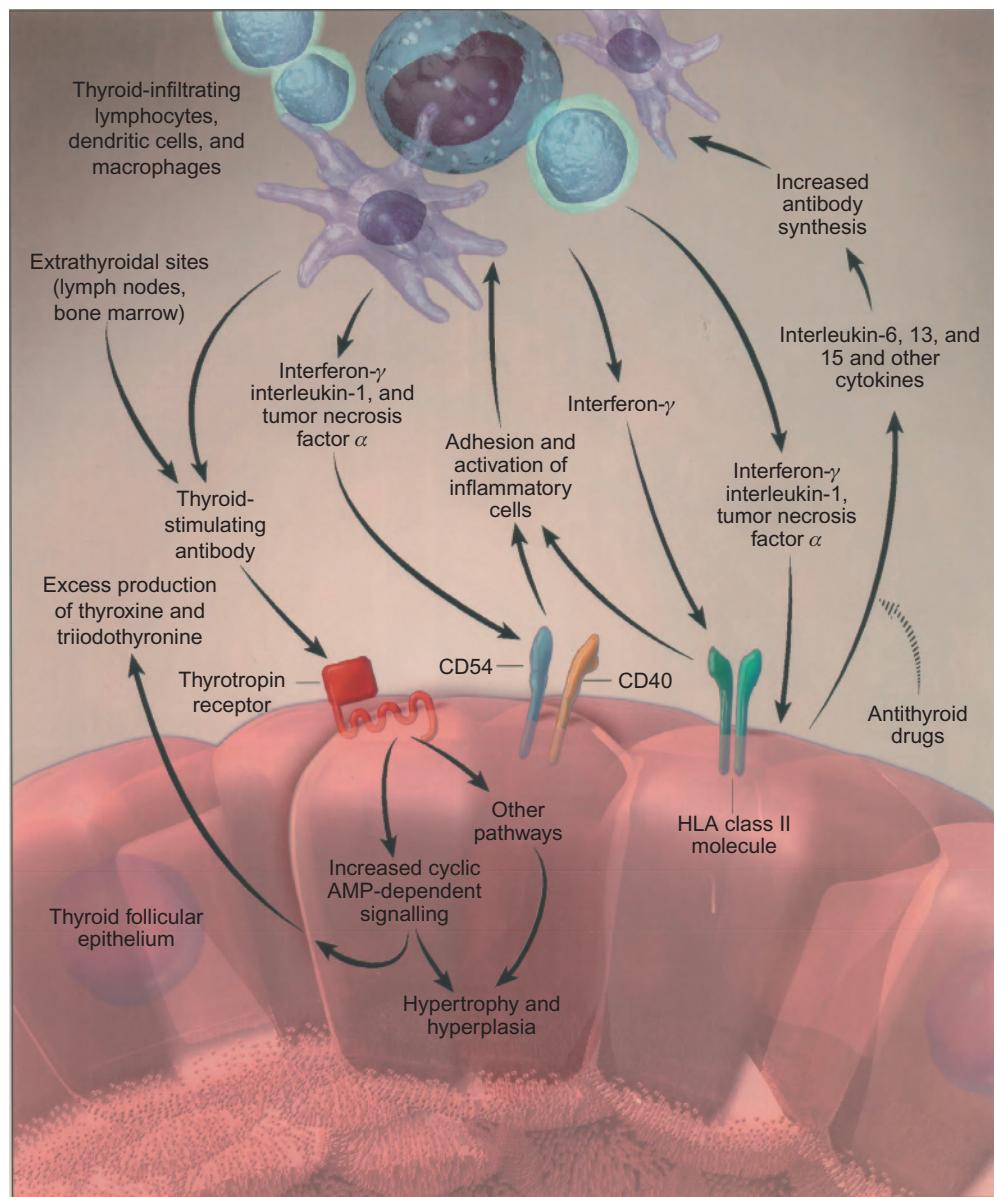

Polymorphisms in the *TSH-R* gene confer susceptibility to Graves' disease, but not autoimmune hypothyroidism, and may be an important factor in determining which members of families with a predisposition to develop thyroid autoimmunity actually get Graves' disease (Brand et al., 2009). Genome-wide association studies using thousands of patients with Graves' disease have revealed many new susceptibility loci including the *RNASET2-FGFR1OP-CCR6* region at 6q27, *MMEL1*, *LPP*, *BACH2*, *FGFR1OP*, and *PRICKLE1*, as well as the gene encoding TG (Chu et al., 2011; Cooper et al., 2012; Zhao et al., 2013).

## Environmental Influences

Women are predisposed to Graves' disease and, as with AT, parity increases the risk by around 10% (Jørgensen et al., 2012). Retrospective studies have shown a significantly higher number of adverse life events during the year preceding the recognition of Graves' disease when patients are compared to matched controls, and stress is also associated with a worse outcome after antithyroid drug treatment (Falgarone et al., 2013). Presumably this effect of stress operates through the interactions between the nervous, endocrine, and immune systems. A high iodine intake increases the risk of developing an autoimmune response against the thyroid, the type being determined by genetic factors. However, in an animal model of Graves' disease produced by immunizing NOD mice with adenovirus expressing the TSH-R A-subunit, increased iodine intake increased the severity of thyroiditis, but not hyperthyroidism, suggesting a dichotomy in these two autoimmune responses (McLachlan et al., 2005).

Evidence for a role of infections is circumstantial (Tomer and Davies, 1993). It remains possible that a variety of infections could precipitate Graves' disease either specifically by molecular mimicry or modulation of TFC behavior, or nonspecifically, by enhancing any ongoing immune responses. Such nonspecific enhancement, presumably mediated by cytokines, would explain the association between attacks of allergic rhinitis and recurrence of Graves' disease (Hidaka et al., 1993).

Smoking is strongly associated with the development of ophthalmopathy and weakly with the development of Graves' disease, although negatively associated with the presence of TG and TPO antibodies in Graves' patients (Bartalena et al., 1995; Hou et al., 2011). Cytokine treatment is sometimes complicated by the development of Graves' disease, although this is less frequent than AT (Hamnvik et al., 2011). Perhaps the most striking example of Graves' disease caused by an obvious external agent is its appearance during the period of immune reconstitution following alemtuzumab or highly active antiretroviral treatments (Weetman, 2009). This type of response may be the result of alteration levels of Tregs as the lymphocyte population is recovering.

**FIGURE 40.6** Pathogenesis of Graves' disease. Hyperthyroidism is the result of TSH-R activation by thyroid-stimulating antibodies. The intrathyroidal inflammatory response is enhanced by cytokines, some of which are derived from the thyroid cells themselves: antithyroid drugs interfere with this step in the pathway. Thyroid cells produce other molecules such as CD54, CD40, and HLA class II which help perpetuate the autoimmune response. TSH-R, Thyroid-stimulating hormone receptor. From Weetman, A.P., 2000. Graves' disease. *N. Engl. J. Med.* 343, 1236–1248, with permission.

## In Vivo Models

There is still no entirely satisfactory animal model of Graves' disease. All are induced rather than spontaneous, and the likely absence of Graves' disease even in great apes suggests that there is something unique about the susceptibility factors for Graves' disease in man (Nagayama, 2007; McLachlan et al., 2011). In the first attempts to produce an animal model, immunization of BALB/c mice with the extracellular domain of TSH-R and adjuvant containing *Bordetella pertussis* induced TBAb, but not TSAb, and a severe thyroiditis (Costagliola et al., 1994), while genetic immunization with TSH-R cDNA produced thyroiditis but without TSAb production (Costagliola et al., 1998). Immunizing AKR/N mice with fibroblasts double transfected with human TSH-R and haploidentical MHC class II genes led to hyperthyroidism caused by TSAb, although without thyroiditis (Yamaguchi et al., 1997).

Subsequently, immunization experiments with adenovirus encoding the TSH-R, especially the A-subunit alone, have been successful in producing a high frequency of disease in mice (Chen et al., 2004). Such immunization in transgenic mice expressing human TSH-R A-subunit has provided an insight into the role for Tregs in determining the disease outcome; the depletion of these cells led to thyroiditis, hypothyroidism, and spreading of the autoimmune response from TSH-R to involve TPO and TG (McLachlan and Rapoport, 2007). This model has also been used to show that pretreatment with the TSH-R A-subunit can deviate the immune response from pathogenic epitopes to the production of neutral TSH-R antibodies (Misharin et al., 2009). NOD mice made transgenic for the human TSH-R develop pathogenic antibodies to the human receptor, especially in females with iodine excess (Rapoport et al., 2015).

Reproducing ophthalmopathy has proved even more challenging. Genetic immunization by electroporation with the TSH-R A-subunit leads to the production of antibodies against the IGF-1 receptor, a possible autoantigen in ophthalmopathy, and orbital fibrosis, in addition to TSAb and thyroiditis (Zhao et al., 2011). However, this was not a consistent response in all animals. Deep-muscle electroporation with plasmid encoding the A-subunit produced either extraocular muscle inflammation or adipogenesis, with associated proptosis, in some, but not all, animals, and this was accompanied by TBAb rather TSAb production (Moshkelgosha et al., 2013). Equally inconsistent results between animals have been obtained using immunization with a different A-subunit vector, with a very little evidence of orbital muscle inflammation or proptosis, although these animals had features of hyperthyroidism (Xia et al., 2017).

## Pathologic Effector Mechanisms

Clearly the main effector mechanism in Graves' disease is the production of TSAb (Fig. 40.6), but the circulating levels of these do not correlate closely with the level of thyroid hormones or the clinical severity of disease, because of a variable, concurrent response against other autoantigens and, in some patients, production of TBAb, which reduce the effects of TSAb. Women with the highest levels of TSAb who become pregnant give birth to babies with transient neonatal thyrotoxicosis.

## Autoantibodies as Potential Immunological Markers

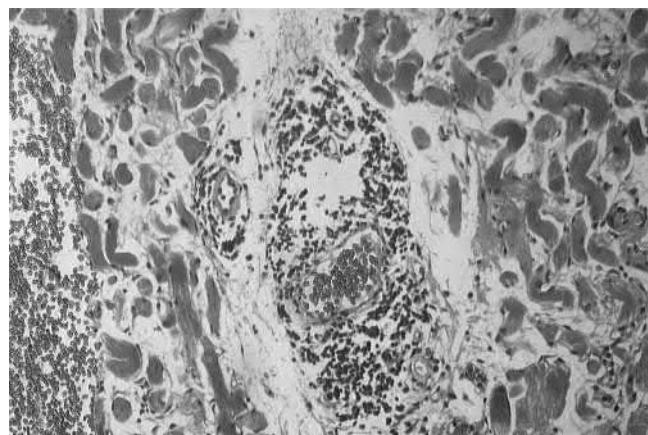

TG and TPO antibodies provide readily available evidence for Graves' disease; although not specific, their presence in a patient with hyperthyroidism strongly suggests the diagnosis. These antibodies are present in 20%–30% of the cases 5–7 years before diagnosis (Hutfless et al., 2011). Although TSAb are not generally measured because present bioassays are laborious, TBII estimation is a cheap, commercially available surrogate which is very useful in confirming the diagnosis of Graves' disease in the absence of clinical evidence such as ophthalmopathy. TSAb or TBII levels have been investigated as predictive markers for the success of antithyroid drug treatment in Graves' disease. Although patients with the highest levels tend to relapse the most, the results are insufficiently accurate for clinical use (Aijan and Weetman, 2008). The most important indication for TBII assay in Graves' disease is in women with known Graves' disease during pregnancy, when a level more than threefold higher than normal predicts the risk of neonatal thyrotoxicosis (Alexander et al., 2017).

## Treatment and Outcome

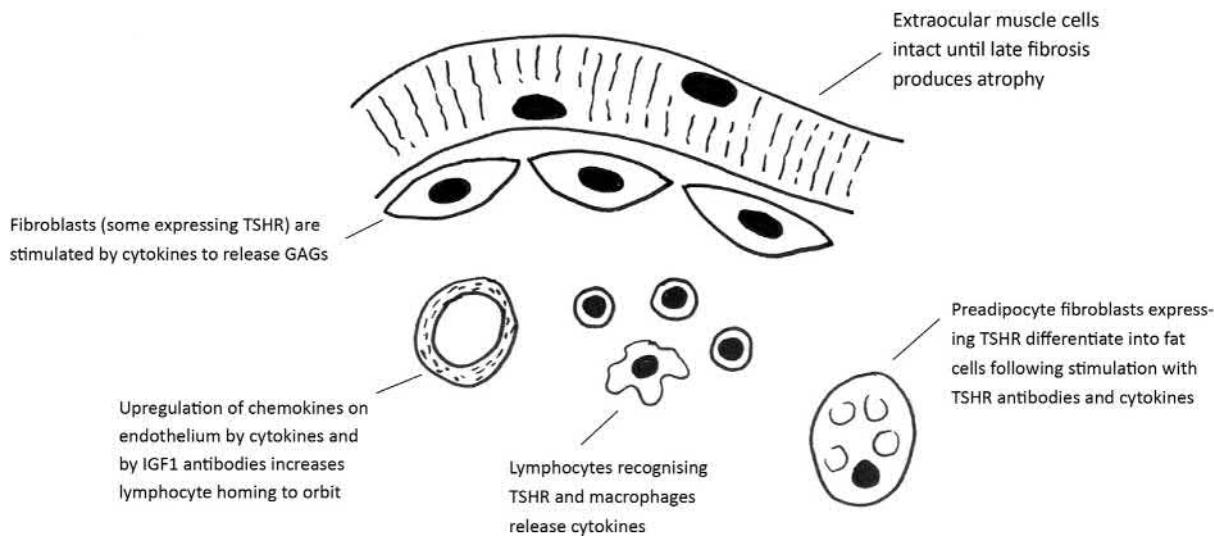

Treatment consists of antithyroid drugs (carbimazole, methimazole, or propylthiouracil), radioiodine, or thyroidectomy (Ross et al., 2016). Around 40% of the patients treated with antithyroid drugs achieve a permanent remission. These drugs ameliorate EAT and TSAb levels fall during treatment due to a decrease in the expression of proinflammatory molecules by TFC (Weetman et al., 1992). Relapse after antithyroid drugs is particularly likely in younger patients with severe hyperthyroidism or a large goiter, and those who smoke or have evidence of a strong Th2 response (Hidaka et al., 1993, Komiya et al., 2001). Radioiodine treatment is followed by a striking rise in TSH-R (and other thyroid) autoantibodies at 3–6 months, whereas TSH-R antibody levels gradually fall in most, but not all, patients over the year following subtotal thyroidectomy (Laurberg et al., 2008). The complete ablation of thyroid tissue results in disappearance of all thyroid autoantibodies, confirming the need for these autoantigens to maintain antibody production (Chiavato et al., 2003).

## Thyroid-Associated Ophthalmopathy and Dermopathy

These complications of Graves' disease are most likely due to an autoimmune response, which stimulates fibroblasts localized within the extraocular muscle or dermis, causing glycosaminoglycan release and edema, and accompanied by fat expansion (Bahn, 2010). The extraocular muscles and dermis are infiltrated by activated T cells and local cytokine production (IFN- $\gamma$ , IL-1, and tumor necrosis factor) can be demonstrated: these cytokines stimulate glycosaminoglycan synthesis by fibroblasts in vitro (Figs. 40.7 and 40.8). The main target of the autoimmune response appears to be the TSH-R which is expressed on a subset of fibroblasts, but the response may be enhanced by antibodies against the IGF-1 receptor (Wang and Smith, 2014). The treatment of mild TAO usually consists of supportive measures, and in many the condition spontaneously becomes stable or regresses; in moderate-to-severe disease, corticosteroids or other immunosuppressive agents are useful (Wiersinga, 2017).

**FIGURE 40.7** Photomicrograph of an extraocular muscle from a patient with thyroid-associated ophthalmopathy. There is an extensive lymphocytic infiltrate and edema: the muscle fibers are intact. (Original magnification:  $\times 200$ .)

**FIGURE 40.8** Pathogenic mechanisms in thyroid-associated ophthalmopathy. The inflammatory infiltrate in the orbit releases a variety of cytokines that stimulate orbital fibroblasts to secrete GAGs, which trap water and lead to edema; later fibroblast activation leads to fibrosis. A subset of orbital fibroblasts differentiates into adipocytes as a result of cytokine signaling, leading to fat expansion within the orbit. GAGs, Glycosaminoglycans. From Weetman, A.P., 2016. Autoimmune thyroid disease. In: Ratcliffe, M.J.H. (Editor-in-Chief), *Encyclopedia of Immunobiology*, vol. 5. Academic Press, pp. 150–158 with permission.

## Concluding Remarks—Future Prospects

Graves' disease shares many features with AT, and what determines the type of disorder is a critical issue. Apart from *TSH-R* polymorphism, genetic susceptibility factors have proven relatively nonspecific, and more detailed analysis should reveal specific genotypes for Graves' disease. Future studies will clarify the relative importance of stress, iodine intake, smoking, and other environmental factors, as well as how these interact with each other and with genetic factors. It will be particularly important to study mechanisms at the earliest possible stage of disease, so that an initiating rather than an enhancing role for these factors can be assessed. Experiments of nature, such as the appearance of Graves' disease after immunological treatments, may provide fresh insights into regulatory mechanisms and the early phase of disease.

The recent development of animal models of TAO will be useful in clarifying the relative roles of TSH-R, the IGF-1 receptor, and other putative orbital antigens in pathogenesis and may improve treatment options. Our current therapies for Graves' disease are effective, but not ideal, with many patients having recurrences or exchanging hyperthyroidism for permanent hypothyroidism. Immunologically based treatment offers considerable potential advantages but will need to be specific and innocuous: the recent description of a small molecular antagonist of TSAb suggests one possible approach (Neumann et al., 2011).

## INTRODUCTION

Autoimmune diabetes, commonly referred to as type 1 diabetes mellitus (an older synonym is insulin-dependent diabetes mellitus), is a chronic immune-mediated disease characterized by insulin deficiency due to pancreatic islet beta-cell destruction with increasing blood glucose levels (Table 41.1) (Katsarou et al., 2017; Atkinson et al., 2014). Type 1 diabetes is a disease of unidentified etiology and mode of inheritance but strongly associated with essentially two different human leukocyte antigen (HLA) haplotypes on chromosome 6. Young genetically predisposed individuals are exposed to hypothetical environmental factors which trigger an aggressive and selective autoimmune response against the pancreatic islet beta cells. The beta-cell destruction is thought to be an immune-mediated attack, often referred to a T cell–mediated disease and results eventually in insulitis and finally to a lost production of insulin (Richardson et al., 2016; Kaddis et al., 2015; In't Veld et al., 2007; Krogvold et al., 2016). The insulitis appears to be a late event during the prolonged asymptomatic prodrome but may be associated with the actual killing and major loss of beta cells (In't Veld et al., 2007; Pipeleers et al., 2008). The patient becomes dependent on lifelong exogenous insulin treatment.

Autoimmune diabetes is increasing worldwide and has been increasing 3%–5% per year in the last few decades, doubling approximately every 20 years (Group, 2008). The incidence rate varies dramatically between countries and within Europe, with the exception of Sardinia, it shows a north–south gradient, with a high incidence in the northern latitude (Visalli et al., 2003). Finland is the country with the highest annual incidence of autoimmune diabetes with 57.6 patients/100,000 people aged <15 years. The genetic risk is more important than the

geographical location as Sardinia has an incidence rate close to that of Finland (Tuomilehto, 2013; Soltesz et al., 2007); Saudi Arabia has a marked increase in incidence (Abdullah, 2005; Alotaibi et al., 2017), but in Asia, autoimmune diabetes seems yet to be a rare disease (Patterson et al., 2014).

Our understanding of autoimmune diabetes has improved, although the etiology is not completely understood (Katsarou et al., 2017). It is generally assumed that the disease is hereditary, but most patients do not have a family history of diabetes; and the proportion of children with an affected first-degree relative (FDR) is only about 10%–12% (Parkkola et al., 2013; Harjutsalo et al., 2008). The HLA class II genes in the major histocompatibility complex (MHC) are the most important susceptibility genes for autoimmune diabetes, accounting for approximately 50% of the genetic contribution to the disease (Pociot and Lernmark, 2016; Rich et al., 2006). The triggering event is unknown, but antigen presentation by dendritic cells is expected to activate a T and B lymphocyte-mediated autoimmune reaction targeting specific beta-cell autoantigen. It is still not clear whether the triggering antigen presentation is with an antigen from an infectious agent or with an autoantigen. It cannot be excluded that an immune response to an infectious agent antigen may turn itself onto autoimmunity due to a mechanism of molecular mimicry (Srinivasappa et al., 1986; Shoenfeld and Aron-Maor, 2000).

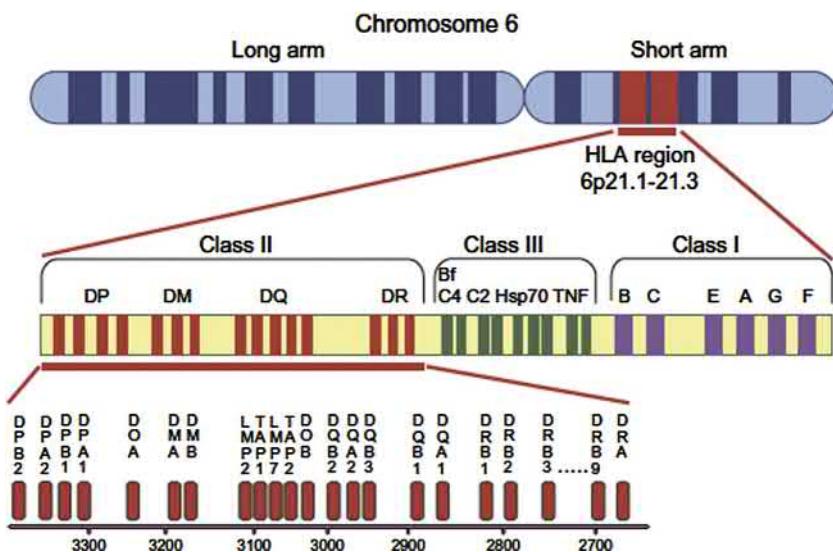

Autoimmune diabetes is characterized by a complex and prolonged subclinical phase (prodrome or prediabetes) with asymptomatic subclinical stages lasting month to years before the clinical onset. The prodrome is initiated by an autoimmune reaction against either insulin in HLA DR4-DQ8 children or glutamic acid decarboxylase (GAD65) in HLA DR3-DQ2 children (Krischer et al., 2015, 2017a,b.; Lynch et al., 2018). Within 12 months, 60% of the children with a first autoantibody may develop a second autoantibody perhaps to be followed by a third or fourth against either insulin (IAA), GADA, islet antigen-2 (IA-2A), or the zinc transporter 8 (ZnT8A).

The number of positive islet autoantibodies correlates to the risk of progressing to clinical disease (Ziegler et al., 2013). The cumulative risk of diabetes varies according to age and younger age at seroconversion, positivity for multiple autoantibodies, high antibody levels, and persistent positivity for IAA (Steck et al., 2015). The combination of genetic analysis—primarily of HLA—in combination with analyses of standardized islet autoantibodies has made it possible to dissect both the etiology and the pathogenesis as well as to predict autoimmune diabetes (Katsarou et al., 2017; Pociot and Lernmark, 2016; Todd et al., 2011).

## EPIDEMIOLOGY

### Asymptomatic Islet Autoimmunity

Recent efforts to develop and standardize reliable islet autoantibody tests of high throughput have made it possible to test to what extent these biomarkers are present in the general population. Incidence rate of first appearing autoantibody has been reported in studies of children followed since birth (Krischer et al., 2015, 2017a; Ziegler et al., 1999; Ziegler and Bonifacio, 2012; Ilonen et al., 2013). The incidence rate in TEDDY (The Environmental Determinants of Diabetes in the Young) showed a difference between IAA first and GADA first. The IAA first peaked at 1–3 years of age followed by a decline, and it did occur primarily in children with the HLA DR4-DQ8 haplotype (Fig. 41.1). In contrast, GADA first developed at 3 years of age and reached a plateau which did not decline (Krischer et al., 2015; Aronsson et al., 2015). In these high-risk children, the prevalence of the first appearing autoantibody was IAA first 43%, GADA first 38%, and both IAA and GADA first 14%. IA-2A first was only found in 4% (Krischer et al., 2015, 2017a).

**FIGURE 41.1** The HLA region on the short arm of chromosome 6. The genes at the DRB3', DRB4' and DRB5' along with DRB1\* as well as DQA1\*-B1\* are the strongest alleles which affect both the risk for a first appearing autoantibody as well as progression to clinical onset. *HLA*, Human leukocyte antigen.

A true incidence rate would require a study of all children born to be followed from birth regardless of genetic risk. This type of incidence study would be of interest in high incidence countries such as Finland and Sweden as data would reflect environmental exposures associated with the triggering of a first appearing autoantibody be it IAA or GADA.

The prevalence of islet autoantibodies regardless of genetic risk was determined in 2–5 year olds (two autoantibodies in 0.39%) in the Fr1da study (Raab et al., 2016), in school children (one autoantibody in 2.4% and two autoantibodies in 0.5%) in the Karlsburg School Children study (Schlosser et al., 2002), in school children (one autoantibody 0.3%) in the Washington School Children study (LaGasse et al., 2002) or in Australia (Colman et al., 2000), and in nondiabetes 30–60 year olds (one autoantibody 1%) in the Swedish Västerbotten study (Rolandsson et al., 1999). The possibility to develop (Raab et al., 2016) tests that simultaneously detect multiple autoantigen autoantibodies should prove useful for future screening efforts (Wasserfall et al., 2016; Ankelo et al., 2007; Amoroso et al., 2016).

## Symptomatic Autoimmune (Type 1) Diabetes

According to the International Diabetes Federation, 8.8% of the adult population worldwide has diabetes. Only 10%–15% of the adult diabetes population have autoimmune diabetes; but in children <15 years of age, autoimmune (type 1) diabetes is the most common form of diabetes, and 90,000 children are diagnosed every year. The highest incidence of autoimmune diabetes is in Scandinavia, Europe, and North America. In the Asian countries, the incidence is still low. Saudi Arabia seems to be the country with the fastest growing incidence rate ([Abduljabbar et al., 2010](#); [Habeb et al., 2011](#)). In resource-poor countries, autoimmune diabetes may not be diagnosed correctly.

High-risk genotypes vary between countries. Genotypes conferring a low risk in one country may go on to confer a risk in children born to parents who immigrate to a high-risk country such as Sweden (Katsarou et al., 2017; Delli et al., 2010; Hussen et al., 2015).

## DIAGNOSTIC CRITERIA AND CLASSIFICATION OF DIABETES

The diagnosis of diabetes is based on blood glucose levels according to combined recommendations of the WHO and the American Diabetes Association (2017) ([Table 41.1](#)).

The HbA1c value reflects 90 days moving average of blood glucose concentrations and has been proposed as an alternative criterion for the diagnosis of diabetes. The recommended threshold is 5.7% or higher for impaired glucose tolerance and 6.5% or higher in two separate tests for the diagnosis of diabetes. These values of HbA1c are based on studies on adults with type 2 diabetes, and according to recent studies, HbA1c level on 6.5% or higher is not an adequate alternative criterion for diagnosing early type 1 diabetes in high-risk asymptomatic

subjects <21 years of age. Oral glucose tolerance test (OGTT) is a sensitive indicator of diabetes and early impaired glucose homeostasis and type 1 diabetes (Vehik et al., 2012). The utility of HbA1c with or without continuous glucose monitoring to diagnose diabetes in children is still uncertain (Xu and Krischer, 2016; Danne et al., 2017; Buysschaert et al., 2016).

To properly classify autoimmune diabetes mellitus the presence of beta-cell autoantibodies must be confirmed in combination with elevated blood glucose (Leslie et al., 2008).

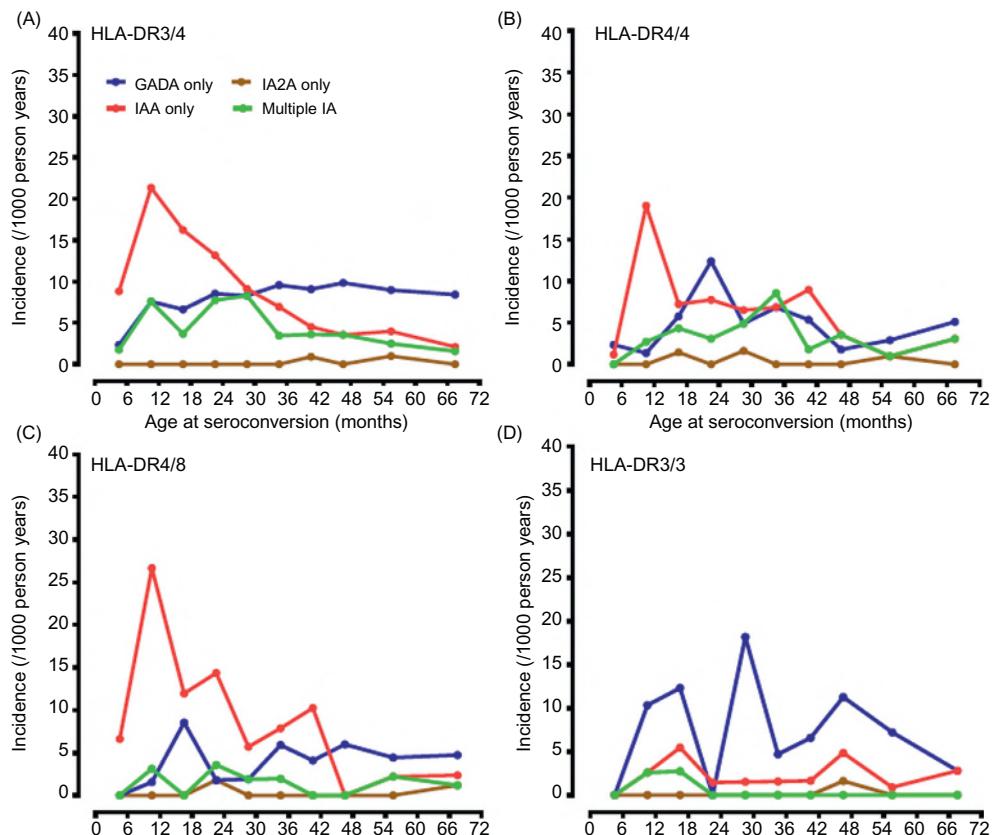

The classification of autoimmune (type 1) diabetes has been updated by the American Diabetes Association (Insel et al., 2015) to include Stage I and II as subclinical stages with two or more islet autoantibodies and Stage III as the clinical stage (Table 41.3).

## ETIOLOGY

### Genetic Etiology of Islet Autoimmunity

Genetic factors for the risk of a first appearing biomarker for autoimmune diabetes require longitudinal studies from birth. Such studies have either followed all newborns (Ludvigsson et al., 2017), utilized HLA-DR-DQ as inclusion criteria for follow-up (Nejentsev et al., 1999; Rewers et al., 1996; Group, 2007), or followed children born in families already affected by autoimmune diabetes (Ziegler et al., 1999; The Environmental, 2008).

In the TEDDY study (Fig. 41.2), IAA first was associated with HLA DR4-DQ8 while GADA first was associated with DR3-DQ2 (Krischer et al., 2015, 2017a,b; Lynch et al., 2018). Non-HLA genetic factors were differently associated with either IAA first or GADA first (Table 41.2). For example, the genetic polymorphism at the *INS* gene was strongly associated with the risk for IAA first but not for GADA first. Conversely, the risk for GADA first was associated with *CTLA4*, *ERBB3*, and *BACH2* but not with IAA first.

**FIGURE 41.2** Incidence rate of GADA only, IAA only, IA-2A only, and multiple autoantibodies as first appearing islet autoantibody at the time of seroconversion. The incidence is shown by HLA type with HLA DR3/4 in (A), DR4/4 in (B), DR4/8 in (C), and DR3/3 in (D). Gestational respiratory infections interacting with offspring HLA and CTLA-4 modifies incident beta-cell autoantibodies. *J. Autoimmun.* 86, 93–103.

The HLA class II genes in the MHC region on chromosome 6 (6p21) (Fig. 41.1) (Group, 2008) are directly involved in autoimmune diabetes (Fig. 41.1) (Group, 2008). HLA genes are necessary but not sufficient causal factors for the triggering mechanisms as well as for progression to clinical disease, and their penetration is low. Concordance in monozygotic twins is only 30% (Peakman et al., 1993). The development of autoimmunity is a multifactorial process and the major genetic risk factors are the HLA class II haplotype, HLA DR3-DQ2 and HLA DR4-DQ8. The haplotypes vary between countries, and the risk for autoimmune diabetes, for example, in Japan, is associated with DRB1\*04:05-DQB1\*04:01 (DR4-DQ4), DRB1\*08:02-DQB1\*03:02 (DR8-DQ8), and DRB1\*09:01-DQB1\*03:03 (DR9-DQ9) (Kawabata et al., 2009).

There is a large number of HLA-DRB1 alleles in humans, and some alleles have protective effects on both the appearance of a first autoantibody as well as clinical onset (e.g., DRB1\*04:03, 04:07, and 04:10 are protective alleles), whereas others are associated with greater risk of both the trigger and the subsequent disease process (e.g., DRB1\*04:01 and DRB1\*04:04). The HLA region is subject to further analysis by direct sequencing and HLA typing referred to as next-generation sequencing to resolve all alleles at the DRB\*3, 4, and 5 loci as well as DRB1\*, DQA1-B1, and DPA1-B1 (Erlich et al., 2013; Smith et al., 2014; Zhao et al., 2016). Understanding which alleles, DRB and DQ, are necessary for the triggering of an islet autoantigen autoimmunity reflected in the appearance of a first islet autoantibody should make it possible to identify the initial cellular mechanisms resulting in self-reactive T and B lymphocytes as well as autoantibodies.

Normally, the HLA–autoantigen complex in the thymus presents weak- and low-affinity signals to T lymphocytes, which will be educated (positive selection) to identify self-antigen as “self.” If these signals were deficient or were too strong, these T lymphocytes will be deleted (negative selection) as part of central tolerance induction (Ohashi, 2003). T cells play a central role in controlling the acquired immune response, and there is strong evidence for the association between defects in thymic T cell–negative selection related to insulin reactivity (Bluestone et al., 2010). The central role in autoimmune responses against islet autoantigens is related to the structural features of the HLA class II molecules and their interaction with T lymphocytes (Eerlich et al., 2011; van Lummel et al., 2012). Some of the HLA alleles coding these molecules may modify the timing, intensity, and rate of an autoimmune response and thereby affect subsequent pathogenesis.

The DQA and DQB loci code for the alpha and beta subunits, the two chains of the HLA-DQ heterodimer molecules. These molecules are expressed on the cell surface of antigen-presenting cells (APC) and allow the presentation of peptide antigens to T lymphocytes through the T-lymphocyte receptor. The binding of islet autoantigen peptides to HLA-DQ molecules was found to modulate the autoimmune response (van Lummel et al., 2012; Eerlich et al., 2011; Bach et al., 1997; Ge et al., 2011). The transheterodimer between HLA DQ2 and DQ8 may be of particular interest in antigen presentation as it is increasing the number of potential antigen-presenting

heterodimers (van Lummel et al., 2013). Binding insulin peptides to DQ8 molecules induced proinflammatory responses while binding to DQ6 molecules induced regulatory T (Treg) lymphocytes responses (Erlich et al., 2011). These differences may be related to the structural differences in the DQ molecules and the affinity of these molecules to accommodate certain antigens and thereby facilitate thymic recognition of such antigens as “self” or propagate proinflammatory response leading to the activation of autoreactive T lymphocytes.

Structural studies of autoantigen peptide binding to HLA DQ2, DQ8, and DQ6.4 have suggested differences that may be related to the features of autoimmune diabetes. It was proposed that the DQ2 heterodimer has the ability to bind multiple peptides due to a wider binding groove compared to DQ8 which is less accommodating (Lee et al., 2001; Suri et al., 2005). Structural differences between the risk-conferring alleles such as DQ8 and DQ2 and also the protective allele DQ6 were suggested to modify their binding properties through modification of the volume and polarity of binding grooves (Jones et al., 2006). Similarly, HLA-DQ6.4, which is strongly associated with ZnT8 autoantibodies, showed an epitope-binding pattern that would be consistent with a reduction in ZnT8 peptide presentation in the thymus. It has been speculated that a reduction in thymic presentation increases the risk for autoimmunity (Pugliese et al., 1997; Delli et al., 2012). As both IAA first and GADA first may be related to virus infection (Lynch et al., 2018; Lee et al., 2013; Lonnrot et al., 2017), it will be important to determine how virus antigen peptides are presented by DR and DQ heterodimers and how presentation of virus may be related to the subsequent induction of autoimmunity. It needs to be resolved by which mechanisms either a virus or a vaccine such as Pandemrix in DQ6.2 subjects afflicted with narcolepsy (Tafti et al., 2014; Ollila et al., 2015) induced cell-specific autoimmunity. Other mechanisms may prevail as gestational respiratory infections and the risk for IAA first or GADA first may depend on offspring HLA and CTLA-4 alleles (Lynch et al., 2018). These observations support a bidirectional trigger for IAA or GADA as a first appearing beta-cell autoantibody in early life.

Genetic factors have also been shown to alter the risk of autoimmune diseases. The HLA molecules largely determine the distinction between “self” and “nonself” antigens, and HLA compatibility between the mother and fetus could therefore affect autoimmune reactions in the offspring. Microchimerism refers to a small number of cells or DNA in one individual which derives from another genetically distinct individual. Microchimerism takes place during pregnancy through the maternal–fetal cell trafficking which is bidirectional through the placenta. During pregnancy, the fetus would be exposed to the noninherited maternal antigen which may modify the negative selection of T cells in the thymus and alter the generation of specific T cells, inducing central lasting tolerance (Nelson et al., 1998; Bronson et al., 2009). The development of central tolerance is important in allotransplantation and may also play a role in development of autoimmune disorders. Interest in chimerism has been increased due to the development of DNA technology, now using short tandem repeats of DNA or single-nucleotide polymorphism (SNP) to resolve the role of microchimerism and its possible role in autoimmunity (Bluestone et al., 2010; AKMN, 2004; Yunis et al., 2007). Other mechanisms of triggering islet autoimmunity are yet to be elucidated.

## Environmental Factors Associated With First Appearing Autoantibodies

Dietary exposure, such as maternal diet during pregnancy, breastfeeding, and diet in early childhood, may be related to triggering islet autoimmunity (Virtanen, 2016; Lamb et al., 2008; Sorkio et al., 2010). Earlier studies have examined the association between age at first exposure to cow’s milk and type 1 diabetes, resulting in inconsistent findings (Akerblom et al., 2005; Knip et al., 2010, 2014). However, TEDDY study reported that early weaning to an extensively hydrolyzed cow’s milk-based formula was rather associated with an increased risk for islet autoimmunity (Hummel et al., 2017). TEDDY also found higher plasma 25(OH)D concentrations in the child to be associated with a decreased risk of islet autoimmunity (Norris et al., 2018), and an early exposure to probiotics was shown to be protective (Uusitalo et al., 2016). The role of dietary factors associated with triggering beta-cell autoimmunity as marked by a first appearing autoantibody will require further studies.

A major question to understand the etiology of autoimmune diabetes is whether either insulin or GAD65 autoimmunity may be induced by virus. The mechanism may involve a common virus infection associated with a poor immune response that tends to involve the appearance of low-affinity, multiple reactive IgM (Chen et al., 1996; Zhou et al., 2007). Subsequent isotype shift may favor the formation of autoantigen IgG dependent on T-cell help and genetic propensity. Recently, it was reported in the diabetes prediction and prevention (DIPP) study (Honkanen et al., 2017; Sioofy-Khojine et al., 2018) that Coxsackie B1 virus infections may contribute to IAA first but not GADA first.

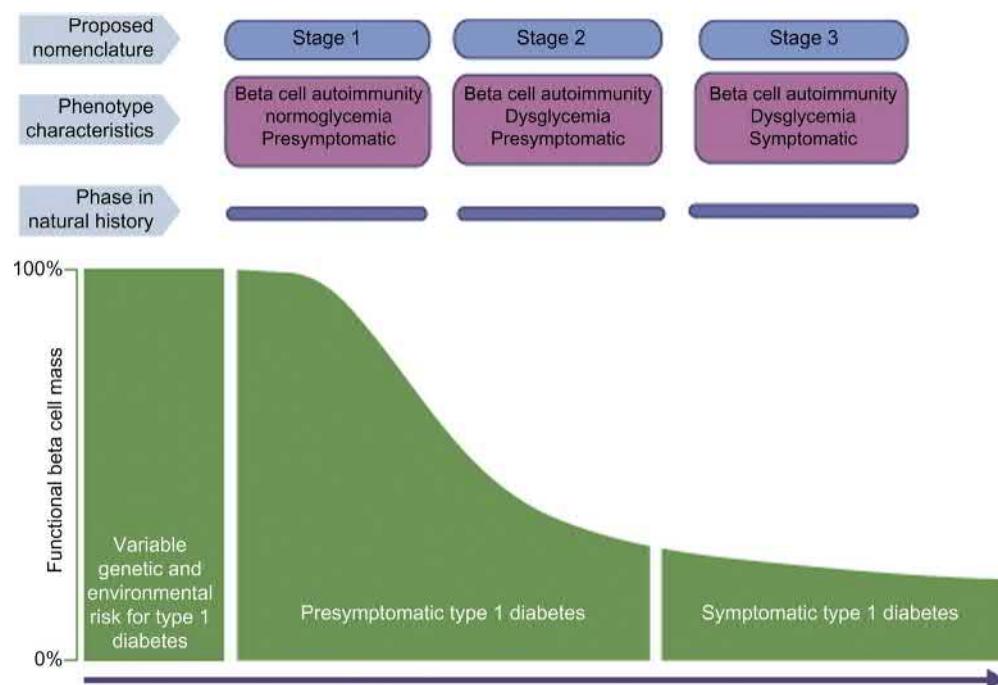

In Russia, children with a history of several infections had lower risk of autoimmunity compared to children with the same genetic risk but fever infections (Katsarou et al., 2017; Knip et al., 2005). It cannot be excluded that molecular mimicry may contribute. Coxsackie virus shares the sequence PEVKEK with GAD65, and it has been proposed that this type of molecular mimicry may explain the association between the virus and first appearing autoantibody (Sioofy-Khojine et al., 2018; Coppieters et al., 2012; Atkinson et al., 1994).

Other possible mechanisms are vaccinations early in life. Vaccinations may alter the immune response to infections and modulate the identification of foreign and self-antigens and thereby increase the risk of autoimmune diseases. A unique instance is the trigger of autoimmunity against hypocretin neurons and development of narcolepsy in only HLA-DQ6.2 subjects after vaccination with Pandemrix (Tafti et al., 2014; Ollila et al., 2015). The vaccine was the trigger, which may help to dissect the mechanisms by which this environmental factor was able to induce disease. However, the research effort is hampered by the fact that an autoantigen is yet to be identified (Lind et al., 2014). It is noted that Pandemrix vaccination did not increase the risk for islet autoantibodies in children with increased genetic risk for autoimmune diabetes (Elding Larsson et al., 2018a). Rather in children from Finland, Pandemrix was negatively associated with the risk for a first appearing islet autoantibody.

Further studies on the possible relation between a common virus infection and the subsequent appearance of a first islet autoantibody as a biomarker of islet autoimmunity will be needed.

## PATHOGENESIS

The pathogenesis of autoimmune type 1 diabetes is currently divided into three stages that relate to the detection of autoantibodies indicating autoimmunity, level of beta-cell destruction, and clinical symptoms of disease (Fig. 41.3; Table 41.3). The prodrome stages may last for weeks up to years before the onset of clinical symptoms of disease. The autoantibodies circulating in the blood are not pathognomonic for autoimmune type 1 diabetes but serve as biomarkers of autoimmunity (Stage 1). Two or more islet autoantibodies were selected to define

**FIGURE 41.3** Staging of autoimmune type 1 diabetes. Variable genetic and environmental risk represents the etiology of type 1 diabetes. The etiological stage is likely to be short term and is concluded by the appearance of a first islet autoantibody as the biomarker of islet autoimmunity. In Stage I, two or more islet autoantibodies have been formed but normoglycemia prevails, and there are no symptoms. In Stage II, islet autoantibodies remain, dysglycemia has developed, but there are no symptoms while in Stage III, diabetes has been diagnosed and there may be symptoms. The staging of type 1 diabetes pathogenesis was proposed by Insel et al. (2015). Source: The figure was reproduced by permission from Regnell, S.E., Lernmark, A., 2017. Early prediction of autoimmune (type 1) diabetes. *Diabetologia* 60, 1370–1381 (Regnell and Lernmark, 2017).

**TABLE 41.3** Classification of Autoimmune Diabetes

Stages of autoimmune diabetes mellitus (type 1 diabetes)

- Stage I: Subclinical stage. Autoimmunity: two or more islet autoantibodies: IAA, GADA, IA-2A, or ZnT8A. Normoglycemia
- Stage II: Subclinical. Autoimmunity and dysglycemia some indication of islet beta-cell loss. Rising glucose levels detectable with OGTT
- Stage III: Clinical disease. Autoimmunity and beta-cell destruction with insulin deficiency, dysglycemia, and hyperglycemia-related symptoms

*Insel, R.A., Dunne, J.L., Atkinson, M.A., Chiang, J.L., Dabelea, D., Gottlieb, P.A., et al., 2015. Staging presymptomatic type 1 diabetes: a scientific statement of JDRF, the Endocrine Society, and the American Diabetes Association. Diabetes Care 38 (10), 1964–1974.*

Stage I as the progression to clinical onset is slow in single autoantibody-positive subjects (Ziegler et al., 2013; Vehik et al., 2016). Islet autoantibodies serve as biomarkers of presymptomatic or subclinical disease (Table 41.3). Major islet autoantibodies target insulin (IAA), the 65 kDa GADA, insulinoma-associated protein 2 (IA-2A), or ZNT8As are found in a blood sample. ZnT8As are complicated as there are three variants, amino acid tryptophan (W), arginine (R), or glutamine (Q) at position 325 (Wenzlau et al., 2008b). Subjects may develop ZnT8As which are either specific to one of these variants or positive to two or all three (Skarstrand et al., 2015).

In young children, the first autoantibody detected was found to be IAA, possibly in combination with GAD (Katsarou et al., 2017; Krischer et al., 2015; Ilonen et al., 2013; Sioofy-Khojine et al., 2018; Ilonen et al., 2018). The appearance of IAA may be preceded by an enterovirus infection (Sioofy-Khojine et al., 2018). A second autoantibody may appear within 12 months in 60% of the children developing a first autoantibody (Iilonen et al., 2013; Vehik et al., 2016). In the first subclinical stage (Stage I, Table 41.3), the individual has developed autoimmunity, defined by the presence of two or more islet autoantibodies, but is still asymptomatic and normoglycemic. The beta-cell function is normal. Despite that two or more autoantibodies are detectable in the blood, there is no indication of insulitis (In't Veld et al., 2007; Pugliese, 2014; Diedisheim et al., 2016). In the second subclinical stage (Stage II, Table 41.3), the individual has developed dysglycemia but is still asymptomatic. Signs of insulitis may be detected during late Stage II (In't Veld et al., 2007) although not as common as expected (Reddy et al., 2015; Wiberg et al., 2015; Lundberg et al., 2017). In this stage, rising glucose intolerance is often detected in an OGTT (Lundberg et al., 2017; Sosenko et al., 2015). In the third stage of disease, the individual has autoimmunity with islet autoantibodies, and beta cells have been lost leading to insulin deficiency, dysglycemia, and symptoms of hyperglycemia such as polyuria and thirst. Lifelong treatment with exogenous insulin is needed for survival and the majority of these patients develop secondary micro- and macrovascular complications later in life (Katsarou et al., 2017; Insel et al., 2015; Hammond and Kronenberg, 2003).

## Pathophysiology

When 80%–90% of the beta-cell mass has been lost, clinical symptoms of hyperglycemia and overt diabetes are prevalent. The rate of progression from an asymptomatic, autoimmune stage to symptomatic disease varies with age. Young children lose proportionally more beta cells compared to teenagers, young adults, and adults (Wallensteen et al., 1988). The clinical onset is therefore not only a function of a reduced beta-cell mass but also of beta-cell function and insulin resistance (Fourlanos et al., 2004). The risk of progression to Stage III disease is associated with the number of autoantibodies, age at seroconversion of the first presenting autoantibody, autoantibody type, affinity, and autoantibody titer (Katsarou et al., 2017; Krischer et al., 2017b). Progression is often faster in girls than in boys and in young children <3 years of age (Katsarou et al., 2017). Young patients may show classic symptoms such as weight loss, thirst, frequent urination, and hunger. Adult subjects may develop diabetes symptoms that would be consistent with type 2 diabetes (Insel et al., 2015; Achenbach et al., 2013).

Islet autoantibodies are important indicator of progression to diabetes as well as the disease outcome (Harel and Shoenfeld, 2006). The type and number of these autoantibodies signify the advancement of islet autoimmunity, therefore predict autoimmune type 1 diabetes not only in FDRs (Verge et al., 1996) but also in subjects from the general population (Ziegler et al., 2013; Bingley et al., 1997).

Islet cell autoantibodies have been standardized in international workshops since 1985 (Gleichmann and Bottazzo, 1987). A WHO standard for autoantibodies against GAD65 and IA-2 was established by the Immunology of Diabetes Workshops (Mire-sluis et al., 2000) and further developed by the Diabetes Autoantibody and Islet Autoantibody Standardization Programs (Torn et al., 2008; Schlosser et al., 2010; Lampasona et al., 2011). A DK standard was developed to be used in NIH-sponsored research (Bonifacio et al.,

2010). The interlaboratory variation in analyzing autoantibodies to insulin, GAD65, IA-2, and ZnT8 has been reduced through the use of common standards in several international workshops.

The risk of developing autoimmune type 1 diabetes increases with increasing number of autoantibodies (Ziegler et al., 2013; Krischer et al., 2015). Autoantibodies against all four autoantigens are used to follow children at increased genetic risk from birth to determine triggers of islet autoimmunity (Ziegler et al., 2013; Hagopian et al., 2011) randomize subjects to secondary prevention trials (Yu et al., 2012) as well as to improve clinical classification (Delli et al., 2012). Interestingly, nearly half of younger patients who were autoantibody negative at the time of diagnosis showed later seroconversion (Hameed et al., 2011) indicating that islet autoantibodies may exist invariably in pre- and postdiabetes diagnosis as well as at the time of diagnosis. Islet autoantibodies, therefore, remain robust markers of autoimmune type 1 diabetes and should prove useful to assist progress toward assays that better reflect environmental exposures as well as seroconversion.

The mechanisms responsible for the variable progress to clinical onset during Stage III are poorly understood. Parallel testing for autoantibodies against GAD65 and IA-2 followed by insulin autoantibodies was found to identify 50% of the patients younger than 20 years of age and was associated with a 71% risk within 10 years (Bingley et al., 1999). In FDR, being 20–39 years of age, this strategy conferred 51% risk. Primary screening for IA-2 and GAD65 autoantibodies followed by testing for insulin autoantibodies conferred a 63% risk to develop diabetes. Further studies including subjects also from the general population will be needed to establish the positive predictive value of an islet autoantibody test to predict autoimmune type 1 diabetes. Studies of children followed since birth because of increased genetic risk for autoimmune (type 1) diabetes are of particular interest in this regard (Rewers et al., 1996; Ziegler et al., 2013; Hagopian et al., 2011).

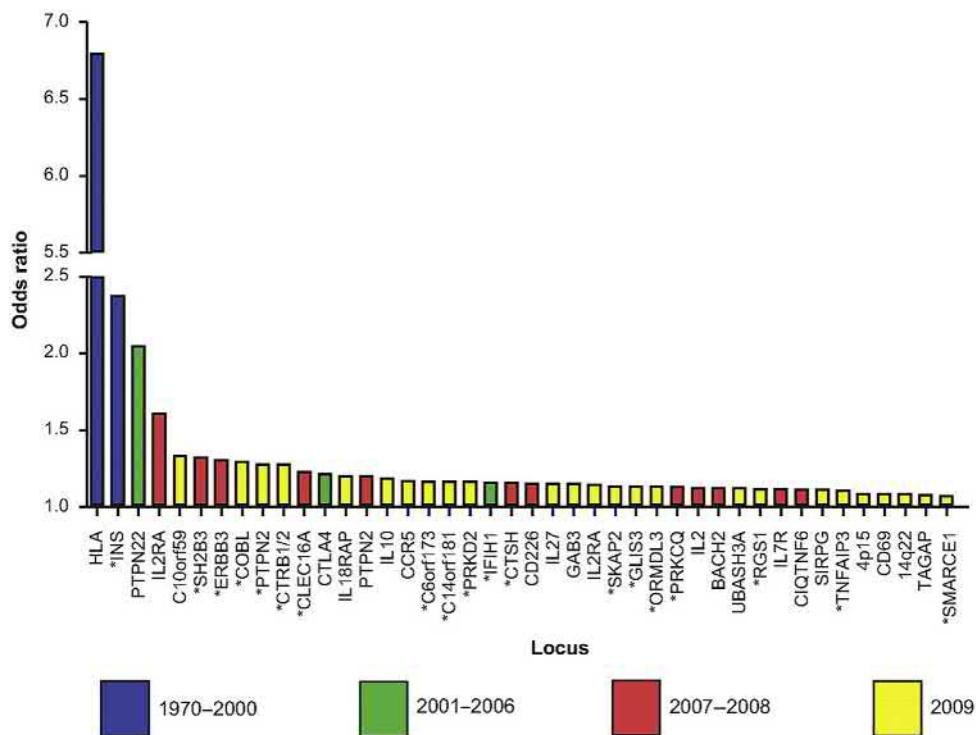

## Genetic Factors

The genetic predisposition of HLA-DR-DQ confers the highest risk for type 1 diabetes but is not enough to cause the autoimmune reaction to the insulin-producing beta cells. It is important to determine the mechanism by which antigens are presented to immune cells on HLA class II molecules, expressed on APC. It is speculated that an etiological trigger such as a common virus infecting beta cells resulting in reactivity with specific autoantigens. Once autoimmunity has been triggered against one autoantigen, be it insulin or GAD65, the pathogenesis is initiated as reflected by the appearance of a second, third, etc. autoantibody. Data suggest that after the appearance of a first autoantibody, 60% develop a second autoantibody within 12 months (Krischer et al., 2017b). However, it is important to note that the appearance of a second islet autoantibody was not associated with HLA (Ilonen et al., 2013). Other mechanisms promoting spreading to other autoantigens will need to be identified. Other possible mechanisms during pathogenesis may include genetic factors that are associated with apoptosis (Cnop et al., 2005; Grieco et al., 2014), autophagy (Rojas et al., 2018), or endoplasmic reticulum stress (Cnop et al., 2005; Eizirik et al., 2013).

Notwithstanding the major importance of HLA in the association with the etiology of diabetes, it cannot be excluded that HLA also is related to the pathogenesis of the disease. Major efforts have been made through genome-wide association studies to identify non-HLA genetic factors associated with type 1 diabetes and more than 60 loci have been identified (Pociot and Lernmark, 2016; Rich et al., 2009; Ram et al., 2016; Pociot et al., 2010) (Fig. 41.4).

Apart from the recent rapid progress in detecting genes contributing to type 1 diabetes risk, the data also illustrate that the majority of the genes have a low risk.

It is possible to distinguish genes that contribute to the risk of developing the first autoantibody from genes that contribute to the risk of progressing to clinical onset (Krischer et al., 2017b; Torn et al., 2015). In children with two or more islet autoantibodies, there may be rapid as well as slow progressors. The two groups may be distinguished by the combined presence or absence of type 1 diabetes risk alleles of non-HLA genes, most notably IL2, CD25, INS VNTR, IL18RAP, IL10, IFIH1, and PTPN22 (Achenbach et al., 2013). The T1DBase (<http://www.t1dbase.org>) lists risk genes and their functions. It is noticed that the majority of the type 1 diabetes risk genes are related to the function of the immune system. Moreover, in analyzing type 1 diabetes, rheumatoid arthritis, celiac disease, and multiple sclerosis, there were 90 regions associated with at least one disease. A total of 33 (37%) regions were associated with two or more disorders. Most of these gene regions are related to the pathogenesis and recent approaches are to employ the genetic information to develop genetic risk scores (GRSs) (Oram et al., 2016). One GRS based on the TEDDY study identified infants without a family history of type 1

**FIGURE 41.4** HLA and non-HLA genetic factors detected by comparing the frequency of genetic polymorphisms in type 1 diabetes patients with healthy controls to calculate odds ratio. The color code indicates that year span of the observations was made. It is noticed that the progress to detect novel genetic factors that increase the risk for type 1 diabetes has accelerated after year 2000. HLA, Human leucocyte antigen. Genetics of type 1 diabetes: what's next? *Diabetes* 59, 1561–1571.

diabetes who had a >10% risk for islet autoimmunity (pre-Stage 1 in Fig. 41.3) (Bonifacio et al., 2018). This GRS may be used to enroll children in primary prevention studies (Ziegler et al., 2016). Another GRS may be used to better detect autoimmune type 1 diabetes in the adult population (Thomas et al., 2018). Taken together, combining the genetic information from HLA and non-HLA genes or genetic regions into GRS may prove useful for prediction of risk of etiology as well as pathogenesis to better identify and delineate progression to clinical onset. However, the mechanisms that explain the contribution of individual genes remain to be determined also in relation to the possible gene–environment interactions that may take place during years of Stage I and II islet autoimmunity.

## Environmental Factors

Many environmental factors, most importantly viral infections, have been assumed to either trigger an autoimmune response (Honkanen et al., 2017; Sioofy-Khojine et al., 2018) or affect the pathogenesis to alter the rate of progression to clinical onset (Stene et al., 2010). Viral infection of remaining beta cells may induce local inflammatory mechanisms, secretion of proinflammatory cytokines, and involvement of APC to accelerate pathogenesis. This activation may recruit additional autoreactive T lymphocytes. It has been suggested that these T lymphocytes need to be provoked by molecular mechanisms before being able to propagate autoimmunity (von Herrath et al., 2003), but it cannot be excluded that virus infections may contribute to epitope spreading and the appearance of additional autoantibodies.

There is limited information of the extent by which virus infection of islet autoantibody-positive subjects may result in the beta cells being infected (Stene et al., 2010).

Dietary factors that may affect the pathogenesis in islet autoantibody-positive subjects may include gluten (Bosi et al., 2005) and vitamin D (Norris et al., 2018; Raab et al., 2014). Gluten-free diet was tested in subjects with islet autoantibodies but did not affect the frequency or levels of autoantibodies (Hummel et al., 2002). Beta-cell function after 6 months of gluten-free diet in islet autoantibody-positive subjects was improved (Pastore et al.,

2003). Further studies on possible effects of environmental factors, such as diet, in subjects in Stage I and Stage II (Fig. 41.3) on the progression to clinical onset (Stage III) will be needed.

## Cellular Mechanisms

In the preclinical prodromal phase of autoimmune type 1 diabetes, there is initially no sign of reduced beta-cell function (Stage I). A selective loss of pancreatic islet beta cells seems to appear late and it cannot be excluded that Stage II dysglycemia is associated with insulitis that escalates and involves T cell-mediated destruction (Bluestone et al., 2010; Bronson et al., 2009). T lymphocytes play a central role in controlling the acquired immune response. There is a strong evidence for association between defects in thymic T cell-negative selection related to insulin reactivity (Bluestone et al., 2010). Normally, the HLA-autoantigen complex in the thymus presents weak and low-affinity signals to T lymphocytes, which will be educated (positive selection) to identify self-antigen as "self." If these signals were deficient or were too strong, these T lymphocytes will be deleted (negative selection) as part of central tolerance induction (Woo et al., 2017). In the periphery, Treg cells help to maintain normal response to "self"-antigens through eliminating autoreactive T lymphocytes that escape negative selection by a process called "clonal deletion," which is part of peripheral tolerance. In Stage I and II autoimmune diabetes (Fig. 41.3), there is likely a loss of the normal regulatory immune mechanisms. An imbalance between Treg cells and effector T lymphocytes has been described and the current view is that both negative and positive selection and Treg induction in the thymus are important for effective control of autoreactivity in peripheral tissue (Woo et al., 2017; Morran et al., 2008). Cellular studies of subjects in Stage I and II are rare. Using HLA Class II tetramers, GAD65 peptide-specific CD4+ T cells were observed in GADA positive but not negative subjects with increased genetic risk for type 1 diabetes (Oling et al., 2012). Stage I subjects compared to controls did not show quantitative or functional differences in Treg cells. Children with multiple autoantibodies compared to controls showed decreased mRNA expression levels of T-cell subtype markers. This may reflect an exhaustion of the immune system after the strong immune activation during a prolonged autoimmune process (Hamari et al., 2016). T-cell exhaustion may play a central role in determining outcome in autoimmune disease (McKinney et al., 2015).

## Humoral Biomarkers

Four major autoantigens have been identified in type 1 diabetes along with a growing list of minor autoantigens (Hirai et al., 2008). Proinsulin is the exclusive beta cell-specific antigen (Pugliese et al., 2001) and insulin was described as a major target for the T-lymphocyte attack especially in young children (Arif et al., 2004). GAD65 is specific for beta cells but is expressed in other cells as well (Karlsen et al., 1991). The IA-2 and the isoform IA-2 $\beta$  are important antigens especially in carriers of the HLA-DQ8 haplotype (Delli et al., 2010). The development of persistent ( $>3$  months) single or multiple ( $\geq 2$ ) islet autoantibodies is thought to occur shortly following the appearance of a first islet autoantibody but this seems to occur regardless of insulitis (In't Veld et al., 2007). A large group of minor autoantigens have also been proposed; however, the role of T- and B-lymphocyte reactivity as well as autoantibodies against most of these autoantigens has not been fully determined. Among these autoantigens are the secretory vesicle-associated proteins, chromogranin A, VAMP2 and NPY, HSP-60 and HSP-70, IGRP, Glima-38, and many others (detailed list is given in Wenzlau et al., 2008a). It cannot be excluded that the autoimmunity against these minor autoantigens reflects antigen and epitope spreading (Morran et al., 2008) (presentation of new antigen to inflammatory cells of the immune system leading to activation of new T lymphocytes). Further studies are needed to determine if the autoreactivity to minor autoantigens affects the progression from Stage I to II and reaching Stage III (Fig. 41.3).

## Pathology

Historically, the involvement of immune cells in autoimmune type 1 diabetes was described when inflammatory cell infiltrate, fibrosis and atrophy of the islets were demonstrated in postmortem pancreatic tissues obtained from some children who died soon following diagnosis (Gepts, 1965). The pathological feature of type 1 diabetes is the conspicuous loss of the pancreatic islet beta cells (Pipeleers et al., 2008). An infiltration of mononuclear cells in islets is often but not always observed (In't Veld, 2011). Insulitis ( $\geq 2$  mononuclear immune cells per islets) appears as a late manifestation and is observed primarily in multiple autoantibody-positive subjects prior to clinical diagnosis (In't Veld et al., 2007). Quantitative immunocytochemistry revealed a specific loss of beta cells and

that the neighboring cells producing glucagon, somatostatin, pancreatic polypeptide, or ghrelin were not affected. In subjects with insulitis, the islets of Langerhans may be infiltrated by T and B lymphocytes as well as monocytes and dendritic cells supporting a state of chronic inflammation (Eizirik et al., 2009). In some insulitis-positive islets, it has been possible to demonstrate markers of inflammation along with viral antigens (Foulis, 2008; Foulis et al., 1991).

The possible role of subclinical pancreatitis and infiltration of immune cells, in particular dendritic cells, needs to be explored (Skog et al., 2013).

The known insulitis characteristics are derived from specimens that mostly reflect an advanced stage of the disease or more extensive form of it when obtained from postmortem autopsies. Little is understood about early stages of propagation of autoimmune pathological features in the prolonged phases of Stage I and II. T lymphocytes, especially the CD4+ and CD8+ cell subsets, dominate the insulitis (Pinkse et al., 2005), compared to B lymphocytes, and may be found in larger populations in the islets (Kent et al., 2005). Therefore the infiltration of pancreatic islets by inflammatory cells, beta-cell destruction, and the resulting insulitis is a multistep process, which may vary widely in duration and intensity before diabetes becomes clinically manifested. Furthermore, in recent-onset type 1 diabetes, residual beta-cell function was temporarily preserved through the use of monoclonal antibodies targeting CD3 on T lymphocytes, CD20 on B lymphocytes, or drugs such as cyclosporine targeting monocyte/macrophage populations (Pescovitz et al., 2009; Herold et al., 2002; Bougnères et al., 1988). These observations in addition to the significant role of cellular immunological pathway, predominantly CD8+ lymphocytes, suggest that type 1 diabetes is primarily a cell-mediated autoimmune disease (Notkins and Lernmark, 2001; Willcox et al., 2009).

## IN VIVO AND IN VITRO MODELS

Several animal species were studied as models for autoimmune type 1 diabetes, although their diabetes phenotype was found to differ from the human type. Nevertheless, research on these animals yielded valuable guidance to human diabetes, where ethical issues or difficulties in obtaining human pancreatic samples may limit research. Type 1 diabetes-like syndromes develop spontaneously in the BioBreeding (BB) (Mordes et al., 2004), the LEW.1AR1-iddm (Jorns et al., 2010), and the Komeda diabetes-prone rat (Yokoi et al., 2003). All three types of rats have features similar to human type 1 diabetes; however, the trigger is due to mutations in different genes. Diabetes in all three rats is RT1.u, an ortholog of HLA DQ2. None of the rats develop islet autoantibodies that predict diabetes. The nonobese diabetic (NOD) mouse, which also develops diabetes with features comparable to human type 1 diabetes, has been studied extensively (Thayer et al., 2010; Mathis et al., 2001; Driver et al., 2011). The NOD mouse and its many congenic lines may be useful to dissect the genetic and pathogenic basis for T lymphocyte-mediated diabetes. However, while sharing many similarities, it is becoming increasingly clear that there are major differences in the immunopathogenesis between humans and NOD mice. Combination therapy with rapamycin and interleukin-2 prevented NOD mouse diabetes (Rabinovich et al., 2003) but accelerated the loss of residual beta-cell function in newly diagnosed type 1 diabetes patients (Long et al., 2012). Wild bank voles (*Myodes glareolus*) were reported to develop diabetes in laboratory captivity in association with autoantibodies against GAD65, IA-2, and insulin in standardized radioligand-binding assays as well as antibodies to in vitro transcribed and translated Ljungan virus antigens. It was speculated that bank voles may have a possible zoonotic role as a reservoir and vector for a virus that may contribute to type 1 diabetes (Niklasson et al., 2003).

## PRIMARY PREVENTION

The association between age at first exposure to cow's milk and type 1 diabetes raised the question if hydrolyzed cow's milk-based formula would prevent the appearance of islet autoantibodies. The clinical trials resulted in inconsistent findings (Akerblom et al., 2005; Knip et al., 2010, 2014). Also the TEDDY study reported that early weaning to an extensively hydrolyzed cow's milk-based formula was rather associated with an increased risk for islet autoimmunity (Hummel et al., 2017).

The possibility to identify newborn children with increased genetic risk to develop either IAA or GADA as the first appearing autoantibody (Krischer et al., 2015; Ziegler et al., 1999) raised the question of primary prevention through antigen exposure to induce immunological tolerance. A first study with oral insulin to prevent IAA first showed high safety and sign of immune activation (Bonifacio et al., 2015). A phase 2 study, Primary Oral

Insulin Trial (NCT03364868), has been initiated using GRS to screen newborns to identify children with 10% risk of developing IAA first (Bonifacio et al., 2018) and treat them with 67.5 mg insulin per day or placebo (Ziegler et al., 2016).

## SECONDARY PREVENTION

A large number of secondary prevention studies have been carried out to test if progression to clinical onset of type 1 diabetes can be prevented. The study of parenteral injections of insulin to autoantibody-positive individuals did not show protection (Effects, 2002). In subjects at lesser risk given oral insulin, there was no protection (Skyler et al., 2005). However, an ad hoc analysis suggested that a subgroup representing high titer IAA showed a delay in the progression to clinical diagnosis (Skyler et al., 2005). These results encouraged TrialNet to carry out a controlled clinical trial in a large number of IAA-positive subjects (Writing Committee for the Type 1 Diabetes TrialNet Oral Insulin Study Group et al., 2017). Overall, there was no benefit with oral insulin to prevent or delay the onset of diabetes; however, in one predetermined subgroup, there was a significant delay in the progression to diabetes. Further studies will be needed to better define treatment regimen and dosage of oral insulin.

A prevention study with GAD65-alum, Diabetes Prevention-Immune Tolerance, showed safety but no effect on the progression to diabetes (Elding Larsson et al., 2018b).

## INTERVENTION

The very first intervention studies with immune suppression were carried out already in 1975 shortly after the first description of islet cell antibodies (ICA). These early attempts to intervene with the autoimmune process have been followed by a very large number of both open and controlled studies using essentially every immune suppressive agent reaching the market [comprehensive reviews are available by Sherr et al. (2008), Skyler (2011), and Skyler (2013)]. None of the efforts have prevented the loss of beta cells and preserved residual beta-cell function long term.

## CONCLUSION AND FUTURE DIRECTIONS

Our understanding of the etiology and pathogenesis of autoimmune (type 1) diabetes mellitus is in rapid progress through several major efforts. The sequencing of the human genome has made it possible to better define the genetic contribution to the risk of islet autoimmunity and diabetes. Further studies are needed to better understand the genetic propensity for type 1 diabetes when moving between countries. Second, studies from birth in genetically susceptible individuals may uncover triggers that launch seroconversion. A current challenge is to better uncover the series of events that contribute to islet autoimmunity. It will also be a challenge to define the APC, T and B lymphocytes during the chronic stage of islet autoimmunity, and their contribution of to the beta-cell destruction. More than 50 non-HLA genes and possible SNPs should be examined one-by-one to reveal their possible contribution to the variable progression. These non-HLA genetic factors may also represent potential drug targets to secondary prevention or intervention. The limited success in secondary prevention and intervention studies with immunosuppressive agents suggests that novel approaches perhaps in combination trials with islet autoantigens will be required to successfully halt progression to the clinical onset or the loss of endogenous beta-cell function that invariably takes place after clinical diagnosis.

At present, the number of positive islet autoantibodies correlates to the risk of developing clinical disease. The cumulative risk of diabetes varies according to age and, the younger age at seroconversion, positivity for multiple autoantibodies, high antibody levels and persistent positivity for IAA, the greater the risk for type 1 diabetes.

Recent data from the TEDDY study show that seroconversion tends to occur during the first years of life, suggesting that environmental exposures in early in life may have a unique impact on children with increased genetic risk for diabetes. Large cohort studies on genetically susceptible individuals are needed to better uncover environmental and genetic triggers and/or protectors, to answer the question: Why only a minor part of individuals with genetic susceptibility develop autoimmune diabetes, while others with the same genetic risk do not?

### INTRODUCTION

Bartolomeo Eustachius was the first to describe the existence of the adrenals as "de glandulis quae renibus incumbent" in the *Opuscula Anatomica* published in Venice on 1563. Subsequently, Casserius (1561–1616) validated the discovery, depicting and naming them as "corpuscola reni incumbentia sive renes succenturiati" (Hiatt and Hiatt, 1997). In 1855 Thomas Addison first proved that the adrenals were vital organs when he described the symptoms and signs of patients with "anaemia, feebleness of the heart action, a peculiar change

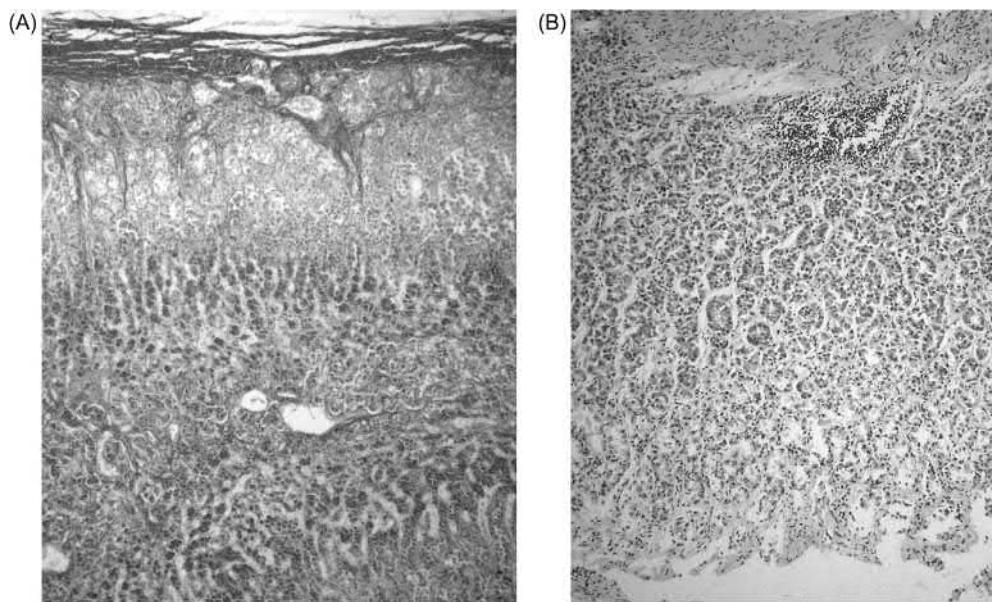

of colour in the skin occurring in connection with a diseased condition of the suprarenal capsules." He called this disorder "melasma suprarenale," postulating that it might be due to abnormal lesions in the adrenal glands. In this first description from the autopsies of 11 patients, he found 6 cases with tuberculosis, 3 with malignancies, 1 with adrenal hemorrhage, and 1 with adrenal fibrosis of an unknown origin. In this case, Addison (1855) reported, "The two adrenals together weighed 49 grains, they appeared exceedingly small and atrophied, so that the diseased condition did not result as usual from a deposit either of a strumous or malignant character, but appears to have been occasioned by an actual inflammation, that inflammation having destroyed the integrity of the organs, which finally led to their contraction and atrophy." Probably, this last case was the first description of an autoimmune adrenalitis. In 1856 the adrenal insufficiency was named "Addison's disease" by Troussseau, 1856. In the same year, Brown-Séquard (1856) demonstrated that dogs, cats, and guinea pigs subjected to bilateral adrenalectomy died, and adrenal glands were recognized as "organs essential for life." In 1896 William Osler administered the extracts of adrenal gland to treat a patient with Addison disease, but only from 1937 to 1955 corticosteroid hormones were isolated, their structures identified and synthesized (Medvei, 1993).

## ANATOMY AND PHYSIOLOGY OF THE ADRENALS

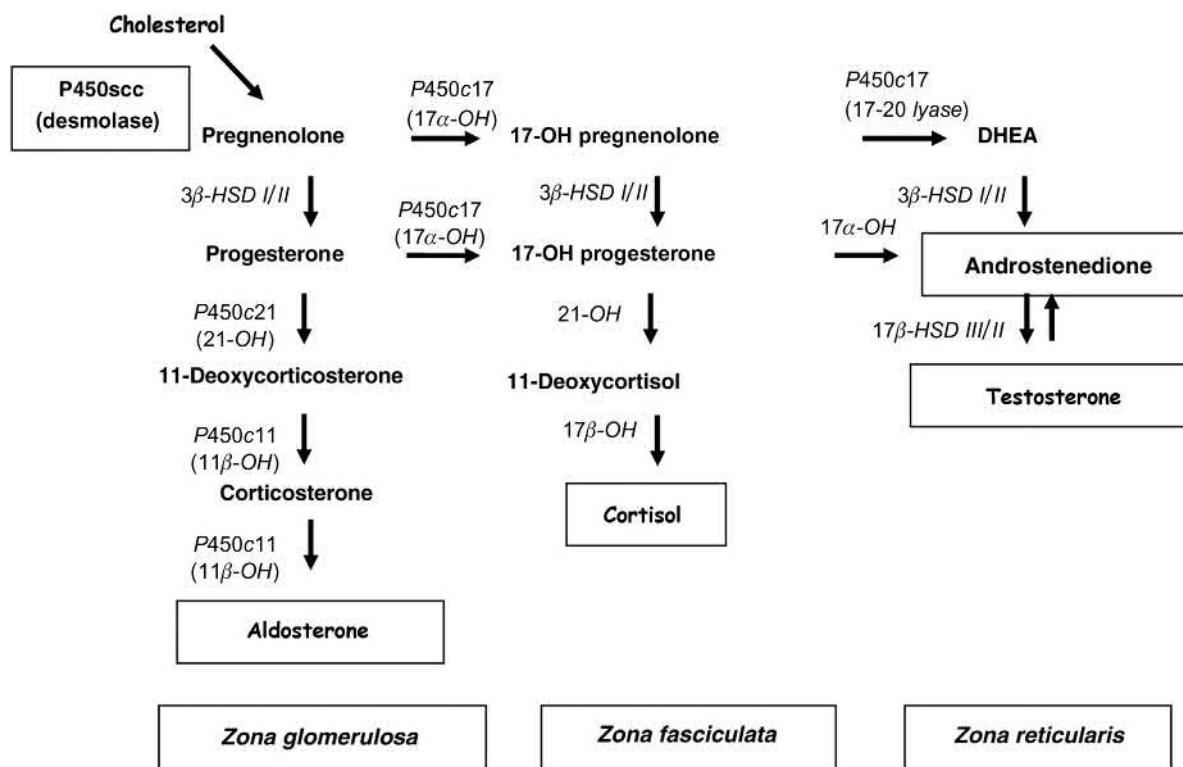

The adrenal glands develop from the mesenchyme the outer part (cortex) from the mesoderm and the central part (medulla) from the neuroectoderm, which comprises part of the chromaffin system (Kannan, 1988). The adult adrenal gland has a pyramidal configuration and is approximately 4 g in weight, 2 cm wide, 5 cm long, and 1 cm thick that lies immediately over the kidney on its posteromedial surface. The vasculature of the adrenal cortex is complex. Adrenal blood supply derives from 3 main suprarenal arteries that pierce the gland surface, dividing into 50–60 small branches and forming a subcapsular plexus which embraces the cell clusters in the zona glomerulosa and then run among the cellular cords in the zona fasciculata. The capillary branching from the arterial system forms a microvascular network around the zona reticularis which drains into the medullary sinusoids by relatively few small venules that eventually form a large central vein. The right adrenal vein is short and empties directly into the inferior vena cava, while the longer left adrenal vein usually empties into the left renal vein (Stewart and Newell-Price, 2016). The adrenal cortex is divided into three layers. The *zona glomerulosa* (5%–15% of the cortex) comprises discontinuous subcapsular aggregates of small cells, containing less cytoplasm than the other cortical cells. The middle zone or *zona fasciculata* (70%–75% of the cortex) is formed by radial cords of large cells arranged in columns with abundant lipid-filled cytoplasm. The inner cortical zone or *zona reticularis* is composed of cells arranged in cords with compact, finely granular, eosinophilic cytoplasm (Fig. 42.1A). The maintenance of normal adrenal size probably involves a progenitor cell population lying between the *zona glomerulosa* and the *zona fasciculata*. Cell migration and differentiation occur within the *fasciculata*, and senescence occurs within the *zona reticularis*, but the factors which modulate adrenal regeneration are unknown. ACTH administration results in *glomerulosa* cells acquiring a *fasciculata* phenotype and, in turn, the deepest *fasciculata* cells acquire a *reticularis* phenotype that is reversible on withdrawal of ACTH (Stewart and Newell-Price, 2016).

The adrenal cortex synthesizes three main groups of hormones (glucocorticoids, mineralocorticoids, and adrenal androgens) (Auchus and Miller, 2001). The homeostasis of glucocorticoids is regulated by a feedback mechanism through the hypothalamus by means of corticotropin-releasing hormone, the pituitary gland by ACTH, and the adrenal cortex by cortisol (Koch, 2004). The main steps in the synthesis of the adrenal cortex hormones and the enzymes involved are described in Fig. 42.2.

By immunocytochemical techniques, the normal adrenal cortex shows the presence of many proteins (Thiebaut et al., 1987; Henzen-Logmans et al., 1988; Sasano et al., 1989; Muscatelli et al., 1994; Fogt et al., 1998; Pelkey et al., 1998). Immunopositivity has been demonstrated for the class II major histocompatibility complexes (MHCs) (found in 10%–20% of the cortical cells) including the human antigen D-related leukocyte (HLA-DR) (McNicol, 1986; Jackson et al., 1988) and interleukin-6 (Gonzalez-Hernandez et al., 1994), which is involved in the communication process between the immune and endocrine system. Using specific antibodies against the steroidogenic enzymes and cytochrome P450 (Sasano et al., 1994), it was demonstrated that cytochrome P450 is involved in the adrenal steroid biosynthesis process, while the AdBP/SF-1 transcription factor regulates the expression of the CYP genes (Orth and Kavacs, 1998).

## EPIDEMIOLOGY OF ADDISON'S DISEASE AND AUTOIMMUNE ADRENALITIS

Addison's disease (AD) is a very rare disorder and formerly tuberculosis was the most frequent cause. Of the 11 cases originally described by Addison (1855), 6 (55%) had tuberculosis and only 1 (9%) had an idiopathic fibrotic form probably the first case of an autoimmune AD (AAD). For many years, tuberculosis was the most

frequent form of adrenal insufficiency. **Guttman (1930)** examined 566 autopsied patients with AD and found 70% with tuberculous adrenalitis. **Dunlop (1963)** reviewed 86 cases of AD and reported 79% with tuberculous adrenalitis. In the following years the frequency of tuberculosis AD progressively decreased. On the contrary, the prevalence of the autoimmune form in the past was reported to be 31% in London (**Mason et al., 1968**), 17% in Denmark (**Nerup, 1974**), and 21%–33% in Italy (**Betterle et al., 1989; De Rosa et al., 1987**) of all patients with AD.

During the last four decades, AAD progressively increased and has now become the most frequent cause of AD. From 1974 to 2002, 1557 patients with AD were evaluated in Europe, and the prevalence of AAD ranged from 44.5% to 94% (**Betterle et al., 2002**). On 633 patients with AD collected in Padua from 1960 to 2012, AAD was found to be 54% of the cases in the decade from 1960 to 1970, but its prevalence increased to 83.7% in the years from 2000 to 2012 (**Betterle et al., 2013**). In spite of the reduction of the AD due to tuberculous adrenalitis, the total frequency of AD was increasing. The prevalence of AD was estimated to be of 39 cases per million in London area in 1968 (**Mason et al., 1968**), 60 cases per million in Denmark in 1974 (**Nerup, 1974**), 93 cases per million in Coventry in 1997 (**Willis and Vince, 1997**), 110 cases per million in Nottingham in 1994 (**Kong and Jeffcoate, 1994**), 117 cases per million in Italy in 1999 (**Laureti et al., 1999**), and 144 cases per million in Norway in 2009 (**Erichsen et al., 2009a**). Moreover, a very high prevalence has been recently found in Iceland with 221 cases per million (**Olafsson and Sigurjonsdottir, 2016**). The incidence of AD in Europe has been estimated to be of 5–6 new cases per 1000,000 inhabitants per year (**Kong and Jeffcoate, 1994; Erichsen et al., 2009b**). However, based on the recent epidemiological data, the real incidence of AD in Europe could be more elevated.

The prevalence of AD varies also in relation to different geographic areas: in New Zealand (**Eason et al., 1982**) 4.5 cases per million, in Japan 5 cases per million (**Takayanagi et al., 2000**), in the United States 50 cases per million (**Jacobson et al., 1997**), and in Europe 110–221 cases per million, as mentioned above. Despite the constant decrease of tuberculous forms of AD, the overall prevalence of AD has progressively increased, and this may be due to an absolute increase of AAD.

## AUTOIMMUNE ADDISON'S DISEASE

AAD depends on a combination of genetic, environmental, and endogenous factors able to both induce a break of immune tolerance and initiate an autoimmune attack on the adrenal cortex, as for other autoimmune diseases (**Kamradt and Mitchinson, 2001; Bratland and Husebye, 2011**).

### Focal Lymphocytic Adrenalitis

**Duff and Bernstein (1933)** and **Kiaer and Rytter Norgaard (1969)** described a focal adrenalitis in patients without signs or symptoms of AD. **Petri and Nerup (1971)**, studying 2 groups of patients (413 and 161 miscellaneous cases), reported the presence of very small numbers of lymphocytes in 15% and 18.6% of the adrenal glands, respectively. Subsequently, in up to half of the autopsied patients without AD, a focal accumulation of lymphocytes and plasma cells was demonstrated in the adrenal cortex, associated with chronic inflammatory diseases in the retroperitoneum (**Fidler, 1977; Orth and Kavacs, 1998**). The percentage of these infiltrates was similar to that reported in focal thyroiditis. In 1989 Hayashi et al. evaluated 174 cases at autopsy and demonstrated that the mononuclear cell infiltration in the adrenal cortex increased with age, being present in about 7.4% of those aged over 49 years and 63% aged over 60 years. Immunohistochemical studies also revealed that the infiltrating mononuclear cells were mainly composed of CD3+ T cells. The major proportion of CD3+ T cells expresses the CD4 phenotype, whereas CD8+ T cells were fewer. A proportion of the CD4+ T cells was activated (**Hayashi et al., 1989**). These findings indicate that the focal lymphocytic infiltration of the adrenal glands is not rare and may represent a latent adrenalitis which, however, rarely reaches clinical expression since adrenal cortex antibodies and symptomatic AAD are extremely rare in the population.

A comprehensive investigation of the cellular and molecular components of the infiltrate has never been performed on the adrenal glands in patients with AAD so that the mechanisms by which the adrenal cortex is destroyed remain hypothetical (**Bratland and Husebye, 2011**).

## Diffuse Lymphocytic Adrenalitis

The pathologic findings initially described by Addison (1855) as "idiopathic" are constantly present in the adrenal glands of patients affected by AAD. On macroscopic examination, both the adrenals are small (weight 1–2 g), and sometimes their identification is difficult in the retroperitoneal tissue. The capsule is fibrous so that the adrenal glands are not detectable macroscopically and adrenal tissue is not visible in multiple sections (Drury et al., 1979).

On microscopic examination, there is complete destruction of the three-layer architecture. The adrenal cortical cells are single, enlarged, or pleomorphic, with increased eosinophilia, depleted in lipids, or present as part of a cluster. Residual cortical nodules are seen as the disease progresses. The tissue is diffusely infiltrated by small lymphocytes, plasma cells, and macrophages (McNicol and Laidler, 1996). The histopathologic finding of infiltrating lymphocytes sometimes is associated with follicle formation and fibrosis (Fig. 42.1B). The medulla in AAD remains normal. This pattern is present in patients with AAD, either isolated or associated in the context of autoimmune polyendocrine syndromes (McIntyre Gass, 1962; Irvine and Barnes 1975; Betterle et al., 2002).

## Induced Immunity in Animal Models

Colover and Glynn (1958) reported isoimmunization in guinea pigs by injection of adrenal antigens and complete Freund's adjuvant, with distinctive and "specific" lesions of the adrenals. Subsequently, some authors (Steiner et al., 1960; Barnett et al., 1963) reported examples of experimental autoimmune adrenalitis (EAA) in different species (rabbits, guinea pigs, rats, and monkeys), including an antibody reaction in the guinea pigs and a lymphocytic infiltration in the rabbit adrenal tissue (Witebsky and Milgrom, 1962; Barnett et al., 1963). The adrenal lesions in rabbits were characterized by foci of lymphocytes and histiocytes, with a small number of plasma cells and eosinophils, and degenerative changes in adrenal cells. Andrade et al. (1968) and Werdelin and Witebsky (1970) demonstrated that EAA in a Lewis rat model was induced at day 7 after immunization. The histology was studied by autoradiographic tracing of H<sub>3</sub> thymidine and H<sub>3</sub> adenosine-labeled cells and demonstrated that adrenalitis was initiated with the appearance of a few specifically reactive lymphocytes, followed by an infiltration of mononuclear cells, mainly lymphocytes and plasma cells, throughout the adrenal cortex. Eosinophilia, cytoplasmic vacuolization, and a loss of nuclear definition were evident in cortical cells.

Using electron microscopy, Hoenig et al. (1970) studied the inflammatory lesions in paraffin-embedded tissues; 5 days after immunization, lymphocytes were present in sinusoids and adrenal parenchyma where the damage was in the vicinity of lymphocytes, with enlargement of intercellular spaces and ischemic areas with inflammatory cells and fibrin.

Fujii et al. (1992) demonstrated that in mice repeated immunizations caused a delayed type of hypersensitivity to adrenal antigens and that transfer of adrenalitis from an affected to a healthy animal was not possible by serum but only by using spleen cells, confirming the previous reports (Levine and Wenk, 1968; Werdelin et al., 1971) in which the disease was passively transferred by immunocytes derived from lymph nodes.

## Spontaneous Animal Models

Spontaneous AD occurs in dogs (Harlton, 1976; Kaufman, 1984; Little et al., 1989; Kintzer and Peterson, 1994; Sadek and Schaer, 1996; Dunn and Herrtage, 1998) and cats (Kaufman, 1984; Peterson et al., 1989; Tasker et al., 1999; Stonehewer and Tasker, 2001) with hypoadrenocorticism due to immune-mediated destruction of the adrenal glands. While biochemical laboratory data were reported, none of the authors described positivity for the adrenal cortex autoantibodies (ACAs), but only the presence of lymphocytic infiltration in the adrenal glands, at autopsy. Beales et al. (2002) found the adrenal glands of a nonobese diabetic (NOD) mouse to contain a mononuclear cell infiltration in the adrenal cortex but without signs of hypoadrenalinism. Thus the NOD mouse was proposed as a spontaneous model suitable for investigating mechanisms involved in diffuse lymphocytic infiltration of the adrenal glands.

## Family History of Autoimmune Addison's Disease and Genetic Predisposition

In Norwegian patients with AAD, 10% of patients had another family member with AAD (Erichsen et al., 2009a). In our studies a family history for AAD was found in 2% of the patients with AAD in the context of autoimmune polyglandular syndrome (APS) type 2, Type 4 or isolated AAD, whereas this association was present in

25% of the patients with AAD in the context of APS type 1 (Betterle et al., 2013). In a Swedish study a family history for AAD was found in 6.4% of the patients with AAD without APS-1 (Dalin et al., 2017). The majority of identical twins with an autoimmune disease have unaffected twins, that is, they are discordant for the disease (Salvetti et al., 2000). However, there are only limited case reports with concordance or discordance of the disease in twins with AAD (Simmonds and Lister, 1978; Emy, 1998). As regards the genetic predisposition of AAD, the majority of the studies were performed in patients with isolated AAD or in the context of APS type 2. In these patients the association was primarily related to class II HLA alleles in the MHC (Myhre et al., 2002). Reports from several different populations have demonstrated that the risk of AAD is significantly increased in the presence of *HLA-DRB1\*03-DQA1\*0501-DQB1\*0201* (*DR3/DQ2*) and *DRB1\*0404-DQA1\*0301-DQB1\*0302* (*DR4/4/DQ8*). *DRB1\*0404* is much more frequent and indicates that peptides from 21-hydroxylase (21-OH) are well presented to autoreactive T lymphocytes in the presence of *DR4/4*. In addition to the abovementioned alleles, it has been demonstrated that *HLA-B8* was significantly increased independently of *DR3* (Bratland and Husebye, 2011). Furthermore, an association between AAD and the 5.1 allele of MHC class I chain-related A (MIC-A) has been demonstrated. Homozygosity for the 5.1 allele of *MIC-A* in the presence of high-risk HLA genotype (*DR3-DQ2/DR4/4-DQ8*) may define subjects at very high risk of AAD. *MIC-A* is not involved in the antigen presentation but as a mediator of activating natural killer cells and T cytotoxic lymphocytes (Bratland and Husebye, 2011). A number of other genes outside the MHC have also been reported such as the cytotoxic T lymphocyte (CTL)-associated protein-4, a key negative regulator in adaptive immunity, the MHC class II transactivator (*MHC2TA*) which regulates the expression of class II molecules, the tyrosine-protein phosphatase nonreceptor type 22 (*PTPN22*) involved in the regulation of T-cell receptor signaling, and the programmed death ligand 1 (PD-L1) which is an inhibitory molecule expressed on activated T cells. In addition to the abovementioned genes, AAD is associated with genes involved in the metabolism of vitamin D with the gene encoding NACHT leucine-rich-repeat protein 1 (*NLRP1*) (Bratland and Husebye, 2011). Other involved genes are *STAT4*, *FCRL3*, *GPR174*, *GATA3*, and *CYP27B1* (Mitchell et al., 2014; Falorni et al., 2016). A study of multiplex AAD in families comprising two or more individuals with the disease from the United Kingdom and Norway reported that the non-HLA locus *NFATC1* (nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1) was a possible susceptibility gene for AAD. *NFATC1* is a candidate gene as it is expressed in adrenal cortex and encodes a transcriptional factor which plays a central role in gene transcription during the immune response (Mitchell et al., 2015).

Finally, it is worthwhile remembering that in patients with APS-1, where AAD is one of the major components, there are mutations of the autoimmune regulator (*AIRE*) gene (Cervato et al., 2009; Bratland and Husebye, 2011). So far, about 100 *AIRE* mutations have been identified (Bruserud et al., 2016). This gene is involved in the presentation of autoantigen to autoreactive T lymphocytes in order to induce tolerance, and the presence of the *AIRE* gene with mutated proteins may inhibit the apoptosis of autoreactive T lymphocytes at the thymic level. These cells can migrate at the peripheral level where they can initiate an autoimmune aggression in a very young age in these patients. In Scandinavian patients with type 1 APS, AAD seems to be associated with *HLA-DRB1\*03*, alopecia with *HLA-DRB1\*04-DQB1\*0302*, whereas *HLA-DRB1\*15-DQB1\*0602* alleles are protective for type 1 diabetes (Halonen et al., 2002). However, in APS-1 the association with HLA alleles is limited or lacking (Cervato et al., 2009; Bratland and Husebye, 2011).

## Cellular Immunity

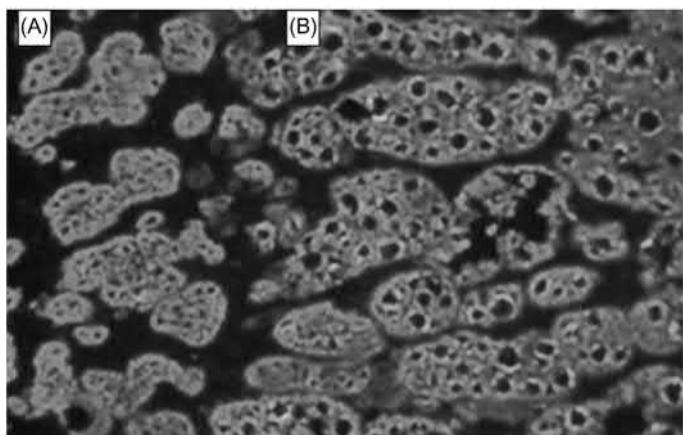

Although autoantibodies are strong markers of autoimmune adrenalitis and may identify individuals at high disease risk or have a cytotoxic effect *in vitro*, they have not been demonstrated to display pathogenic effects *in vivo* (Boscaro et al., 1996). The early studies on AD, using the assay for migration inhibition factor, reported cell-mediated immunity in affected patients, with claims for organ-specific hypersensitivity (Nerup and Bendixen, 1969). Subsequent studies, by means of an intracutaneous test with adrenal extracts, showed a delayed-type hypersensitivity reaction but no collateral evidence based on blast transformation experiments (Nerup et al., 1970). Other studies reported a decrease in suppressor T-cell function (Vergheze et al., 1980) and an increase in circulating Ia-positive T lymphocytes (Rabinowe et al., 1984), which indicated the involvement of cellular immunity. Initially, studies of cellular immunity in AAD were carried when a proliferative T-cell response to an adrenal-specific protein fraction of 18–24 kDa molecular weight was described out (Freeman and Weetman, 1992). Additionally, and an impaired suppressive function of CD4+CD25+ regulatory T cells were described in APS 2 patients (Kriegel et al., 2004). Subsequently, in order to identify the autoepitopes recognized by T lymphocytes, BALB/c and SJL

inbred mouse strains were immunized with recombinant 21-OH. T lymphocytes of the immunized animals were stimulated by the peptide 342–361 of 21-OH. This region may be involved in the pathogenesis of AAD (Husebye et al., 2006). It was also demonstrated that patients with AAD have circulating 21-OH-specific T cells recognizing the amino acidic fragment 342–361 of 21-OH, who constitute a disease-specific epitope presented by *HLA-DRB1\*0404*. Furthermore, cellular proliferation and secretion of interferon- $\gamma$  in response to 21-OH were significantly higher in patients with AAD respect to controls (Bratland et al., 2009). It was recently demonstrated that 21-OH-specific T cells are frequently detectable in patients with AAD. Immunodominant CD8+ and CD4+ T-cell responses were detectable in a large proportion of AAD, both *in vivo* and *in vitro*. *HLA* class I-guided isolation of 21-OH-specific CD8+ T cells showed the ability to lyse 21-OH-positive target cells, consistent with a potential mechanism for disease pathogenesis (Dawoodji et al., 2014). These data indicate that strong CTL responses to 21-OH often occur *in vivo* and that reactive CTLs have substantial proliferative and cytolytic potential.

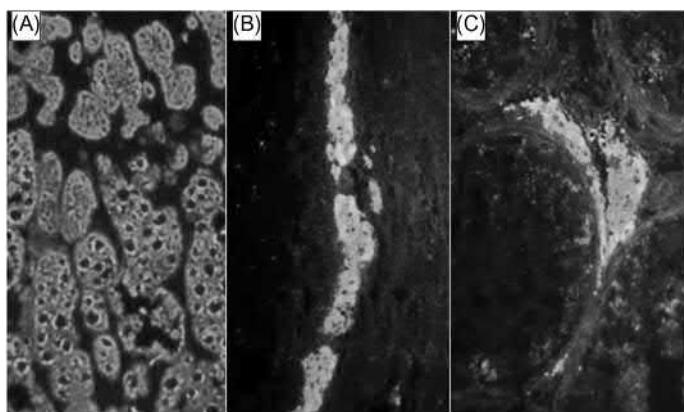

## Humoral Immunity

Anderson et al. (1957), using a complement fixation test with a homogenate of adrenal cortex tissue, first demonstrated that two out of eight (i.e., 25%) patients with “idiopathic” AD had complement-fixing antibodies.

Subsequently, Blizzard and Kyle (1963), using the indirect immunofluorescence (IIF) on animal or human cryostatic sections of adrenal gland, demonstrated that ACAs are organ-specific, but not species-specific, antibodies reacting with all the three layers of the adrenal cortex and producing a homogeneous cytoplasmic staining pattern (Fig. 42.3). Sometimes, there is a reactivity against one or two of the three layers of the cortex (Irvine and Barnes, 1975; Sotsiou et al., 1980). The autoantibodies also reacted with the surface of living cortical cells in culture (Khoury et al., 1981), indicating that microsomal antigens are also expressed on the surface of adrenal cortical cells. Between 1963 and 2002, using IIF, ACAs were found to be positive in 61% of 1637 patients with AAD and in 6.7% of 267 with tuberculous AD, as reviewed by Betterle (2002). The prevalence of ACA has varied considerably between different laboratories because of differences in the substrates used (animal or human), time of incubation, geographic or racial origins of individuals, gender, age of onset, duration of the disease, or whether other associated diseases were present (Rees Smith and Furmaniak, 1995; Betterle et al., 2002; Nigam et al., 2003). Two studies (Kendall-Taylor et al., 1988; Wulfraat et al., 1989) reported the presence of autoantibodies blocking the ACTH receptor in 90% of the patients affected by AAD, but these data could not be confirmed (Wardle et al., 1993). Finally, autoantibodies to hydrocortisone were detected in patients with an Addison-like syndrome and AIDS (Salim et al., 1988). In 1968 the steroid-producing cell antibodies (StCA) were first described (Anderson et al., 1968) in two males affected by AAD without gonadal failure (Fig. 42.4). Subsequently, StCA were detected in 60%–80% of the females affected by type 1 APS, in 25%–40% of those with type 2 APS, and in 18% of those with isolated AAD (Betterle et al., 2002, 2005). The presence of StCA correlates with premature ovarian failure (POF) characterized by lymphocytic oophoritis (Betterle et al., 1993; Hoek et al., 1997; Betterle and Volpato, 1998). A study in Norway demonstrated that 6.7% of females with AAD had POF (Erichsen et al., 2009a). An Italian study performed on 258 females with AAD revealed a POF in 20% of the patients. Particularly, POF was found in 40.8% of patients with APS-1, in 33.3% with APS-4, and in 16% with APS-2. StCA were detected in 72% of AAD with POF of various duration, but with a higher prevalence (92%) in patients with POF duration of less

**FIGURE 42.3** Immunofluorescence pattern on normal human adrenal cortex given by serum of a patient with autoimmune Addison's disease. This serum diffusely reacted with the cytoplasm of the cells in all the three layers of the cortex, but shown here are only *glomerulosa* (A) and *fasciculata* (B) zones.

**FIGURE 42.4** Immunofluorescence pattern given by serum of a patient with autoimmune Addison's disease (AAD) and premature ovarian failure. This serum reacted against adrenal cortex (A), follicular theca of the ovary (B), and Leydig cells of the testis (C) and reflects autoantibodies to steroid-producing cells (StCA).

than 5 years. StCa were also found in 25.7% of patients without POF. However, a follow-up study on young females with AAD without POF but positive for StCA revealed that 38% developed POF at a mean age of 23 years, thus demonstrating that steroidogenic autoantibodies are predictive markers of future clinical POF (Reato et al., 2011). We also searched for StCA in 154 Italian males with AAD (mean age 34 years) and they were found in 18.8% of the patients (60.7% with APS-1 and 10% with other APS types or isolated AAD). Differently from females, all males with StCA had a normal gonadal function, and during a mean follow-up of 7 years, none of the positive patients developed hypergonadotropic hypogonadism (Dalla Costa et al., 2014).

### Identification of Autoantigens of Adrenal Cortex Autoantibodies

Furmaniak et al. (1988) described a specific 55 kDa protein in human adrenal microsomes which was reactive with ACA. In 1992 two independent laboratories (Baumann-Antczak et al., 1992; Bednarek et al., 1992; Winqvist et al., 1992) demonstrated by means of purification of native 21-OH that this adrenal enzyme is a major antigen of adrenal cortical cells. Subsequently, this was confirmed in experiments with specific absorption with purified human 21-OH, using sera from six patients with different forms of AAD (Morgan et al., 2000). 21-OH is an adrenal-specific enzyme of the cytochrome P450 family and plays a key role in the synthesis of the cortical hormones (Furmaniak et al., 1999; Furmaniak and Rees Smith, 2002). 21-OH is encoded by the CYP21B gene, whereas the CYP21A gene is inactive (Wilson et al., 1995). 21-OH catalyzes the conversion of progesterone and 17-hydroxyprogesterone into 11-deoxycorticosterone and 11-deoxycortisol (see Fig. 42.2). It is a 55 kDa microsomal protein containing a heme group, located in the active site of the C-terminal end of the molecule, which is important for antibody binding (Wedlock et al., 1993; Asawa et al., 1994) and in oxidation-reduction reactions (Picado-Leonard and Miller, 1987; Lin et al., 1994). Analysis of antibody-binding sites on 21-OH indicated that the epitopes on 21-OH were conformational (Wedlock et al., 1993) and confirmed the participation of both the central and C-terminal parts of the molecule. These studies identified the presence of three different, short 5-, 6-, and 15-amino acid sequences in the C-terminal part of the 21-OH involved in the binding of antibodies to 21-OH (Chen et al., 1998). These observations are important in relation to effects of 21-OH antibodies on 21-OH enzyme activity. In fact, in studies *in vitro*, using sera positive for 21-OH Abs from patients with AAD, a dose-dependent blocking activity was identified (Furmaniak et al., 1994), although this is not usually evident *in vivo* (Boscaro et al., 1996). Furthermore, maternal 21-OH Abs of IgG class crossing the placenta during pregnancy do not induce hypoadrenalinism in newborns (Betterle 2014a). On the basis of these data we cannot consider that these autoantibodies had a pathogenetic role *in vivo*.

### Identification of Autoantigens of Steroid-Producing Cells Autoantibodies

With regard to StCa autoantigens, in addition to 21-OH, Krohn et al. (1992) reported that screening of a human fetal adrenal cDNA expression library with sera from patients with APS type 1 identified a protein with high homology to 17 $\alpha$ -hydroxylase (17 $\alpha$ -OH) reacting also with a fragment of recombinant 17 $\alpha$ -OH expressed in bacteria. 17 $\alpha$ -OH, coded by a single gene on the human chromosome 10, showed 30% homology with 21-OH antigen. Winqvist et al. (1992), using immunoblotting and immunoprecipitation studies, also observed a reactivity of sera from APS-1 patients with a cytochrome P450 side-chain cleavage enzyme (P450scc), a heme-binding protein coded by a single gene on human chromosome 15 that showed 20%

homology with 21-OH sequence (Chung et al., 1986). The binding sites of these two antigens and their enzyme activity have not been studied, even though Peterson and Krohn (1994) reported the presence of four distinct reactive regions in the 17 $\alpha$ -OH molecule and an inhibiting effect *in vivo* of the P450sccAbs in the APS-1 patients' serum (Winqvist et al., 1993).

### Techniques for Identification of Autoantibodies to 21-Hydroxylase

Following the discovery that 21-OH is the major adrenal cortex autoantigen, a specific and sensitive technique was described, by labeling the protein with  $^{35}\text{S}$ -methionine in an *in vitro* transcription translation system, and using a radioimmunoprecipitation assay (RIA), for the detection of antibodies (Colls et al., 1995; Falorni et al., 1995; Chen et al., 1996). Thereafter, because of certain limitations of this technique, a more convenient assay to measure 21-OH Abs was developed based on the use of  $^{125}\text{I}$ -labeled recombinant human 21-OH and the precipitation of the immunocomplexes using solid-phase protein A (RIA) (Tanaka et al., 1997). Using these techniques, from 1995 to 2002, a group of 572 patients with AAD and 76 with tuberculosis was studied; 78% and 1.9%, respectively, were 21-OH Abs positive, reviewed by Betterle (2004).

In order to compare techniques for ACA and 21-OH Abs determinations, we studied 165 patients with AD, with different duration of disease, and found that 81% of those with AAD were positive by both techniques, whereas none with non-AAD was positive (Betterle et al., 1999). The prevalence varied in relation to both the clinical presentation (type 1 or 2 APS or isolated AAD) and the length of the disease, being higher in patients with recent (100%) onset than in those with long-standing disease (79%), and in those with type 2 APS than in those with isolated AAD (Betterle et al., 2002). In these studies, results using IIF for ACA and RIA for 21-OH Abs were in good agreement. Some discrepancies were reported by Falorni et al. (1997) and Betterle et al. (1999) on the relationships between ACA measured using IIF and 21-OH Abs measured by RIA. For example, a few patient samples were positive for 21-OH Abs while negative for ACA, and this may reflect greater sensitivity of 21-OH Abs IPA. In contrast, a small number of sera were positive for ACA while negative for 21-OH Abs by RIA. This discrepancy may be related to serum reactivity with adrenal cortex antigens in the IIF that are distinct from 21-OH.

An international standardization program for 21-OH Abs detection was first carried out in 2010 to compare the measurements from four laboratories with different methods and perform an interlaboratory concordance study. This investigation showed a very good agreement among the laboratories on reporting 21-OH Abs-positive/negative samples. The sensitivity for AAD was greater than 80% in all participating laboratories. However, the study highlighted the need to produce the international standard preparation to enable the harmonized expression of the results (Falorni et al., 2011). Another standardization study for 21-OH Abs measurement was organized by the EurAdrenal Consortium in 2014, and 13 different laboratories across Europe and one from the United States participated in this program. The results demonstrated good diagnostic sensitivity, specificity, and accuracy for "in-house" and commercial assays (Falorni et al., 2015). In the future the standardization program is needed to identify common standard sera and common measuring units.

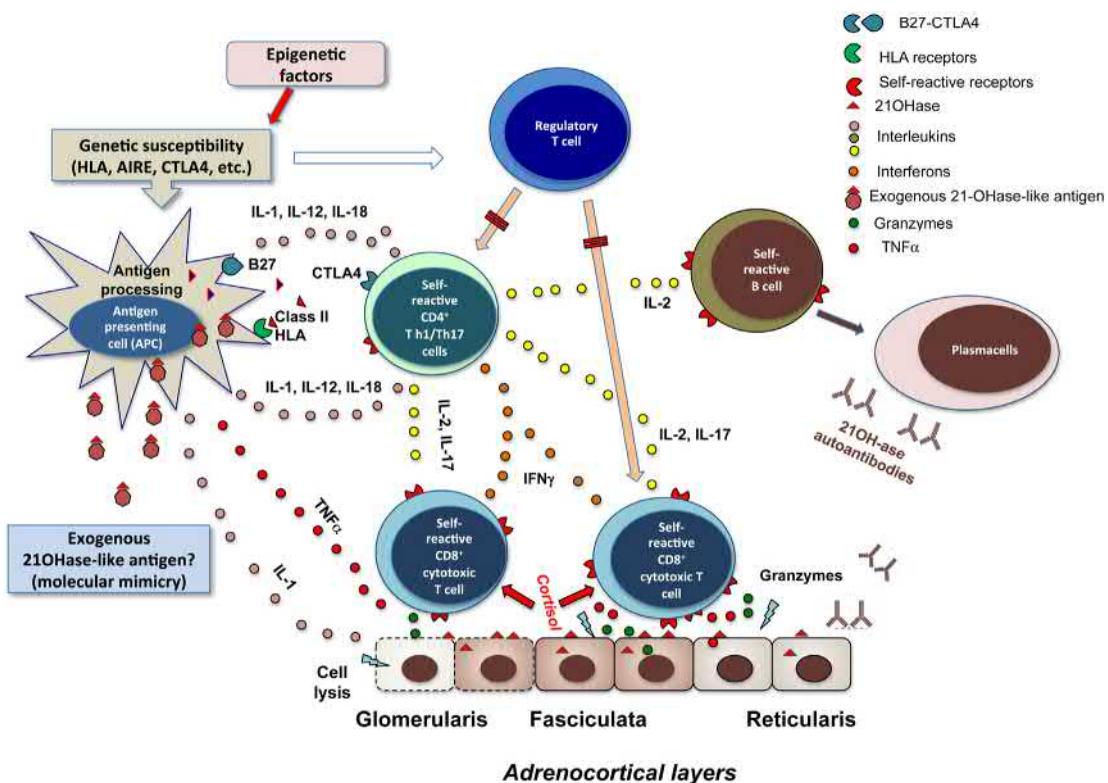

### Techniques for Identification of Autoantibodies to Other Steroidogenic Enzymes

From 1996 the 17 $\alpha$ -OH Abs and P450sccAbs are detectable by a RIA kit, using recombinant human antigens (Chen et al., 1996), and the results are correlated with StCA detected by IIF (Betterle et al., 1999, 2002; Reato et al., 2011; Dalla Costa et al., 2014). A hypothetical mechanism of autoimmune aggression against the adrenal cortex is shown in the Fig. 42.5.

A hypothetical mechanism of autoimmune aggression against the adrenal cortex is shown in the Figure 42.5.

### Other Autoantibodies Detected in Patients With Autoimmune Addison's Disease

In addition to the main autoantibodies previously mentioned (ACA, 21-OH Abs, StCA, 17 $\alpha$ -OH Abs, and P450sccAbs), other autoantibodies have also been discovered that are characteristic of patients with APS-1, where the AAD represents one of the principal diseases (Husebye et al., 2009). Winqvist et al. (1996) identified an autoantibody of 51 kDa, recognizing the aromatic l-amino acid decarboxylase (AADCAbs) involved in the generation of serotonin and dopamine. AADCAbs was reported in the sera of patients in association with chronic hepatitis, vitiligo, and type 1 diabetes mellitus (Husebye et al., 1997), and also with autoimmune gastrointestinal

**FIGURE 42.5** Hypothetical pathogenesis of autoimmune adrenalitis. A currently unknown exogenous antigen (viruses, bacteria, chemicals) may activate antigen presenting cells (APCs). After antigen uptake, APCs process and present antigens to CD4 + T-helper 1 and T-helper 17 (Th1/Th17). In turn, T-helper cells promote activation and clonal expansion of cytotoxic T lymphocytes to exogenous antigen but also of auto-reactive cytotoxic T lymphocytes (CD8 +) and autoreactive B cells which release self-destructive cytokines and steroid 21-hydroxylase autoantibodies (21-OHAbs), respectively. This self-reactive process might be allowed by deficiency of T-regulatory (T-reg) cells. The progressive destruction of glomerular, fascicular, and reticular cells of adrenal cortex is mediated by cytotoxic T cells through local production of cytokines. 21-OHAbs may also activate the complement system and antibody-dependent cellular cytotoxicity. Yet, these mechanisms of damage have been demonstrated in vitro but not in vivo. Local release of cortisol by zona fasciculata may hamper or at least delay this process. dysfunction (Kluger et al., 2015). Autoantibodies against a 230 kDa enzyme, identified as tryptophan hydroxylase (TPHAbs) (Ekwall et al., 1998; Dal Pra et al., 2004), and against histidine decarboxylase (HDAbs) (Skoldberg et al., 2003) were demonstrated in patients who had a gastrointestinal dysfunction (Ekwall et al., 1998; Scarpa et al., 2013; Kluger et al., 2015). Autoantibodies to cytochromes P450, CYPIA2, and CYP2A6 were associated to patients with autoimmune hepatitis (Clemente et al., 1997, 1998). Autoantibodies to SOX9 (SOX9Abs) and SOX10 (SOX10Abs) were reported in patients with vitiligo (Hedstrand et al., 2001), while autoantibodies to tyrosine hydroxylase (THAbs) in those with alopecia areata (Hedstrand et al., 2000). Autoantibodies to NALP5 (NALP5Abs) were found in patients with type 1 APS and chronic hypoparathyroidism (Alimohammadi et al., 2008), while autoantibodies to a potassium channel regulator (KCNRGAbs) in those with autoimmune bronchiolitis (Alimohammadi et al., 2009). In addition, autoantibodies to various interferon types (IFNAb) were demonstrated to be markers of APS-1 independently of the major or minor clinical manifestations (Larosa et al., 2017). Analysis of these autoantibodies in APS-1 patients is a useful tool for establishing autoimmune manifestations of the disease, as well as providing diagnosis in patients with suspected disease and predicting future clinical manifestations (Söderbergh et al., 2004).

## NATURAL HISTORY OF AUTOIMMUNE ADDISON'S DISEASE

ACA can be detected also in patients without AAD and specifically in 0.2% of normal controls, in 4% of first-degree relatives of AAD patients, in 4% of hospitalized patients, and in 1.3% of patients with organ-specific autoimmune disease, with a much higher prevalence in POF (2.5%–20%), in chronic hypoparathyroidism and/or

chronic candidiasis (Nerup, 1974; De Bellis et al., 1993; Betterle et al., 1997a, 1997b). AAD is a chronic disease with a long silent period marked by the presence of the ACA. The natural history of the disease could entail five main functional phases: one potential, three subclinical, and one clinical (Betterle et al., 1988, 2002, 2016; Coco et al., 2006). To recognize these different phases, it is necessary to measure basal plasma levels of cortisol, ACTH, plasma renin activity or concentration, aldosterone, cortisol 30 and 60 minutes after an intravenous injection of 250 µg of cosyntropin ( $\alpha$ 1-24-corticotropin) (Synacthen) (ACTH test) (Stewart et al., 1988; Grinspoon and Biller, 1994). Stage 0 is characterized by the presence of adrenal-specific autoantibodies and a normal adrenal cortical mass, in the absence of any detectable dysfunction of the adrenal glands by ACTH test, representing the “potential” phase of chronic adrenalitis. Subclinical Stage 1 is characterized by an increase in plasma renin activity, together with normal/decreased levels of aldosterone (reduced production of mineralocorticoids); subclinical Stage 2 by normal ACTH values with normal basal cortisol but a low cortisol peak (low reserve of glucocorticoids); and subclinical Stage 3 by an increase in ACTH and low level of basal cortisol, indicating reduced glucocorticoid production. Stage 4, the clinical stage, is when the ACTH is significantly increased and the basal cortisol is very low (Table 42.1).

Stage 1 indicates that the *zona glomerulosa* of the adrenal glands is first affected by the autoimmune attack probably because it is smaller and thus exhibits greater sensitivity to diffuse lymphocyte infiltration, or because the deeper zones are immunologically protected by local production of glucocorticoids (Betterle et al., 2002) or for their greater ability to self-regenerate. The adrenal cortex is indeed one of the most plastic tissues in the human body. For more than 60 years, it has been known that bilateral subcapsular enucleation of the adrenals in rodents leads to the regeneration of adrenocortical cell mass within 4–6 weeks (Gan et al., 2017). For the study of patients with ACA and/or 21-OHAbs, it was proposed to use also the ACTH test with a low dose (1 µg) of ACTH (Laureti et al., 2000). It has been found that this low-dose test has a diagnostic accuracy as high as that of the classical high-dose intravenous 250 µg test, but it remains unclear whether “low-dose” ACTH (Synacthen) tests have better sensitivity for detecting adrenal failure compared to standard test.

Various previous follow-up studies carried out in ACA/21-OHAbs-positive patients without clinical AD have allowed to understand the importance of these autoantibodies as markers for defining the natural history of AAD (Betterle et al., 1997a,b, 1983; Ahonenm et al., 1987; Peterson et al., 1997; Laureti et al., 1998; Yu et al., 1999; Coco et al., 2006), but the positive predictive value greatly varied (range 0–90). In one of these follow-up studies (Coco et al., 2006), 100 patients were investigated for a mean period of 6 years and for a maximum period of 21 years. A multivariate analysis demonstrated that the occurrence of AAD was significantly correlated to four main conditions: gender, ACAs titers, adrenal cortex functional status at enrollment, and type of autoimmune preexisting disease. The study allowed to identify the *point of no return* toward AAD on Stage 1 of subclinical hypoadrenalinism and that the development of AAD can occur after a maximum period of 11 years from the detection of autoantibodies (Coco et al., 2006; Betterle et al., 2016). In a recent paper 143 patients with autoimmune diseases (29 patients with APS-1 and 114 patients with APS-2 or APS-4) being positive for adrenal cortex autoantibodies, were followed-up for a median of 10 years (range 6 months–33 years) and assessed by ACTH test. The risk of AAD was estimated according to age, gender, stage of adrenal dysfunction, associated diseases and antibody titer. Univariate and multivariate Cox proportional hazard models were used for statistical analysis. We found that the cumulative risk (CR) of developing AAD was higher in APS-1 patients (94.2%) compared to

**TABLE 42.1** ACTH Test: Stages of Adrenal Cortical Function in ACA/21-OHAbs-Positive Patients

Adrenocortical function	Stage	Autoimmune Addison's	ACA and/or 21-OHAb	Basal PRA	Basal aldosterone	Basal ACTH	Basal cortisol	Cortisol response 60 min after ACTH i.v.	Clinical manifestations
Normal	0	Potential	+	Normal	Normal	Normal	Normal	Normal	Absent
Reduced production of mineralocorticoids	1	Subclinical	+	High	Normal or low	Normal	Normal		Absent
Reduced reserve of glucocorticoids	2	Subclinical	+	High	Low	Normal	Normal	Reduced	Absent
Reduced production of glucocorticoids	3	Subclinical	+	High	Low	High	Low	Absent	Absent
Important mineralocorticoids and glucocorticoids deficiency	4	Clinical	+	Very high	Very low	Very high	Very low	Absent	Absent

patients with APS-2/APS-4 (38.7%). The CR was high in both males and females with APS-1 patients, while in patients with APS-2/APS-4 it was high only in males. *Stage 1* (increased plasma renin) for patients with APS-1 and *Stage 2* (no response of cortisol to ACTH-test) for patients with APS-2/APS-4 were established as the *points of no return* in the progression to AAD. Adjusted hazard ratio analyses by multivariate Cox model for AAD showed that gender, diseases, adrenal function were independent risk factors for developing clinical AAD. The risk of developing clinical AAD appears to subside after 19 years of follow up. On the basis of these data a model for estimating the probability to survive free of AAD has been developed and should be a useful tool in designing appropriate follow-up intervals and future therapeutic strategies ([Naletto et al. 2019](#)).

## DIAGNOSIS OF AUTOIMMUNE ADDISON'S DISEASE

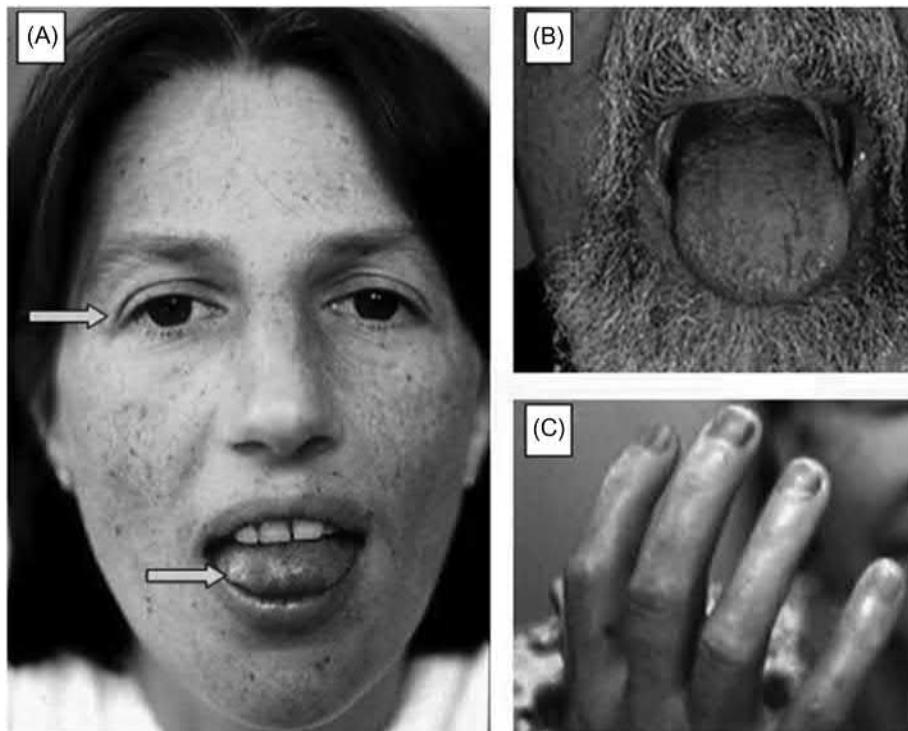

### Clinical Manifestations

AAD has a long preclinical period and clinical features do not appear until 80%–90% or more of the adrenal cortex is destroyed. The main clinical signs at onset are general malaise, fatigue, weakness (99%), anorexia, nausea and vomiting (90%), weight loss (97%), cutaneous and mucosal hyperpigmentation ([Fig. 42.6](#)) caused by the enhanced stimulation of the skin MC1-receptor by ACTH and other proopiomelanocortin-related peptides (98%), and severe hypotension (87%). Other signs (abdominal pain, salt craving, diarrhea, constipation, and syncope) have a variable frequency (34%–39%) ([Williams and Dluhy, 1998](#)). In women a loss of axillary and pubic hair, dry skin, reduced libido and an impairment of well-being also occur.

### General Biochemical Indices

In AAD at diagnosis, the serum levels of sodium, chloride, and bicarbonate are reduced, while those of potassium are elevated. The hyponatremia (in 100% of patients) is due to loss of sodium in urine and increase in both plasma vasopressin and angiotensin II which impair free water clearance; hyperkalemia (in 50%–70%) is due to aldosterone deficiency, impaired glomerular filtration, and metabolic acidosis.

A percentage of 10–20 of patients have a mild or moderate hypercalcemia for unknown reasons ([Williams and Dluhy, 1998](#)). Anemia is present in 40%–50%, and eosinophilia and lymphocytosis in 10%–15% of the cases.

**FIGURE 42.6** Clinical manifestations of autoimmune Addison's disease at onset. (A) Hyperpigmentation of the skin, melanosis of the tongue, and exophthalmos as a sign of dehydration. (B) Male showing a melanosis of the tongue. (C) Hyperpigmentation of the nails.

## Hormonal Tests

The association between a morning (0800 hours) immunometric determination of both plasma ACTH and basal cortisol levels differentiates cases of primary adrenal failure from both a healthy status and other type of adrenal disease (Oelkers et al., 1992).

A recent Endocrine Society Clinical Practice Guideline on diagnosis and treatment of primary adrenal insufficiency suggests that a decrease (below 140 nmol/L or 5 µg/dL) in basal morning cortisol with an increase in levels of ACTH (>twofold the upper limit of the reference range 22.0 pmol/L) indicate primary adrenal failure (Bornstein et al., 2016). The simultaneous measurement of plasma renin and aldosterone is recommended to determine the presence of mineralocorticoid deficiency, an elevated plasma renin activity or concentration in combination with a normal or low serum aldosterone concentration is suggestive of AD (Bornstein et al., 2016). In relation to differential diagnosis, in the case of secondary adrenal failure, levels of both ACTH and cortisol are low and, in general, aldosterone and plasma renin activity are normal. Dehydroepiandrosterone (DHEA), which is the major precursor of sex steroid synthesis, is involved in the adrenal failure, causing a pronounced androgen deficiency in women, with the loss of both axillary and pubic hair, dry skin, reduced libido, and, frequently, an impairment in well-being (Arlt and Allolio, 2003). In cases in which there are no clear clinical manifestations of AD, and/or in the presence of ACA, it may be necessary to execute the ACTH stimulation test. The standard dose of synthetic corticotropin to establish the diagnosis of adrenal insufficiency is 250 µg (one ampule) by the intravenous injection in adults and in children ≥ 2 years of age, 125 µg for children (<2 years of age) testing plasma cortisol after 30 or 60 minutes. Peak cortisol levels below 500 nmol/L (18 µg/dL) (assay dependent) at 30 or 60 minutes lead to the diagnosis of adrenal insufficiency (Bornstein et al., 2016). Once AD is diagnosed,

**FIGURE 42.7** Adrenal imaging. Computed tomography of the adrenal glands of two patients with autoimmune Addison's disease at diagnosis. The adrenals are small (see *white arrows* in the figures).

thyroid stimulating hormone (TSH) levels are increased in 30% of patients, because of the lack of the inhibiting effect of cortisol on TSH production or the presence of coexisting autoimmune hypothyroidism (Orth and Kavacs, 1998). It has been demonstrated that the measurement of salivary and serum cortisol in the morning has a low sensitivity and specificity for detecting primary adrenal insufficiency (Raff, 2009).

## Imaging

Computed tomography or nuclear magnetic resonance shows the adrenals with optimal resolution and clarity and greatly facilitates the diagnosis and characterization of adrenal insufficiency. In patients with AAD, either isolated or as a component of APS syndromes, the adrenal glands appear bilaterally minuscule without calcifications (Doppman, 2001) (Fig. 42.6).

The imaging of the adrenal glands was performed in 250 patients with AAD. Normal adrenal glands were found in 76% of the patients. In 23.6% of the cases the adrenals were reduced in size/volume or undetectable, and only in one patient (0.4%) there was a modest increase in adrenal volume. None of the examined adrenal glands showed calcifications. There were no differences in the adrenal imaging between different forms of AAD in the context of the various APS (Betterle et al., 2013). For these reasons, in case of ACA/21-OHAbs positivity, it is not necessary to perform adrenal imaging, that is otherwise required in cases without ACA (Falorni et al., 2004; Betterle et al., 2013; Bornstein et al., 2016) (Fig. 42.7).

## DIFFERENT CLINICAL PRESENTATIONS OF AUTOIMMUNE ADDISON'S DISEASE

Neufeld and Blizzard (1980) first proposed the classification of autoimmune syndromes into four main groups, involving different endocrine glands, and named them "autoimmune polyglandular syndromes" (APS) (see Box 42.1). According to this classification, AAD can be associated with type 1, type 2 APS.

Betterle and Presotto (2008) proposed the existence of three different types of APS involving AAD (APS-1 associated with chronic candidiasis and/or chronic hypoparathyroidism; APS-2 associated with autoimmune thyroid diseases and/or type 1 diabetes mellitus; and APS-4 associated with other autoimmune diseases not included in the previous list). So, AAD can present in four main clinical forms: isolated or composite in the context of APS-1, APS-2, or APS-4.

## Association With Other Autoimmune Disorders

In a cohort study on 426 Norwegian patients with AAD, the presence of one or more clinical, subclinical, or latent autoimmune diseases was found in 88% of the patients (Erichsen et al., 2009). Another study from United Kingdom on 48 patients with AAD revealed that 73% had associated autoimmune comorbidities (Leelarathna et al., 2010). In an Italian study on 524 patients with AAD, 82.4% had one or more clinical, subclinical, or potential autoimmune diseases, and only 17.6% was isolated AAD (Betterle et al., 2013). In studying a cohort of 660 Swedish patients with AAD, it was demonstrated that 97% presented with at least one additional autoimmune disease or tested positive for any of the autoantibodies analyzed

### BOX 42.1

#### CLINICAL CLASSIFICATION OF APS ACCORDING TO NEUFELD AND BLIZZARD (1980) (MODIFIED)

- APS-1 Chronic candidiasis, chronic hypoparathyroidism, Addison's disease (*at least two diseases must be present*)
- APS-2 Addison's disease (*always present*) 1 thyroid autoimmune diseases and/or type 1 diabetes mellitus
- APS-3 Thyroid autoimmune diseases 1 other autoimmune diseases (*excluding Addison's disease and/or hypoparathyroidism*)
- APS-4 Combinations of other autoimmune diseases not included in previous classifications

(Dalin et al., 2017). The most frequent concomitant diseases were hypothyroidism, type 1 diabetes mellitus, pernicious anemia, POF, hyperthyroidism, in agreement with the previous studies from Norway, Italy, and United Kingdom. These data confirm that AAD is the autoimmune disease with the highest association with other autoimmune disorders. For these reasons, we suggest that every patient with a diagnosis of AAD is investigated for personal and family history of thyroid and/or gastric diseases, gonadal failure, type 1 diabetes mellitus, chronic hypoparathyroidism, chronic candidiasis, vitiligo, alopecia, hepatitis, celiac disease, and other minor autoimmune disease. In addition, in the absence of clinical manifestations of these disorders, it is also suggested to detect periodically (annually) an organ- and nonorgan-specific autoantibody screening (Husebye et al., 2014; Bornstein et al., 2016). This is because a proportion of patients with apparently isolated AAD can be positive for one or more autoantibodies which can recognize patients at risk for future target organ dysfunction (Betterle et al., 2013). Any associated autoimmune disease contributes to classify the patients with AAD in four subtypes of the disease (i.e., APS-1, APS-2, APS-4, and isolated), and every subtype of AAD has some common (e.g., family history for AAD and for other autoimmune diseases, autoantibodies to adrenal cortex, adrenal imaging) and some different features (e.g., age at onset, female/male ratio, adults/children ratio, genetic predisposition, association with the minor autoimmune diseases, and association with cancer) (Betterle et al., 2013). The typical profiles of the four different forms of AAD are summarized in Table 42.2.

**TABLE 42.2** Four Different Clinical Presentations of Autoimmune Adrenalitis [Number of Autoimmune Addison's Disease (AAD) Patients = 524]

Subgroups	APS-2	APS-1	APS-4	Isolated
Frequency	61.6%	13.6%	8%	17.5%
F/M	2.3	2.1	1	0.6
Adults/children	16	0.8	5.3	4
Mean age (in years) at onset of AAD	34.6	15	32	32
Range	1–85	2–41	6–62	1–84
Family history for autoimmune diseases	Frequent	Frequent	Frequent	Frequent
Family history for AAD	Rare	Frequent	Rare	Rare
Genetic	HLA-DR3 and/or DR4	AIRE gene Mutations	HLA (?)	HLA (?)
Autoimmune Addison's disease (%)	100	80	100	100
Chronic candidiasis	Absent	76%	Absent	Absent
Chronic hypoparathyroidism	Absent	90%	Absent	Absent
Thyroid autoimmune diseases	93.7%	30%	Absent	Absent
Type 1 diabetes mellitus	15.5%	6%	Absent	Absent
Other autoimmune diseases (vitiligo, alopecia, autoimmune gastritis, pernicious anemia, celiac disease, myasthenia gravis, Sjögren's syndrome, Werlhof's syndrome, multiple sclerosis, etc.)	Until 43%	Until 57%	100%	Absent
Ectodermal dystrophy	Absent	Present	Absent	Absent
Cancer	5.3%	9.9%	2.6%	4.3%
ACA at onset of AD	88%	91%	95%	69%
21-OHAb at onset of AD	94%	92%	100%	86%
Adrenals imaging	Normal/ Atrophic	Normal/Atrophic	Normal/Atrophic	Normal/Atrophic

AD, Addison's disease; ACA, adrenal cortex autoantibody; APS, autoimmune polyglandular syndrome.

## Therapy

### Conventional Therapy

Glucocorticoids are secreted into the bloodstream in a circadian fashion, with a peak at 0800 hours, and a nadir at 2400 hours. Normal adults produce 9–11 mg of cortisol daily per square meter of body surface, corresponding to about 15–19 mg/day (Esteban et al., 1991; Kraan et al., 1998). Life-saving therapy for patients with chronic adrenal insufficiency is two or three daily doses of a specific hormone replacement (Groves et al., 1988; Howlett, 1997; Williams and Dluhy, 1998; Arlt and Allolio, 2003). All patients with confirmed aldosterone deficiency need to receive mineralocorticoid replacement with fludrocortisone recommended at 50–200 µg in adults at awakening (Husebye et al., 2014) or 50–100 µg and not restrict their salt intake (Bornstein et al., 2016). During the summer period, especially in the Mediterranean or tropical climates, the doses of mineralocorticoids should be increased (Arlt, 2009). The new formulation instructions (e.g., for Florinef) require patients to keep the medication refrigerated. The actual decay rate is, however, only 0.1% in the first 6 months at room temperature (Husebye et al., 2014). It was recommended monitoring of mineralocorticoid replacement deficiency or over therapy primarily based on the clinical assessment (i.e., salt craving, postural hypotension, or edema), and blood electrolyte measurements (Bornstein et al., 2016). If essential hypertension develops in patients with mineralocorticoid replacement therapy, the dose may be first slightly reduced. If hypertension persists, antihypertensive drugs need to be started (Arlt, 2009; Husebye et al., 2014; Bornstein et al., 2016), favoring calcium-channel blockers or adrenergic receptor antagonists because they less interfere with the renin–angiotensin–aldosterone system.

DHEA (dehydroepiandrosterone) is the most important source of androgens in females; replacement therapy can enhance well-being, mood, subjective health status, energy levels, and libido in women with adrenal insufficiency. Therefore the therapy should be reserved for patients with significant impairment in well-being despite the optimized classical replacement therapy. Doses vary from 10 to 50 mg/day in a single dose in the morning guided by serum DHEA sulfate (DHEAS), androstenedione, and testosterone levels, which should be maintained in the normal range when measured in the morning prior to DHEA ingestion. There is only limited objective evidence of clinical benefit from large studies (Arlt, 2009; Husebye et al., 2014). If the female patient does not report a beneficial effect after 6 months of replacement therapy, DHEA should be discontinued. (Husebye et al., 2014; Bornstein et al., 2016).

### New Therapies

In order to mimic the physiological circadian biorhythm of cortisol, a once-daily dual-release hydrocortisone tablet was produced based on an immediate-release coating together with an extended-release core (Johannsson et al., 2009). In an open randomized, two-period 12-week crossover trial, the once-daily dual-release hydrocortisone tablet, compared to thrice-daily dose of conventional hydrocortisone tablets, produces a more circadian-based serum cortisol profile, reduces body weight, blood pressure, and improves glucose metabolism in patients with AD and concomitant diabetes mellitus (Johannsson et al., 2012).

Subsequent studies confirmed the beneficial effect of a dual-release tablet on glucose metabolism by demonstrating that modified release hydrocortisone reduced significantly either body mass index or glycated hemoglobin in the subgroup of diabetic patients when compared with conventional treatment, although absolute changes were small (Quinkler et al., 2015b). Recent studies, performed on a limited number of patients with AD, showed that the dual-release hydrocortisone preparation is effective in reducing central adiposity, improving glucose and lipids metabolism, as well as the quality of life (QoL) (Giordano et al., 2016). The total doses of hydrocortisone administered by the modified-release and conventional tablets are equivalent. Therefore it has been suggested that a more physiological daily cortisol profile (avoiding absorption peaks) related to dual-release delivery may explain the reduction in waist circumference, glycemic, and lipid profiles. However, the treatment with dual-release hydrocortisone preparations has not shown beneficial effect on blood pressure compared to the conventional tablets (Giordano et al., 2016).

Another oral formulation containing multi-particulate, modified-release hydrocortisone administered twice-daily for replacement therapy has become available (Whitaker et al., 2014). The formulation is intended to be taken at 2300 hours with drug release starting approximately 4 hours after administration, resulting in cortisol increase after midnight and very early in the morning with the maximum concentrations approximately 8 hours after administration (Whitaker et al., 2014). However, this formulation is not enough to cover the need for cortisol the day after the administration, and another dose should be taken in the morning. Twice-daily administration of this novel hydrocortisone formulation at 2300 and 0700 hours resulted in more effective decrease of ACTH levels and androgen secretion and may be specially of advantage for therapy of adults with congenital adrenal

hyperplasia (CAH) (Mallappa et al., 2015; Jones et al., 2017). In conclusion, these novel hydrocortisone formulations should be considered in selected categories of AD patients, also because their costs still remain elevated. Moreover, case-controlled studies designed for long follow-up in larger cohorts of patients with AD, either isolated or associated with diabetes mellitus, premature ovarian failure or other main diseases are necessary to verify their promising role in adrenal replacement therapy. Until recently there were no licensed, dose-appropriate formulations of hydrocortisone for neonates, infants and children with adrenal insufficiency. The dosing relied either on parents crushing tablets or pharmacists making up appropriate preparations from adult medicines. This unsatisfactory situation has been improved with the availability of an immediate-release hydrocortisone preparation with the additional advantage of taste masking based on multilayered technology (Whitaker et al., 2015). This multi particulate granule formulation has the maximum granule diameter controlled by passing through a 0.8 mm sieve. The size of the granules is well below FDA guidance for industry on sprinkle formulation limits of 2.5 mm diameter and permits swallowing of granules even by neonates. The granules are presented within a transparent capsule that is opened for dosing, thus allowing accurate pediatric dosing of 0.5, 1.0, 2.0, and 5.0 mg (Whitaker et al., 2015). A phase 3 open-label single-dose study has been performed in three children cohorts with AD; aged 2 to less than 6 years, 28 days to less than 2 years and neonates aged 1 to less than 28 days. This study demonstrated that the formulation is well tolerated, easy to administer to neonates, infants and children, and shows good absorption with cortisol levels at 60 minutes after administration similar to physiological cortisol levels of healthy children (Neumann et al., 2018).

Continuous subcutaneous hydrocortisone infusion (CSHI) is an experimental treatment that could be tested on selected patients not responding properly to regular oral treatment (Løvås et al., 2010; Løvås and Husebye, 2007). A recent phase 2 study performed on eight adult patients with difficult-to-treat classic CAH compared CSHI to conventional oral glucocorticoid treatment. CSHI resulted a safe and well-tolerated modality of cortisol replacement that effectively approximates physiologic cortisol secretion in patients with classic CAH poorly controlled on conventional therapy (Nella et al., 2016). Improved adrenal steroid control and positive effects on health-related QoL suggest that CSHI should be considered as a treatment option for adrenal insufficiency due to classic CAH.

Recent advances in immune intervention therapies allow developing novel strategies to prevent progression to overt AAD. Targeting autoimmune responses have shown some promise in prevention or treatment of type 1 diabetes mellitus, Graves' disease, multiple sclerosis, and other autoimmune conditions. Rituximab is a monoclonal antibody able to block CD20 molecules on the B-lymphocytes and most likely affects the ability of B cells to cooperate in antigen presentation and cytokine secretion. Rituximab was used in six patients with new onset AAD (Pearce et al., 2012). Although serum cortisol and aldosterone concentrations remained low in five throughout the follow-up period, one patient revealed a steady improvement in both serum cortisol and aldosterone, allowing discontinuation of steroids at 15 months after rituximab therapy. This patient remained well without medication for 12 months thereafter (Pearce et al., 2012). However, these preliminary results need to be confirmed in studies with a greater number of patients at the onset of clinical AAD or in high-risk patients with ACA/21-OHAbs at Stage 2 of subclinical AAD.

### **Regenerative Therapy**

Stimulation with ACTH may lead to increased regeneration of glucocorticoid secreting cells. A 20-week trial of regular administration of tetracosactide (ACTH<sub>1–24</sub>) in 13 patients with AAD of more than 1 year duration (Gan et al., 2014) showed an improvement in cortisol and aldosterone concentrations in 2, 1 remained well without steroids for 28 months while the other initial responder needed to resume glucocorticoid therapy after 7 months. It should be noted that this approach may only be effective if there would be sufficient residual adrenal cell function for achieving the sustained regeneration, and it is probably useless in patients with already high levels of ACTH. The recent advances in the understanding adrenocortical stem cell biology and adrenal plasticity will be helpful to comprehend the new therapeutic approaches addressed to modify the natural history of AAD (Gan and Pearce, 2017). Asymptomatic patients at high-risk of developing overt disease (i.e., preclinical adrenal impairment) may be offered an opportunity to participate in prevention trials with immunomodulation and/or regenerative therapeutical strategies.

### **Steroid Replacement During Surgery, Other Illness, Medical Procedures, Physical Activity, and Pregnancy**

Patients with AD need to increase their steroid doses during surgery and medical procedures according to the stress induced. In general, surgery, fever, gastrointestinal diseases, major dental procedures, and child delivery

require parenteral hydrocortisone followed by double oral doses being tapered to replacement doses over subsequent days.

Patients undergoing regular and time-limited physical activity do not generally need to make a dose adjustment. However, in case of intense or prolonged exercise, an increase in hydrocortisone and salt intake may be necessary. Stress dosing of 10 mg hydrocortisone 1 hour prior to exercise is commonly given. However, a recent double-blind study revealed that patients with AD did not find any benefit from a supplemental dose of hydrocortisone in short strenuous exercise evaluated by ergometer test with cardiorespiratory assessment (Simunkova et al., 2016). Yet, the number of investigated patients was limited, and all were females. Whether stress dosing is beneficial if given otherwise and during longer lasting or more strenuous physical activity will have to be investigated further.

Pregnancy is associated with a gradual but pronounced physiological increase in corticosteroid-binding globulin and total serum cortisol. Free cortisol levels rise during the third trimester, and some pregnant patients have a small increase in hydrocortisone requirement (by 2.5 or 5 mg daily) during the third trimester. Serum progesterone has antimineralcorticoid effects, and hence, the fludrocortisone dose may need to be increased during late pregnancy. Plasma renin activity normally increases during pregnancy (Husebye et al., 2014). Usually, the required additional hydrocortisone dose during the third trimester is of 5–10 mg (Lebbe and Aarlt, 2013). The Endocrine Society Clinical Practice Guideline recommends increasing hydrocortisone dose from 10% to 40% in the third trimester, in order to reproduce the physiological rise in free cortisol (Bornstein et al., 2016). Glucocorticoid preparation that should be used in pregnancy is hydrocortisone. Cortisone acetate remains a second choice, while corticosteroids with longer activity or half-life (i.e., prednisolone, prednisone, methylprednisolone, and betamethasone) should not be used (Bornstein et al., 2016). However, some authors believe that pregnancy does not normally require major adjustment of the glucocorticoid substitutive therapy because also in women with primary adrenal failure, there are physiological adaptations in cortisol clearance (Falorni et al., 2013).

At delivery, a bolus dose of 100 mg hydrocortisone should be given and repeated if necessary. The oral dose should be doubled for 24–48 hours postpartum followed by rapid tapering and returning back to oral administration at prepregnancy doses (Husebye et al., 2014; Falorni et al., 2013; Bornstein et al., 2016).

## Acute Adrenal Failure (Adrenal Crisis)

The risk of adrenal crisis is a possible life-threatening event in every Addisonian patient. A study evaluated frequency, causes, and risk factors of adrenal crisis in patients with chronic adrenal failure demonstrating 6.3 crises/100 patient-years. Precipitating causes were mainly gastrointestinal infection and fever (45%) but also other stressful events (e.g., major pain, surgery, psychic distress, heat, and pregnancy). Patients with comorbidities had a higher risk compared to patients with AD alone (Hahner et al., 2009). Adrenal crisis has been observed significantly more frequently in patients with primary (7.6/100 patient-years) than in patients with secondary adrenal insufficiency (3.2/100 patient-years) (Meyer et al., 2016). In addition, a higher prevalence of acute adrenal decompensation has been reported in patients with APS (10.9/100 patient-years) and in those with type 1 diabetes (12.5/100 patient-years) (Meyer et al., 2016). Other studies in patients on a long-term substitutive therapy demonstrated an annual incidence of adrenal crisis from 5 to 10 of 100 patients per year with a mortality rate of 0.5/100 patients/year (Husebye et al., 2014; Allolio, 2015). The crisis can be due to unnecessary reduction of the glucocorticoid therapy or to lack of stress-related glucocorticoid dose adjustment by patients or medical practitioners. Generally, oral glucocorticoid therapy should be increased or doubled during infections with fever, or during any other major stress-producing event, and, in general, needs to be orally increased but parenteral injected in case of gastrointestinal infections with diarrhea, surgical procedures, delivery, vomiting, or major traumas (Arlt, 2009). The Consensus Statement of Euradrenal Consortium (Husebye et al., 2014) recommends to treat adrenal crisis with rapid infusion of 100 mg of hydrocortisone and 1 L/h of i.v. isotonic saline solution. During the following 2 days, 100 mg of hydrocortisone must be given intravenously every 6 hours and 1 L of saline solution every 6 hours. On the third day, if precipitating events improve, the treatment may be continued using oral medications. Mineralocorticoid therapy is not necessary during infusion of hydrocortisone. However, it may be restored when hydrocortisone replacement falls below 50 mg/day. Admission to intensive care unit depends on the severity of underlying or occurring diseases. The Endocrine Society Clinical Practice Guideline recommends that patients with suspected adrenal crisis should be treated with an immediate parenteral injection of 100 mg hydrocortisone (50 mg/m<sup>2</sup> for children), followed by appropriate fluid resuscitation and 200 mg (50–100 mg/m<sup>2</sup> for children) of hydrocortisone in 24 hours via continuous i.v. therapy or 6 hourly injection (Bornstein et al., 2016).

## Emergency Card

The best strategy for prevention of adrenal crisis is the continuous improvement in the education of patients and health professionals (Napier and Pearce, 2012; Wass and Arlt, 2012). Patients with AD should be informed when and how to increase steroid therapy during concurrent illnesses or injury. Furthermore, the training in intramuscular and/or subcutaneous administration of glucocorticoid may be very helpful for the effective prevention of acute adrenal crisis by the patients themselves (Hahner et al., 2013). In any case, patients with AD should carry a medical identification card (or a bracelet), stating the current therapy and recommendations for emergency situations such as febrile illnesses, injury, vomiting, surgical interventions, dental extractions, or pregnancies, when the intake of glucocorticoids must be doubled or tripled (Oelkers, 1996). The Euradrenal Consortium proposed a standard emergency card which has been now produced in collaboration with the National Associations of the patients with AD and made available for distribution in different European countries (Husebye, 2014). In this card, there are specific instructions on management of adrenal crisis in the national language on one side, while in English on the reverse side. This card is a simple and effective strategy to save lives of patients with AD (Quinkler et al., 2015a).

## Quality of Life

The European Euradrenal Consortium developed a Disease-Specific Quality of Life Questionnaire of AD (AddiQoL) with the purpose to quantify altered well-being and treatment effects (Løvås et al., 2010). The original English version of AddiQoL questionnaire translated into various languages had been distributed to all the members participating to the European Consortium. This approach enabled collection of information in a large group of European patients with AD (Øksnes et al., 2012). AddiQoL questionnaire is expected to be a useful tool to evaluate the QoL in patients with AD in clinical practice in the future.

## Mortality

Three Scandinavian studies have made a contribution to the rate of mortality of AD (Berghorsdottir et al., 2006; Bensing et al., 2008; Erichsen et al., 2009a). The two registry studies from Sweden (Berghorsdottir et al., 2006; Bensing et al., 2008) showed that the mortality was more than double that in the control population and particularly elevated in patients with APS-1 with an odds ratio of 4.6. The causes of death were endocrine diseases and cancer (Bensing et al., 2008). It must be said that the two Swedish registries referred exclusively to hospitalize patients were not representative of the entire population of patients and were both based on the codification of the disease without a definitive confirmation of the diagnosis. Potential assignment mistakes may have greatly influenced the outcome. More specifically, it is known that secondary adrenal insufficiency due to ACTH deficiency has an increased risk for mortality (Filipsson et al., 2006) because of the concurrent deficiency of other pituitary hormones, and it is not sure that such patients have been excluded from the analysis. A Norwegian case-control study did not report an overall increase in mortality and also identified a subgroup of young males with doubled mortality rate, the causes of death being adrenal crisis, infections, and sudden death, while cardiovascular mortality was not increased (Erichsen et al., 2009b).

In an Italian study, we investigated the mortality in over 700 patients with AAD followed for a mean period of 15 years and demonstrated the existence of a normal survival rate in patients with AAD, with the exclusion of those with APS-1. Patients with APS-1 revealed an increased mortality rate compared to the general population matched for gender and age with the patients (Betterle et al., personal data).

## Osteoporosis

It is a constant concern that overtreatment with glucocorticoids may have negative health effects on bone mineral density (BMD). An increased incidence of osteoporosis has been reported in patients receiving daily replacement doses of 30 mg of hydrocortisone or higher, whereas replacement doses of 20–25 mg of hydrocortisone do not affect BMD (Arlt, 2009). Earlier studies have been hampered by low numbers of participants. In patients with AD, a reduced BMD was reported along with polymorphisms in genes regulating steroid action that influences BMD (Løvås et al., 2009). BMD revealed an inverse correlation to steroid dose and was especially low in those taking synthetic potent glucocorticoids such as prednisolone. Despite reduced BMD, vertebral fractures were not more prevalent than in the background population. In contrast, a follow-up registry study

from Sweden reported significantly increased frequencies of hip fractures in AD patients with an excess risk about 50% (Björnsdottir et al., 2011). A study in 81 German patients who received low replacement doses of glucocorticoids found no reduction in BMD (Koetz et al., 2012). Thus clinicians should aim to keep the glucocorticoid replacement dose as low as is compatible with normal well-being.

## Acknowledgments

We would like to thank all those who have cooperated with us over the years regarding the study of the clinical, genetic, immunologic, morphologic, and endocrine aspects of AD.  
This study was supported in part by a grant from the European Union Seventh Framework Programme, the Euradrenal project: Pathophysiology and Natural Course of Autoimmune Adrenal Failure in Europe. Grant Agreement No. 2008-201167 (EURADRENAL website: [www.euradrenal.org/](http://www.euradrenal.org/)).

Animal Models	824		

### DEFINITION AND CLASSIFICATION

Autoimmune hypophysitis is a chronic inflammation of the pituitary gland that can be classified according to anatomic location, histopathology, or cause (Leporati et al., 2011).

Location distinguishes hypophysitis into adenohypophysitis, infundibulo-neurohypophysitis, or panhypophysitis depending on whether the clinical and radiological signs (and pathological findings if available) involve the anterior lobe, the posterior lobe and the stalk, or both structures.

Histopathology identifies two main forms of hypophysitis, lymphocytic and granulomatous, as well as xanthomatous, IgG4 plasmacytic, necrotizing, and mixed variants.

Etiology distinguishes primary and secondary hypophysitis. The primary hypophysitis refers to the cases that do not currently have an identifiable cause. It is the most common form of hypophysitis, has an autoimmune pathogenesis, and occurs in isolation or associated with other well-characterized autoimmune diseases. The secondary hypophysitis includes the cases where a clear etiological agent can be identified [e.g., the administration of immunomodulatory drugs such as cytotoxic T lymphocyte antigen 4 (CTLA-4) blocking antibody], the cases where the inflammation of the pituitary is considered a reaction to sellar diseases (Rathke's cleft cyst, craniopharyngioma, germinoma, and pituitary adenomas), and the cases where hypophysitis is part of a multiorgan systemic involvement (such as Wegener's granulomatosis, tuberculosis, sarcoidosis, or syphilis).

In the past few years, an explosion of cases of hypophysitis secondary to the pharmacological treatment has been reported in cancer patients, especially those treated with immune-checkpoint inhibitors such as the CTLA-4 blocking antibody. These treatments can cause hypophysitis as a side effect and have transformed a traditionally rare disease into a common endocrinological abnormality.

## HISTORICAL BACKGROUND

Autoimmune hypophysitis of the anterior lobe (lymphocytic adenohypophysitis, LAH) was first described by [Goudie and Pinkerton \(1962\)](#) in Glasgow. The authors reported a 22-year-old woman who died 14 months after her second delivery, probably because of adrenal insufficiency. Two months before the admission, the patient felt increasingly tired and noticed a neck enlargement; she then developed severe lower abdominal pain, radiating to the right iliac fossa, associated with vomiting and diarrhea. She was brought to the operating room for suspected appendicitis. Surgery revealed an acutely inflamed, gangrenous appendix that, however, had not ruptured. The appendix was removed but 8 hours later the patient went into peripheral circulatory shock and died. The autopsy revealed a firm, enlarged thyroid gland, infiltrated by lymphocytes, atrophic adrenal glands, and a small pituitary. Surprisingly, for that time, the adenohypophysis was extensively infiltrated by lymphocytes and few plasma cells, aggregating in some areas into true lymphoid follicles. The neurohypophysis was normal. Noting the presence of Hashimoto's thyroiditis, a more extensively characterized autoimmune disease, the authors concluded their discussion by writing: "It seems reasonable to assume that the coexistence of Hashimoto's disease and the mononuclear cells infiltration of the anterior pituitary is not fortuitous. Both may be explained by the onset of autoimmune reaction to thyroid and pituitary antigens released during the puerperal involution of these glands." There is no doubt that Goudie and Pinkerton were the first to postulate the autoimmune nature of this condition, at a time when the field of autoimmunity had just begun. Earlier cases, however, are probably hidden in hospital archives or published without the recognition of the disease ([Duff and Bernstein, 1933](#); [Rupp and Paschkis, 1953](#)).

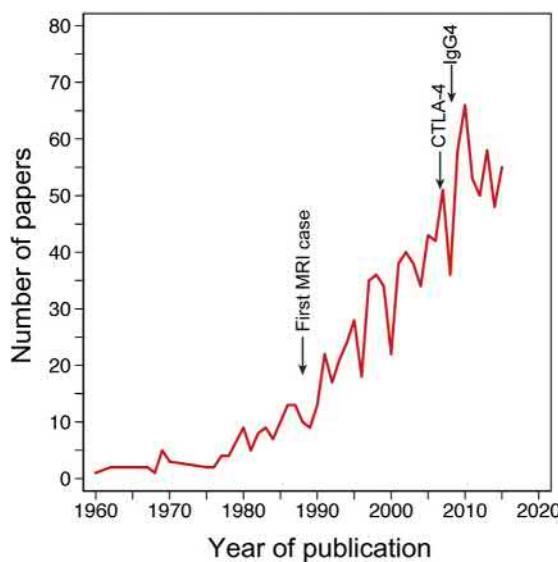

Autoimmune hypophysitis of the posterior lobe and infundibulum (lymphocytic infundibuloneurohypophysitis, LINH) was first described by [Saito et al. \(1970\)](#) in Tokyo. The authors reported a 66-year-old asthmatic woman with a 1-month history of severe dehydration that responded strikingly to the administration of pitressin. Two months after the discharge, however, she developed a severe attack of bronchial asthma and died. Autopsy revealed a marked infiltration of the neurohypophysis and the infundibular stem with lymphocytes and plasma cells, aggregating in some areas in lymphoid follicles. The adenohypophysis was normal, except for vacuolar degeneration of the basophilic cells, likely due to the prolonged use of steroids for asthma.

Autoimmune hypophysitis involving both the anterior and posterior lobe (lymphocytic panhypophysitis, LPH) was first described histologically by [Nussbaum et al. \(1991\)](#) in New York. It was a 40-year-old male with a 3-month history of headache, impotence, polyuria and polydipsia, and a sellar mass abutting the optic chiasm. Transsphenoidal surgery showed that the sella turcica was filled with whitish, fibrous tissue that was almost completely removed. Histology revealed extensive infiltration of the adenohypophysis and the neurohypophysis by lymphocytes, plasma cells, and histiocytes.

Hypophysitis secondary to blockade of CTLA-4 was first reported in 2003 by Phan et al. in Bethesda. It was a 54-year-old male with advanced melanoma metastatic to the lungs and brain who was treated with the CTLA-4 blocking antibody ipilimumab and vaccination with melanoma peptides ([Phan et al., 2003](#)).

## EPIDEMIOLOGY AND BODY OF LITERATURE

Very limited data exist to estimate the incidence of primary autoimmune hypophysitis. Sautner and Fehn analyzed 2500 surgical pituitary specimens collected at Hamburg, Germany, from 1970 to 1996 and found 6 cases (0.24%) ([Fehn et al., 1998](#); [Sautner et al., 1995](#)). Honegger et al. (1997) analyzed 2362 specimens collected from 1982 to 1995 in Erlangen, Germany, and found 7 cases (0.3%). [Leung et al. \(2004\)](#) reported in Charlottesville Virginia 13 cases of autoimmune hypophysitis among 2000 patients who underwent transsphenoidal surgery for pituitary mass lesions from 1992 to 2003 (0.65%). [Buxton and Robertson \(2001\)](#) analyzed 619 consecutive pituitary surgeries performed over 15 years at Nottingham, United Kingdom, and found 5 cases (0.8%). Considering that their hospital served a population of approximately 3 million and that all surgery for pituitary masses was dealt there, the yearly incidence in Nottingham can be estimated to be one case every 10 million people. We recently reviewed all the pituitary surgeries performed at the Johns Hopkins Hospital, from the first US operation performed by Harvey Cushing on March 25, 1909 to July 2017 ([Corsello et al., 2017](#)) and then updated the last year for this chapter. Of the total 3312 pituitary surgeries performed at Johns Hopkins in 109 years, there were 38 cases of hypophysitis (1.1%). Overall, the incidence is likely an underestimate of today's incidence, also considering that some cases of autoimmune hypophysitis cases go undiagnosed because of their indolent, subclinical course.

**FIGURE 43.1** Yearly trend of papers published on hypophysitis and pituitary autoimmunity.

At the Department of Pathology of the Johns Hopkins Hospital, we maintain a database of the papers published on hypophysitis, and pituitary autoimmunity in general, as well as of clinical characteristics of the featured patients (<http://pathology2.jhu.edu/hypophysitis>). A total of 1286 papers have been published as of September 2018, featuring 3175 different authors and 12 languages. The top two publishing authors currently are Patrizio Caturegli (36 articles, The Johns Hopkins University, Baltimore, MD) and Annamaria De Bellis (35 articles, Federico II University of Naples, Naples, Italy). Of the languages, 1075 articles (84%) were written in English, 75 (6%) in Japanese, 34 (3%) in French, 33 (3%) in Spanish, and the remaining 69 articles in 11 other languages. The number of hypophysitis papers published in each calendar year has increased significantly over time, reaching a peak of 66 in 2010 (Fig. 43.1). The causes underlying this increase are multifactorial: in part they relate to the widespread introduction of noninvasive imaging techniques of the sella turcica (mainly MRI); in part to the expansion of the spectrum of pituitary autoimmunity, which now includes forms of hypophysitis that were not existing a few years ago: for example, the IgG4-related form hypophysitis and the form secondary to blockade of CTLA-4; and in part to the increased awareness of hypophysitis in the medical community.

This body of literature describes over 1000 cases with primary hypophysitis, where the diagnosis was established by either surgical pathology (No. = 631), clinical, and imaging criteria (No. = 331), or autopsy (Table 43.1). Patients have been reported in 42 of the 193 countries in the world, but most prominently in Japan and United States (Fig. 43.2).

LAH is more common in women (F:M ratio of 3:1), who present at a younger age ( $38 \pm 14$ ) than men ( $50 \pm 17$ ). In approximately half of the women (49%), LAH manifests during late pregnancy or early postpartum (Fig. 43.3). A history of previous pregnancies does not increase the risk of developing LAH in subsequent pregnancies. This striking temporal association is one of the most interesting features of autoimmune hypophysitis and, at the moment, remains unexplained. LINH affects equally males and females (F:M ratio of 1:1), has a mean age at presentation of 42 ( $\pm 20$ ) years, and is not associated with pregnancy. LPH is slightly more common in women (F:M ratio of 1.4), has similar age at presentation in both sexes ( $43 \pm 17$  years), and does not show association with pregnancy.

Hypophysitis secondary to CTLA-4 blockade reflects the epidemiology of the underlying oncologic populations where the treatment is used. Most commonly, these are patients with not only metastatic melanoma but also renal cell carcinoma, nonsmall cell lung cancer, prostate cancer, and pancreatic cancer. These patients, therefore, are mainly men (80%) and of older ages ( $58 \pm 12$  years) than those with primary hypophysitis. With one notable exception (Caturegli et al., 2016), the diagnosis of secondary hypophysitis has been established by clinical and imaging criteria (rather than by pathology). The single case where pathology was available showed a remarkable destruction of the pituitary gland, as well as the expression of CTLA-4 on the few remaining endocrine cells (Caturegli et al., 2016).

Features	Primary hypophysitis	Hypophysitis secondary to CTLA-4 blockade	P value
No. of published patients: <sup>a</sup>	1005 <sup>a</sup>	148 <sup>a</sup>	
Diagnosis established by:			
Pathology: surgical pathology	631	0	
Autopsy	43	1	
Clinical and imaging criteria	331	147	
F:M numbers (ratio):	718:287 (2.5:1)	30:118 (1:4)	<.001
Mean age at onset (in years):	41 ± 16	59 ± 13	<.001
Time after the initiating event: (mean ± SD)	Unknown, likely years	10 ± 5 weeks after first antibody injection	
Symptoms at presentation:			
Headache	47% (397 of 852)	60% (89 of 148)	
Due to low cortisol	35% (288 of 824)	72% (106 of 148)	.002
Polydipsia and polyuria	35% (297 of 845)	0.9% (1 of 116)	<.001
Visual disturbances	31% (264 of 861)	3% (4 of 117)	<.001
Due to low sex steroids	20% (168 of 834)	15% (17 of 112)	<.001
Due to low thyroxine	16% (132 of 824)	20% (22 of 112)	

<sup>a</sup>Meeting abstracts and pooled patients from clinical trials are not included.

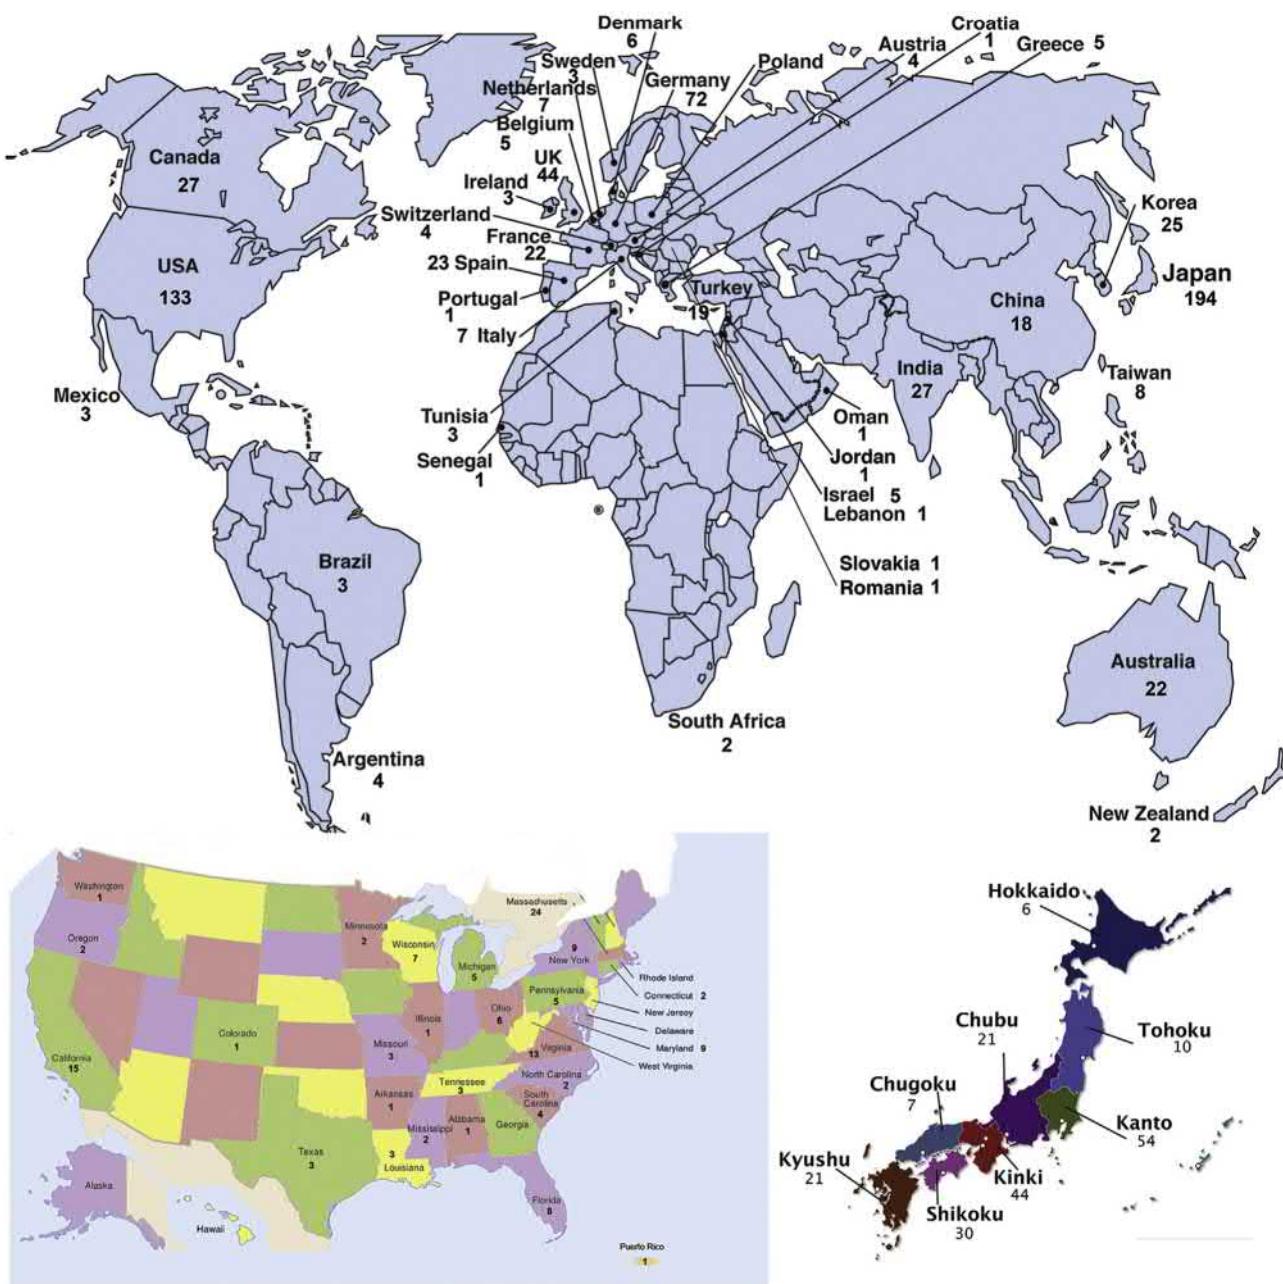

CTLA-4, Cytotoxic T lymphocyte antigen 4.

## CLINICAL FEATURES

The clinical presentation of autoimmune hypophysitis includes four categories of symptoms.

The most common symptoms are those related to the mass effect, that is, to the compression the enlarged pituitary exerts upon the nearby sellar structures. In fact, a pituitary gland that is infiltrated by autoreactive lymphocytes initially enlarges, forming a sellar mass that expands usually upward, impinging upon the optic chiasm and the dura mater, or laterally to invade the cavernous sinuses or temporal fossae. Headache is the most common presenting symptom of hypophysitis and occurs in about 50% of the patients (Table 43.1) (Caturegli et al., 2016; Honegger et al., 2015; Wang et al., 2017). It is sudden, severe, and often generalized. Visual disturbances originate from the compression of the optic chiasm and typically include defects in the temporal quadrants of the visual fields and occasionally deterioration of visual acuity. The encroachment of the cavernous sinus can cause diplopia and pupillary abnormalities from compression of the third, fourth, and sixth cranial nerves. The involvement of the branches of the trigeminal nerve can result in orbital pain or facial paresthesias. Bilateral intracavernous carotid artery occlusion is a rare complication of aggressive lymphocytic hypophysitis (Katsiveli et al., 2016). Although the onset of the mass effect symptoms is often sudden, it can vary greatly from insidious to super acute, mimicking pituitary apoplexy (Hasegawa et al., 2018) or meningitis (Suzuki et al., 2011).

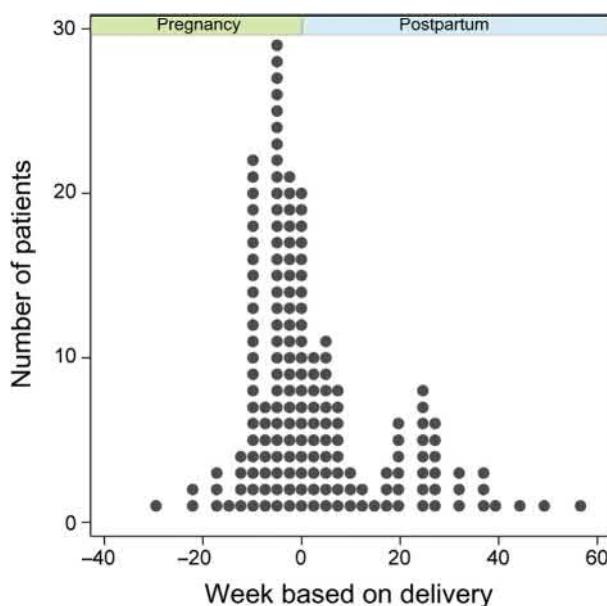

The second most common symptoms are those originating from the defective production of the anterior pituitary hormones and usually present more insidiously. These defects are considered the direct consequence of the attack of the patient's autoreactive lymphocytes onto the hormone-producing cells, although they can also originate from mass effect. The defects can be completed (pan-hypopituitarism) when all five adenohypophyseal axes (corticotroph, thyrotroph, gonadotroph, growth hormone, and prolactin) are impaired, partial when more than one axis is involved, or isolated when only one axis is involved. Corticotropin deficiency is the most common endocrine abnormality (Table 43.2) (Caturegli et al., 2016), causing symptoms such as general malaise, hypotension, nausea, vomiting, dizziness, and loss of pubic and axillary hair. The resulting hypocortisolism is often severe and can be life-threatening if not promptly recognized and treated. Gonadotropin (decreased libido, impotence, and amenorrhea) and thyrotropin (fatigue, lethargy, cold intolerance, and weight gain) deficiencies are also frequently reported in recent large series (Honegger et al., 2015; Wang et al., 2017). The defects of the growth hormone/IGF-1 axis are considered clinically silent in adults, and therefore it is not surprising that this is the

**FIGURE 43.2** Geographical distribution of published patients with the primary hypophysitis.

least studied axis in this patient population. In many of the published patients, there was no information about the growth hormone axis, so it remains to be established whether somatotrophs cells are not frequently targeted by the patient immune system or rather their involvement has not been systematically investigated. Prolactin deficiency, manifested in women as inability to lactate after delivery, is rare but when present should alert the astute clinician on a possible diagnosis of hypophysitis (Iwama et al., 2013).

The third group of symptoms are those due to not only deficit of the posterior pituitary (polyuria and polydipsia), which can be attributed to direct immune destruction of the neurohypophysis and infundibulum, but also compression of these structures. Diabetes insipidus is the defining symptom of LINH, but it can also be observed in about a third of the patients who have defects in the anterior pituitary axes. Diabetes insipidus has been recently identified as a negative prognostic factor in patients with primary autoimmune hypophysitis (Lupi et al., 2017).

**FIGURE 43.3** Distribution of symptom appearance in relation to delivery (indicated as week 0).

**TABLE 43.2** Endocrine Abnormalities Reported at Diagnosis in Patients With Primary and Secondary Hypophysitis

	Primary hypophysitis (%)	Secondary hypophysitis (%)
Secondary hypocortisolism	60	91
Secondary hypogonadism	55	83
Secondary hypothyroidism	52	84
Central diabetes insipidus	39	1
Hyperprolactinemia	37	9
Decreased growth hormone	38	43

Last are the signs of hyperprolactinemia (mainly amenorrhea/oligomenorrhea and galactorrhea), which is due to compression and/or deviation of the infundibular stalk. Hyperprolactinemia is observed in about a third of the patients (Table 43.1).

Autoimmune hypophysitis frequently occurs in association with the other autoimmune diseases, such as Hashimoto's thyroiditis, Graves' disease, or Sjögren's syndrome (Angelousi et al., 2018; Caturegli et al., 2005; Chiloiro et al., 2017; Honegger et al., 2015; Wang et al., 2017), whose specific signs and symptoms enrich and diversify the clinical presentation of hypophysitis.

Primary hypophysitis is uncommon in children, with less than 100 cases reported in literature as reviewed by Kalra et al. (2011). Juvenile hypophysitis differs markedly from adult hypophysitis in the clinical features. Headache is reported much more infrequently (17%) in children than in adults (50%), although an improper communication of this symptoms may be partly responsible for the difference. Diabetes insipidus and growth hormone deficiency are the most common endocrine disorders in children, whereas visual disturbances and hypocortisolism are rare (Kalra et al., 2011).

The clinical features of autoimmune hypophysitis are indistinguishable from those caused by the other non-hormone secreting masses arising in the sella turcica (Table 43.3). Thus although per se rare, hypophysitis enters in the differential diagnosis of about 30 conditions, all characterized by the presence of a sellar mass. Currently, hypophysitis can only be diagnosed with certainty by pituitary biopsy. However, a pathological specimen is not always necessary since a presumptive diagnosis of hypophysitis can often be made on the basis of a combination of clinical and radiological features. Clinical features suggestive of hypophysitis include the association with

**TABLE 43.3** Classification of Sellar Masses With Approximate Frequency Distribution

Disease	% of all sellar masses
